We have further matter in the same issue of this Journal which will well repay careful perusal, in a paper by Mr. Xanthus Smith. He writes most justly on the relation of part to part, a most important consideration in photography. What he says about foregrounds and backgrounds, under particular cases, is pregnant with food for thought. He appears, however, to be wrong in one part of his paper, an unimportant part as regards photography, though the writing is so involved as to leave his meaning in some obscurity. He says that we feel the shortcoming of art, which cannot in any way advance or recede beyond the surface plane of the canvas or paper, except as in the case of scenery in theatres. Now, as a matter of fact, paintings on a flat surface have been exhibited in which advance and retreat were so positive that ninety-nine out of a hundred spectators were utterly unable to say whether it was a painting or nature that was before them. I am not sure whether I have apprehended Mr. Xanthus Smith's meaning, taking his preceding paragraph into consideration, but I think I have.

The paper by Mr. H. J. Channon on the influence of development on graduation is an excellent contribution to a much-discussed subject. He shows clearly by experiment that, as every careful and practical photographer knows is the case, graduation can be controlled by development. Messrs. Hurter & Driffield say in effect, in their original paper, that has been the basis of many arguments, that it cannot be so influenced. It is, however, of little use to prove the existence of this power of control, for if these experimenters intervene they will be able to point to a letter in which they say that they have not asserted the impossibility of this control. This blowing hot and cold with the same breath is disconcerting to a searcher after truth; thus, after all, it may be made to appear as merely incidental, and not proper to the argument proper of Messrs. Hurter & Driffield.

I will conclude my letter by expressing the great pleasure I felt on reading a letter (which I hope will be the forerunner of rigid investigation on the subject) from a firm of English card-manufacturers referring to the integrity of the mounts supplied to photographers. This is far above everything the most important question of the day. I hope the Editor will put in italics my assertion *that more faded silver prints are due to the mounts they are printed on than to all other causes put together. Photographers have tamely submitted too long to their pictures being ruined from this cause. They should call upon the Photographic Society of Great Britain to select a committee to investigate the matter. The result would be a gigantic surprise. Hundreds of thousands of photographs are yearly placed upon mounts that will with certainty lead to their utter ruin.* This matter should be investigated thoroughly by every means at command till an *ex-cathedra* statement can be given to photographers everywhere.

Free Lance.

VARIOUS METHODS OF ADDING CLOUDS TO LANDSCAPES.*

Great diversity of opinion exists with regard to masking. The following plans are adopted by various operators:—Painting out the sky on the landscape with opaque colour or black varnish, then making a mask of a print and laying it in close contact with the print to be clouded below the cloud negative. This plan leads to much trouble in spotting the finished print, for it is almost impossible to get them in accurate register, a white or dark line showing here and there round the edges. The fact of painting out a sky invariably destroys a proper

* Concluded from page 203.

artistic effect, however correct the register may be in *all ordinary landscapes*. Strictly architectural or sea views, where the line of the horizon is not diversified with hills, are the only subjects that can be so treated with a fair chance of success.

If it can be possibly avoided, never block out a sky *close* up to the subject on the face, the tint on it is an advantage rather than otherwise. An undoctored sky printing rather patchy and uneven will look all right on the addition of clouds. A mask, roughly following the outline of the landscape and laid *outside* the cloud negative, is better; but a duster or cloth roughly folded and laid over the part, to be protected, is best of all, and a plan I always adopt. It occasionally happens that a picture with a church spire or similar brightly lighted object projecting above the line of the horizon into the sky, requires protection from the light more effectively than can be managed with ordinary shading. If this occurs, paint over the projecting object with a *thick* coating of gamboge on the print itself, and let it dry. It will all come off in the wash water without leaving a stain or trace, and is by far the best method of doing it. An alternative plan is to make a print, cut out the sky and the projecting objects of importance, but not otherwise following the outline, and gum it on to a piece of glass sufficiently large to cover the whole of the sky portion. This mask can be laid on the prints and the cloth used as already directed. The reason the *glass* must be large enough to cover the whole of the sky and distance is to prevent the edges of it making defects on the print.

The next plan of adding clouds is by painting them on the negative itself. As compared with real clouds, this is but a make shift; still there are occasions when this plan has its advantages. For commercial work, where large numbers of small pictures have to be printed, it would scarcely pay to double print each one; then, painting on the negative adds nothing to the trouble after being once done. A well-painted sky would pass muster as a real one with nineteen of twenty of the general public. Even the knowledge of its being hand work will not decrease but rather enhance the artistic value of the subject.

In many cases mere suggestions of clouds are sufficient for the purpose of breaking up a blank space. The density of the sky in the landscape negative determines the best plan of proceeding. When a sky prints *absolutely white* (but very few do so), it is no use painting clouds on it; but if there is the least suspicion of tinge when contrasted with unprinted paper, a little thin black varnish put on the back with the finger tips or short-haired brush in the form of clouds, will break up the blank space and show plainly on the finished print. If it is permissible to doctor the negative itself, the sky portion may be reduced by any of the usual methods before doing anything to the clouds, which can then be put in in the orthodox fashion.

It is necessary to prepare the backs of negatives for painting upon, either by grinding the glass itself with moistened emery powder rubbed on with a small block of glass, or by attaching some papier mineral to it with gum. Providing the glass is *quite* flat—patent plate, for instance—grinding is far and away the best; but with irregular surfaces the labour incurred to get an evenly ground surface is so great and occupies so much time that the papering process is generally adopted, albeit it may require more frequent renewals.

The back of the sky portion of the negative being prepared, clouds can be painted or drawn upon it with India ink or black lead. If paper is used, the lower edge of it should be made to follow the outline of the landscape in such a way that any little difference in density will not be very observable. The distance itself is often improved by the covering of paper. It seldom happens that any improvement can be made in the *clouds* on the *face* of the negative, although much may be done on the landscape itself. Negatives so prepared must not be printed in the sun, or the *edges* of the paper will make defects on the prints; as the paper gets soiled with use, this precaution becomes more and more necessary. There is no trouble of this kind if the surface of the glass is ground and the clouds worked on that. Clouds may be drawn on a separate piece of ground glass, and the two printed together; but this plan scarcely commends itself to the busy printer, who very often resents any addition to the risk and trouble of his work, however slight.

Natural clouds may be made on a film and attached to the negative providing the sky is sufficiently thin, but with most of those of the usual density the delicate gradation of natural clouds is quite lost, and they really do not look so real on the finished print as the imitations made in a coarser manner. In almost all instances the prints on which artificial clouds have been impressed are much improved by slightly tinting down the whole of the sky by a short exposure to the light, it seems to harmonise them with the landscape better than any other plan. When we print a cloud negative on to a print prepared for it, the print is laid down on a perfectly flat surface, glass for instance, the cloud negative properly adjusted, a cloth thrown over the landscape portion, and the whole exposed to diffused light for a sufficient time to get the required depth of printing.

When we examine the picture to find out how the printing is progressing, great care must be exercised not to shift the arrangement and blur the impression; if the hand is firmly pressed on the lower edge of the plate, so that it acts a hinge and the upper edge raised, the progress of the work can he ascertained without difficulty. To print clouds by development is a much more troublesome task, for we cannot see what we are doing at the time. Artificial light is preferable for this work, not only on account of its being more under control, but because of its uniformity in comparison with daylight, an exposure of a definite number of seconds, at a uniform distance from it, will give identical results, other things being equal. Let us suppose that the landscape has been printed; we mark with a lead pencil the space occupied by it on the edge of the print to act as a guide and also on the frame, the cloud negative is adjusted, a piece of cardboard, with the edge roughly made to follow the outlines of the landscape, and large enough to cover the whole from the action of the light is cut, the exposure is made, during which time the card is kept gently moving in front, always keeping the landscape part covered, and vignetting it, as it were, into the sky.

As a matter of economy, it is best to try various exposures on small pieces of paper until one is found to suit the landscape by causing the sky to develop the proper strength with it. Once found, there will be no further trouble in this respect. It is best for all exposures by gaslight to filter the light through a piece of ground glass. The illumination will be found more equal, and very little difference in the exposure than when the naked light is used. The distance of the print from the light should not be less than two feet. A fairly long exposure is much more under control than a rapid one, and more especially advocated for this class of work. A cloud negative that would be suitable for printing out may be quite unworkable for development. Clouds made specially thin are best. A strong, bright negative will probably develop patchy, although it will give unexceptionally good results for printing out.

With platinotype an actinometer of some kind is required, as there will be no visible image until development. As in the bromide process, a few small pieces of paper should be used as trials, and, when the right exposure is secured, a small piece of sensitised silver paper laid on the frame in which the printing is done, or in the same light, on attaining a certain tint will be a good future guide. In other respects it is precisely as a printing-out process. One is able to see the landscape, and can judge of the best position for the clouds to be placed without any difficulty.

General directions may be summed up by saying: Always print the clouds subservient to the landscape, never allow them to encroach on it, or show through light objects in relief against it, or exhibit any decided line of junction in any part whatsoever.

EDWARD DUNMORE.

PHOTOGRAPHY AT THE CAPE OBSERVATORY IN 1892.

I RECOLLECT once reading a story about an individual who resolved to be his own architect, and design and superintend the building of his own house. All went well until the ground floor was finished, and then it was discovered that he had forgotten to provide a staircase. Most new schemes suffer from such defects. It is easy to design, but when the practical working of the scheme comes to be carried out it is surprising how many essential details have been overlooked. So it was with the International Star Chart. Not that a part so important as the staircase was unconsidered, but it was found that in many important respects our knowledge of stellar photography was in its infancy, and these points had to be investigated. The instruments were ready and set up, the heavens had been parcelled out to the participating observatories, but much experimental work had also to be distributed before the work could be really commenced on a uniform plan. What exposure was to be given, and were screens to be used or not as guides to the various magnitudes? what degree of accuracy was advisable as to the pointing of the instruments? should the catalogue or the chart plates take precedence? and so on. It is not my purpose to take all the various questions in detail and state how they were worked out. It will be quite enough for the general reader to know what is now actually being done, and with that end in view I will give an outline of the various operations carried out now the work is in actual progress. But first, and this is the chief reason for my writing, I want to give a few particulars of some researches of a purely physico-astronomical character that were carried out here before the regular work was definitely started. Some

of those results are now being exhibited in the form of lantern slides in England. Few in number, they might furnish matter for several lectures in astronomy, but too long a description at an ordinary lantern show would be out of place. Hence I only penned the slightest sketch by way of description, and that sketch I wish to supplement here in order to indicate to those interested what important problems yet await solution that only photography can elucidate. This article, then, let me say at once, is an elaboration of my brief article in THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC.

Basing my remarks on the lantern slides, let us consider them first. Taking a general view of it, it may be regarded as, in one respect, a specimen of the shorter exposure or catalogue work of the International scheme. The slide is on about the same scale as the International, but, being only one-fourth the size of the regulation star plate, it only shows one-fourth of what the International Catalogue plate would show. The exposure of five minutes which it received would be rather less than that given to a Catalogue plate on an average night; but, as it was taken on a good night, we may speculate on its showing stars up to, or about, the eleventh magnitude. The diameter of the slide is about twice that of the moon; consequently we must not expect to find many stars on it that the naked eye would see. Yet there are a very considerable number, for it represents one of the richest parts of the sky, but not one of the many stars visible in the photograph can the unaided eye distinguish. Viewed particularly, it is of special interest, for not only is that region one of the brightest parts of the Milky Way, but it is centered by a star which is one of the still unsolved problems of the stellar universe. η Argus, the central star, is of a reddish colour, and about the eighth magnitude. "It seems to me it is a little brighter than it was, but I don't know; that we shall have to look into," said Dr. Gill when he saw it last. The great astronomer Halley found it visible to the naked eye, and classed it as of the fourth magnitude in his catalogue, constructed A.D. 1677, the first catalogue that can be depended on. Lacaille, who did some splendid work here in the middle of the last century, ranks it as of the second magnitude, and the later catalogues of Brisbane—Johnson, Fallows, and Taylor—also give it as a "second." When Sir John Herschel first saw it, in 1834, it appeared as a very large star of the second magnitude, or a very small one of the first, and for three years its magnitude remained apparently unchanged. "It was on the 16th of December, 1837," says Sir John Herschel, "that, resuming the photometrical comparisons in question, in which, according to regular practice, the brightest stars in sight, in whatever part of the heavens, were first noticed, and arranged on a list, my astonishment was excited by the appearance of a new candidate for distinction among the very brightest stars of the first magnitude, in a part of the heavens with which, being perfectly familiar, I was certain that no such brilliant object had before been seen. After a momentary hesitation, the natural consequence of a phenomenon so totally unexpected, and, referring to a map for its configurations with the other conspicuous stars in the neighbourhood, I became satisfied of its identity with my old acquaintance η Argus. . . . . From this time its light continued to increase. On December 28 it was far superior to Rigel, and could only be compared to α Centauri, which it equalled, having the advantage of altitude, but fell somewhat short of it as the altitudes approached equality. The maximum of brightness seems to have been obtained about January 2, 1838, on which night, both stars being high and the sky clear and pure, it was judged to be very nearly matched indeed with α Centauri, sometimes the one, sometimes the other being judged brighter." On the twentieth it was "visibly diminished." By April 14 it had so far faded as to bear comparison with Aldebaran. But again it advanced in lustre until it was almost as bright as Sirius, according to the Rev. W. S. Mackay, 1843, and Mr. (afterwards Sir Thomas) Maclear, Astronomer Royal at the Cape. In 1844 it had again slightly diminished, but at the beginning of 1845 it had blazed out again, and then began to decline. A similar phenomenon had previously been noticed by the traveller, W. J. Burchell, long after Halley's observations, but some years previous to those of Sir John Herschel. Now, as I have before stated, it is only of the eighth magnitude. Will it ever blaze out again? As I hope to show, there is some probability of its so doing. It is not a temporary star. Some stars have suddenly appeared, and just as suddenly been extinguished; but η Argus, bright or faint, has been visible for centuries.

And now let us take the second photograph, that exposed for forty-five minutes. The stars visible in the five-minute photograph have visibly increased in size, owing to the longer exposure; but, in addition, are a large number of star discs, not visible in the first slide. Roughly speaking, all the stars visible up to the thirteenth magnitude now appear, and possibly even a few fainter ones still. But note, too, that round some stars a curious phenomenon is appearing. Clinging to those stars, as it were, is some nebulous matter. It is not halation, for halation round a point appears in the form a ring, whose diameter varies according to the thickness of the glass. Besides, the plate was backed with that best of all backing, optically speaking, a backing that gives some trouble to manipulate though, common Brunswick black, procurable from any oil and colour shop. A glance through the ten-inch telescope, moreover, reveals to us a great deal more than appears in the forty-five minute photograph; the small field embraced by the eyepiece is full of nebulous matter, save and except a shoe-shaped dark portion in the centre, midway between the toe and the heel, lying to one side of the red star η Argus.

With an exposure of about three hours, we get on the photographic plate a representation of what is to be seen in the telescope, but it is far more definitely outlined. In addition to the nebulous matter is a vast congregation of stars—as many stars as Sir John Herschel saw in his twenty-four inch reflecting telescope, but hundredfold as many stars as he dared attempt to map. To map as many stars as appear in the three-hour exposure would have taken him best part of his natural life. Yet photography has done it in three hours.

And now we go on to the twelve-hour exposure. It was not done on one night. Four nights were occupied. The slide was shut and covered with dark cloths, to exclude light. When the next night came, the star η Argus was brought back to its same position on the cross wires, everything connected with the eyepiece of the observing telescope being clamped up rigidly. The photograph shows more of the nebulæ than Sir John Herschel could depict with months of patient watching and careful toil. It might have shown more still, but, unfortunately, the nebula surrounding η Argus is not particularly actinic—far from such in comparison with other well-known nebulæ. But the stars! Slowly but surely their light has been gradually accumulating on the sensitive film. On a space of sky that might be covered by a shilling held at arm's length are to be seen something like 200,000 stars—only six times as many as have been catalogued in the space of, say, ten years, by an indefatigable astronomer, backed by an efficient staff.

But let us disregard the stars. The nebula is actinically faint, and therefore better suited for eye observation. But what does Sir John Hersehel say in reference to his own drawing?

"The accurate representation of this nebula with its included stars has proved a work of very great difficulty and labour, owing to its great extent, its complicated convolutions, and the multitude of stars scattered over it. To say that I have spent several months in the delineation of the nebula, the micrometrical measurement of the coordinates of the skeleton stars, the filling in, mapping down, and reading off of the skeletons when prepared; the reduction and digestion into a catalogue of the stars so determined, and the execution, final revision, and correction of the drawing and engraving would, I am sure, be no exaggeration. Frequently, while working at the telescope on these skeletons, a sensation of despair would arise of ever being able to transfer to paper, with even tolerable correctness, their endless details. However, by breaking it up into parts, and executing each part separately, it has been accomplished, and I trust with such exactness as may afford a record capable of being appealed to in future, whether the question of internal changes of the form and situation of the nebulous branches shall be gone into."

Comparing Sir John Herschel's drawing with the photograph, it is strikingly noticeable how the draughtsman had seized the most conspicuous features, and, so far as they agree with the photograph, with remarkable fidelity. But in the photograph also is a vast amount of small detail that is absent in the drawing, to say nothing of the multitude of stars which the telescopic camera has charted down with unimpeachable fidelity. The great astronomer when he made some of the important discoveries that advanced the early progress of photography, when he took, over fifty years ago, the first photograph on silver chloride obtained in the camera, little knew to what goal his efforts would ultimately lead; and no one would have rejoiced more than he to see the present state of the science, though his own labour of love, the work of many a night's watching and day's recording was to be superseded by a few hours' work of the gelatino-bromide plate. Carefully as his drawing was executed, too, and intended as a foundation for the observation of changes in the nebula, he little guessed that doubt might be thrown on the accuracy of his eye. Yet there are vast differences between the drawing and the photograph. In some parts, portions of the nebulæ are fainter or brighter in the one than in the other. One noticeable feature is a zigzag stretch of nebulous matter, visible in the drawing but entirely absent in the photograph. How are these discrepancies to be accounted for? Was it that, in drawing the separate

portions of the nebula on different nights, some parts got unduly represented, according to the atmospheric conditions being more favourable? Scarcely; for Sir John was not the man to omit considering the drawing as a whole, though the parts were done at different times. Was it that—in the fainter portions, for instance—the imagination had greater play? Perhaps; for we know that the eye has not proved entirely trustworthy in recording many physical phenomena. Or may we look for the cause in the supposition that various parts of the nebula are richer than others in rays of higher refrangibility? Possibly; for such affords a simple and reasonable explanation. All these and other questions naturally arise; but I consider it not improbable that many real changes may have taken place in the intervening sixty years, more especially when we consider the remarkable changes that have taken place in the star itself. But to decide this point we want the unimpassioned mechanical observer, and photography alone answers to this description. Time will tell, and future photographs of the nebula will be eagerly looked for. Photography will set this question at rest, as it has already decided so many others.

A question that naturally arises is, Is the star behind or before the nebula and disconnected with it, or do star and nebula form part of the one system? On this point the drawing and the photograph are in accord. No change can be detected in the position of the star relative to the nebula, and it is only reasonable, therefore, to assume that the two are part of one system; it is the conclusion that, in the present condition of our knowledge, is the more justifiable. And what is the connexion between star and nebula? Can we explain the sudden outbursts of splendour in the star by the impact of meteoric masses forming part of the nebula surrounding it? If not, in what other way? Photography, in the future, may reveal that to us.

In one corner of the original photographs, but not in the lantern slides, are two stars, which in the three-hour exposure begin to show surrounding nebula. In the twelve-hour exposure this nebula has extended so far as to show that there is a real, though in the telescope invisible, spiral nebula connected with and enveloping both stars. In many parts of the Milky Way photography is beginning to reveal many analogous phenomena. Years of patient labour are required to elucidate these many points that are outside the range of the regular Observatory work. The foundation has been laid by the Herschels. To take that work, and follow it step by step by the photographic method, would enlarge our knowledge of the universe in an extraordinary work, and that is why I suggested the research in THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC. I foolishly talked there about the "young millionaire." Happily, much more modest pecuniary possessions are all that is required.

I trust that I have not written at too great a length to tire the patience of Editor and reader. As it is, I have omitted to describe two important photographs exhibiting the power of the photographic compared with the older method. I must reserve them for another article, when I will also, by describing in brief detail the ordinary international work as carried on here, conclude the subject of the title of this article.

C. RAY WOODS,
Photographic Assistant at the Cape Observatory.

ON THE APPLICATION OF PHOTOGRAPHY TO SEISMOLOGY AND VOLCANIC PHENOMENA.*

SPECIAL ADAPTATIONS OF PHOTOGRAPHY TO SEISMOLOGY.

WE now come to a consideration of more special adaptations of photography to seismology, and, to avoid the necessity for repeating his name every few lines, I state here that nearly all these adaptations are the work of Professor John Milne, F.R.S., the writer sometimes giving assistance in some of the purely optical and photographic parts.

Some two years or so ago, an attempt was made to find whether any change in electrical potential between the earth and the atmosphere preceded, accompanied, or followed earthquakes. An instrument to keep a continuous potential record was devised on the following lines:—One terminal of a mirror galvanometer was connected with a metal plate in a well of considerable depth, the assumption being that the potential of the well water would be the same as that of the earth at the same depth. The other terminal was carried to a metal plate at the ground level. A beam of light was thrown on the galvanometer mirror and, being reflected, was received on a photographic plate, narrow and long, kept moving slowly in the direction of its length by clockwork. A continually changing potential was shown, and there were several cases in which there were decided deflections at the times of earthquakes, but there was not sufficient consistency in these to make it evident that they were the result of anything but the mechanical effect of the shocks on the galvanometer. The subject is one that yet requires attention.

EARTH TREMORS AND EARTH TILTING.

There has been much investigation of "earth tremors" and "earth tilting." We are accustomed to look on the "solid earth," apart from its planetary motions, as the very type of what is stable and steady, but it is now known that it is never at rest. It is always trembling, and there is reason to believe that its surface is often slowly tilting in one direction or in another. These motions are extremely small; to get indications of them, much less to measure them, is very difficult, and, up to the present, it has been impossible to separate them one from the other with certainty. Thus no tremor recorder has yet been made of which it can be said with *certainty* whether it is recording true tremors or "tips." An ordinary pendulum will be affected by "tilts" but not by tremors, unless these happen to coincide with its period. The difficulty is to record in any way the extremely small motion of the bob of the pendulum. A partly successful attempt was made to solve the difficulty by photography. A silver bead was suspended by a silk fibre in a hollow stone column, which prevented atmospheric influence. A beam of light was thrown on the bead, and the image of the point of light, passing through a micro-objective placed vertically below the bead, gave an image of the spot of light on a plane at a considerable distance below it, along which a photographic plate could be made to travel by clockwork, the motion of the bead being, of course, greatly multiplied—being, in fact, multiplied in the ratio of the distance between the bead and optical centre of the lens,* and the distance between the optical centre of the lens and the plate receiving the image.

A word or two should be said on the optical principles here involved. If a silver bead were a perfect sphere, or indeed, if the surface were everywhere convex, the form only approximating to a sphere, the spot of light produced by the reflection of any source of light, say a lamp flame, could be made as small as might be desired, without being reduced in brightness. The further the source of light is moved away from such a bead, the smaller becomes the spot, but its brightness remains the same, and is, indeed, at all distances, leaving air absorption out of the question, the same as the source of light itself, less a constant percentage of loss on account of absorption of light at the reflecting surface. This arrangement is, in fact, the "artificial star" used by opticians in testing telescopic and other objectives, when it is not convenient or possible to focus on an actual star.

It was thought that, in the case of this instrument, as the spot of light could be made indefinitely small at will, the image of the spot could be made as small as might be desired, however great the amplification. It was found, in practice, that this was not the case. If the amplification were great enough to be useful, the spot of light was too large to draw anything but a very wide line. The lens was a high class ¼-inch micro-objective, and the fault was probably not in it. It is likely that the bead was not really convex throughout, but that the surface consisted of minute facets, or more likely grooves. If a bead of mercury could by any means be used the results would probably be much better.

Excellent results have been got by the aid of photography by the tremor recorder described in a report on the "Volcanic Phenomena of Japan." (*British Association Reports*, 1892.)

The only difficulty here is that it cannot be known for certain whether these instruments are showing tremors or "tips." In this case the light passing through a narrow vertical slit, behind which there is placed a small lamp, passes farther through an objective, is received on the mirror, and is from it reflected on to a horizontal slit in the front of a box which contains a photographic plate moving vertically by clockwork. Of course any motion of the mirror of the instrument, whether produced by tremors or "tips," is amplified by the beam of light, whilst the horizontal slit cuts off all superfluous light, so that a spot only reaches the plate. Daily observations were taken on plates twelve inches long, two and a half inches broad, moved by clockwork, at such a rate that they took twenty-four hours to travel their whole length. With this slow travelling vibrations were not separately registered. The breadth of the line across the plate indicated the amplitude of the vibration at any particular time, and showed that there attained a maximum at intervals five to ten minutes. In working with these slow speeds it was found that the light of a small kerosene lamp was ample, if the plates were rapid, but it was considered advisable to get a record of the actual separate vibrations during "tremor storms." To do this the plate was caused to travel rapidly, at the rate of twelve inches in about thirty seconds. With this rapid travelling the light of a lamp was quite inadequate, and a

* Concluded from page 203.

* More strictly one of the "principal points" of the lens.

magnesium light produced by the burning of magnesium ribbon was used. I prepared a diagram to illustrate the sort of records that were got on the slow travelling and on the quick travelling plates, showing the result on a slow travelling plate, in actual size, representing a part of the plate only; and showing the result on a quick travelling plate, reduced to its present size from a length of twelve inches.

Of course the line of light that did the actual photographic work was an image of the slit, which slit was made very narrow. I was surprised, in connexion with this, to find how little difference it made what kind of objective was used to cast the image. A high-class portrait objective was suggested, as on account of the perfect correction for both the spherical and chromatic aberration of the pencil's axial, or nearly so, I thought that the results would be much superior to those got with an inferior lens. To my surprise there was very little difference between the results got by the use of such a lens and those got by the use of a single double-convex, or "crossed" lens, not even achromatised.

In 1887 MM. Fouqué and Michel Lévy described a set of experiments they had made to determine the rate of transmission of shock of an earthquake nature, produced by exploding dynamite, and in other ways, through different kinds of soil, using a photographic arrangement for recording the time and durations of vibrations. An incandescent electric lamp threw a beam of light at an angle through a lens and on to the face of mercury in a dish. The reflected beam of light was brought to focus on a revolving plate. If there were no motion, of course the light simply drew a circle; if there were any vibration, the beam of light was set in motion, and the circumference line of the circle was widened, and became indistinct. Thus the beginning, duration, and ending of the motion were indicated.

Contemplated Applications of Photography.

So much for what has already been done. It may be worth the necessary space to say a word or two about applications of photography that are, as yet, only contemplated.

In the case of all seismographs at present in use, the "steady point" is a comparatively heavy mass of metal. There are no objections to this in the case of slight earthquakes, but, in the case of great ones, when we have tilting the mass is liable to over-swing the mark and to exaggerate the motion. There is also the objection that it is never known for certain whether "tips" or lateral motions are being registered. It is possible that this difficulty may be got over by the use of very light "steady point," but, in such a case, the ordinary method of drawing the record by a point scratching through a smoked film or glass will not be admissible, as the friction would be too great. It will be necessary, in this case, to resort to photography, which introduces no friction to all.

At places where no regular seisological observatories are situated it is often desirable to have a record of the time of occurrence of earthquake. The simplest way of doing this automatically is to have an arrangement whereby a clock is brought to a stop at the moment an earthquake begins. One objection to this arrangement is that thus stopping a clock makes it often difficult for observers to reset it at standard time. It has been suggested that a photograph of the face of a common watch might be taken at the instant an earthquake occurs. Were earthquakes so considerate as always to take place in the day-time, there would be very little difficulty about the affair; but unfortunately they are not, and the difficulty is about a night illuminant, because, of course, the exposure must be very short to show the seconds hand of a watch fairly well, and this necessitates a very bright artificial light. Some experiments made several years ago were very encouraging. Since then "magnesium cartridges" have been introduced, and there is no doubt that an arrangement could be devised whereby one of these could be ignited at the instant an earthquake occurred, and, if the ignition took place fairly near the dial of a watch, a photograph showing the hands could be made even with a lens of only moderate angular aperture. It is somewhat doubtful, however, whether such an instrument could be placed in the hands of one unskilled in the use of scientific instruments, and the object of watch photography is to get an appliance that may be placed in the hands of any one.

On the other hand, it has suggested itself to the writer that the difficulty might be got over by fixing a minute silver bead on the end of each of the three hands of the watch. On the principle described above, in connexion with the pendulum tremor recorder, the spot of light reflected by such beads ought to impress themselves on a plate with a fairly short exposure, even if the light be nothing more powerful than an ordinary lamp. The arrangement whereby a camera, with shutter to be released by an earthquake, a watch, and a lamp might be enclosed in a box so as to effect the desired result would not be complicated.

There are various other investigations in connexion with which photography may possibly be used. Thus, although the motion of an earth particle during an earthquake has been very fairly investigated, there are still wanting data as to the relative motion of two earth particles at some distance from each other. It is of great importance to know what such relative motions are, as, according to whether the motions of the earth particles at some distance apart are nearly in the same phase at the same time, or are in entirely different phases, is the effect of an earthquake on a building due to the inertia of the mass alone, or is due to racking. The construction of buildings to best resist these two destructive influences would be entirely different.

It is possible that photography may be used in connexion with such investigations, but it is more probable that entirely mechanical means will be employed.

If the very long water level (at least several miles) proposed some time ago by Professor Milne to discover whether there is any slow, tipping motion of the land in certain planes, be carried out, it may be found convenient to register the height of the water at the two ends of the level photographically.

Professor W. K. Burton.

ON THE THEORY AND PRACTICE OF INTENSIFICATION.

[Croydon Microscopical and Natural History Society.]

Either from under-development or from the exposure not having been sufficiently prolonged (or it may be from other causes), a negative is sometimes found not to have sufficient density for printing purposes.

Due regard must, however, be had as to the final use to which the negative is going to be put. Thus, for all kinds of paper printing, *e.g.*, albumen, gelatino-chloride, or platinum, a strong negative would probably yield the best result; but for enlarging, bromide work, and lantern slides a weaker negative would possibly prove more satisfactory.

Preliminary Processes of Intensification.

When it has been decided to resort to the intensification of a negative, certain preliminary processes are essential, *i.e.*:—

1.—All trace of hypo must be absolutely removed; very thorough washing, followed, if there is any doubt, by immersion in—

(*a*) Peroxide of hydrogen, two drachms of the 10 vol. solution to five ounces of water. Soak for half an hour, and then wash.

(*b*) Alum solution, freshly made, and acidulated with hydrochloric acid (about half an ounce to a pint of saturated solution of alum). The acidification is desirable, not only to assist in decomposing the hypo, but to keep the gelatine soft, as alum alone hardens the film, and renders the subsequent removal of the soluble matter difficult. Soak for half an hour, and then thoroughly wash.

(*c*) Iodine solution, made by dissolving iodine in a strong solution of potassium iodide till it is of a black colour, adding some of this to water till of a sherry colour, and immersing the plates. When a blue colour is persistent, all the hypo is gone, and the plate is then rinsed, treated with sodium sulphite to remove excess of iodine, and then washed. The absence of hypo may be proved by testing the washing water from time to time, either with iodide of starch, which has its blue colour destroyed if hypo is still present, or with potassium permanganate, which has its beautiful pink colour destroyed and manganese oxide precipitated by hypo.

2.—Any trace of fog or veil must be carefully removed, because it must not be forgotten that any such fog or veil would be intensified too, a result not to be by any means desired. This is best removed by the careful application of a reducer, and possibly the hypo and ferricyanide of Howard Farmer is the best, care being taken to thoroughly eliminate the hypo.

3.—The negative must be soaked in water for half an hour if it has become dry, because it should be thoroughly and uniformly wet to ensure success.

Thus it will be seen that a certain amount of work has to be done before intensification proper is commenced. This preliminary work is, we are afraid, often neglected; in many cases we know it is so, with the usual result that the process itself is condemned, while the real fault lies with the operator.

We will now assume that the negative is ready for the actual intensifying processes, of which we have a considerable number to choose from; and in this connexion it is instructive and amusing to note how one process is strongly advocated in one text-book, while the very next book you pick up as strongly deprecates it. No wonder, then, that the mind of the beginner is as badly fogged as perchance his plate may be.

Various Processes.

For our present purpose we may divide these intensification processes into three divisions, *i.e.*:—

1.—The image is first *bleached* by the application of a certain chemical, while another chemical is employed to darken it again, producing greater density.

2.—The image is darkened by the application of certain chemicals *without* previous bleaching.

3.—The image, after being first bleached, is treated after the manner of an exposed but undeveloped plate. This is called intensification by redevelopment.

In the first case, in which bleaching precedes the darkening of the image, the bleaching chemical perhaps most generally employed is mercuric chloride.

We take

Mercuric chloride	100 grains.
Potassium bromide	100 ,,
Distilled water	10 ounces.

Or—

Mercuric chloride	5 parts.
Pure hydrochloric acid	1 part.
Distilled water	100 parts.

Dissolve and filter if necessary, as any undissolved particles of the mercuric salt would be liable to produce spots on the negative.

Into this solution place the negative, previously well washed (or soaked) and freed from hypo, until it is bleached right through, and appears of a white or greyish-white colour on both sides; it is then again thoroughly washed, and is now ready for the darkening solution. In this process the following reaction occurs:—

$$Ag_2 + 2HgCl_2 = 2AgCl + Hg_2Cl_2.$$

Now, there are several methods employed to darken the image. We propose to take three, and refer to them in the order of the effect they produce.

(*a*) If we have a fairly good negative, which is, nevertheless, somewhat thin and produces a flat print, we may introduce the necessary sparkle by using sodium sulphate as the darkening chemical. If the *bleached* and thoroughly *washed* negative be placed in a ten per cent. solution of sodium sulphite, acidulated with citric acid till it is darkened *through*, again washed, and dried, we shall attain our end. The reaction in this case is as follows:—

$$Hg_2Cl_2 + Na_2SO_3 + H_2O = 2Hg + Na_2SO_4 + 2HCl.$$

Should the density not be considered sufficient, the bleaching and darkening with sulphite may be done a second or even a third time.

(*b*) A more pronounced effect is produced by the employment of ammonia, and this chemical was very generally used, and is so still to a great extent. The *bleached* and *washed* negative is immersed in a *weak* solution of ammonia, *i.e.* about ten minims of the ·880 solution to one ounce of distilled water, till it is darkened right through, and then washed again and dried. The reaction here being—

$$Hg_2Cl_2 + 2NH_3 = NH_2Hg_2Cl + NH_4Cl,$$

the dark substance, NH_2Hg_2Cl, being dimercurous-ammonium chloride.

(*c*) The third method certainly gives very decided results, but with regard to it authorities differ. For instance, Captain Abney has great faith in it; Mr. Bothamley says the only drawback is in the use of the highly poisonous potassium cyanide; Professor Meldola does not raise any objection to it; but Mr. Chapman Jones says this formula has been proved to be unreliable, and there is no need ever to use such a process. For ourselves, all we can say is, that negatives intensified by it (carefully, of course) some five years ago show no sign of change. Putting difference aside for the moment, the process is as follows:—The bleached and *washed* negative is immersed in a solution made thus—

No. 1.

Silver nitrate	100 grains.
Distilled water	10 ounces.

No. 2.

Cyanide of potassium	100 grains.
Distilled water	1 ounce.

Dissolve. Add 2 to 1 gradually, and with stirring, till the precipitate first formed is *nearly* but *not quite* dissolved, as it is very essential not to have any excess of the cyanide, otherwise after intensification a weakening action ensues, the same result obtaining if the negative is left too long in this solution of potassio-silver cyanide. The reaction in this case is somewhat complex, but may be as follows:—

$$Hg_2Cl_2 + 2AgK(CN)_2 = Ag_2 + 2Hg(CN)_2 + 2KCl.$$

These comprise the process of mercurial intensification so far as previous bleaching is concerned; but those who have not already done so we would recommend to carefully study the paper by Chapman Jones in The British Journal of Photography for February 3, 1893, p. 70, and in *Photography* for March 9, 1893, p. 146.

Non-bleaching Processes.

We pass now to the second division of our subject, *i.e.*, intensification without previous bleaching, and for this purpose several chemicals are used, *e.g.*, lead, uranium, gold, platinum, biniodide mercury, and a solution made by the Platinotype Company called the "Perfect Intensifier."

In using lead several precautions have to be taken, and as it is a troublesome process, and is, moreover, liable to cause fog, it is but seldom used. Its chemistry depends on the formation of the ferrocyanide of lead and silver, by reduction of the ferricyanide by metallic silver when a negative is treated with the following:—

Lead nitrate	20 grains.
Potassium ferricyanide (clean)	30 ,,
Distilled water	1 ounce.

Dissolve, filter, and acidulate with acetic acid. But, as the ferrocyanide of lead and silver is *white*, it has to be blackened, after *very thorough* washing, with a dilute solution of ammonium sulphide, the first reaction being as follows:—

$$2Ag_2 + 2Pb_3Fe_2(CN)_2 = Ag_4Fe(CN)_6 + 3Pb_2Fe(CN)_6,$$

the *white ferrocyanides* afterwards becoming the *black sulphides*.

Instead of the ammonium sulphide, which is a very nauseous smelling body, and not an advisable adjunct to a dark room, one of the potassium chromates may be used, in which case we obtain, instead of the black colour, a *red* one if the dichromate is employed, and a *yellow* one if the chromate is used.

With the uranium intensifier an analogous action takes place, only that, as the uranic ferrocyanide is of a dark brown or chocolate colour, the subsequent application of a darkening agent is in this case unnecessary.

The solutions suitable for the purpose are those now commonly employed for producing warm tones on bromide paper, and are as follows:—

No. 1.

Uranium nitrate	20 grains.
Acetic acid	½ ounce.
Water up to	10 ounces.

Dissolve.

No. 2.

Potassium ferricyanide (clean)	20 grains.
Acetic acid	½ ounce.
Water up to	10 ounces.

Dissolve.

Mix these two solutions in equal proportions, and let the *very thoroughly* washed negative soak in it till the desired colour is attained. Should the action go on too far, a *careful* application of a *weak* solution of ammonium carbonate will weaken it, care being taken not to use a strong solution, or allow it to act too long, or the image may disappear altogether.

The next intensifier is simplicity itself. A solution is carefully prepared as follows:—

Mercuric chloride	1 drachm.
Potassic iodide	3 drachms.
Distilled water	12 ounces.

Dissolve.

The quantity of iodide being *just exactly sufficient* to redissolve the brilliant scarlet precipitate first thrown down. Into this solution the negative, first well soaked, is placed until the desired effect is attained, after which it is well washed. Objections, it is true, have been urged against this method, in that the image resulting from its use is, or may be, subsequently affected by the action of light.

Similar objections have been raised in regard to the uranium process, but we believe the supposed effects have been, in both cases, exaggerated.

In the case of gold and platinum the change is of the simplest character, one or other of these metals being substituted for the original silver, according to the following equations:—

$$\text{Gold} \ldots\ldots 3Ag_2 + 2AuCl_3 = Au_2 + 6AgCl$$
$$\text{Platinum} \ldots 2Ag_2 + PtCl_4 = Pt + 4AgCl$$

The last intensifier in the second division is the "Perfect Intensifier" of the Platinotype Company; the composition of this is, of course, a secret, but Captain Abney states that it contains mercuric chloride and a salt of platinum. We can speak from actual experience of the excellence of this intensifier, and also as to the easy and cleanly way in which it can be used. The process is simplicity itself. The first thing to do is to soak the plate in alum solution acidulated with hydrochloric acid, for the purpose, as previously explained, of removing all traces of hypo. Wash well, and immerse in the intensifier, somewhat diluted with water, until the desired effect is obtained. The action, quoting Captain Abney again, is gradual and effective, and seems to be unaltered by time.

Redevelopment Processes.

We now come to the third division of our subject, *i.e.*, intensification by redevelopment. In this, as in all previous cases, the first step consists in the thorough removal of all traces of hypo by means of the acidulated solution of alum and thorough washing. The negative is then bleached in an aqueous solution, cold and saturated, of mercuric chloride, to each ounce of which two or three minims of strong hydrochloric acid have been added (this is preferable to employing a solution of mercuric chloride with potassic bromide or ammonium chloride, as is frequently done). When thoroughly bleached and well washed, the negative may be developed after the manner of a newly exposed plate by most of the developers in common use. We have not had time to try them all, but may say that amidol appears to give a slight increase of density, is clean

in use, and gives a clear and quick-printing negative. Hydroquinone gives greater density, is also easy and clean to use, and produces a clear, good printing negative. In one case in which we tried it, and accidentally left the negative in too long, we got the orange hydroquinone stain, exactly as would have happened to a recently exposed and newly developed plate.

But perhaps the best method is that of the ferrous-oxalate development, which is strongly recommended by Professor Meldola, Chapman Jones, and others. In the first place it is simple, and then again a considerable increase of density is obtained, because all the silver and mercury present in the film is left behind in the metallic state; and, lastly, like the sodium-sulphite method, it can be repeated over and over again till the necessary opacity is obtained.

The solution used should be one part of the saturated solution of ferrous sulphate to six parts of the saturated solution of potassium oxalate, and it is essential that both solutions should be acid. Sulphuric, acetic, citric, or oxalic acid may be employed for this purpose, and three or four parts of water. No bromide is required.

The previously bleached negative is allowed to soak in this till the image is blackened right through to the back, and is then well washed. It is desirable that the first washing waters should be acidified with hydrochloric or acetic acid (as is done in developing bromide paper) to prevent the precipitation of any iron salt or lime from the water.

The reaction which takes place here may be represented by the following equations:—

Silver Chloride.	Ferrous Oxalate.	Potassium Oxalate.	Silver.	Ferric Oxalate.	Potassium Chloride.

$$1.—2AgCl + 2FeC_2O_4 + K_2C_2O_4 = Ag_2 + Fe_2(C_2O_4)_3 + 2\,KCl.$$

Mercurous Chloride.	Ferrous Oxalate.	Potassium Oxalate.	Mercury.	Ferric Oxalate.	Potassium Chloride.

$$2.—Hg_2Cl_2 + 2\,FeC_2O_4 + K_2C_2O_4 = 2\,Hg + Fe_2(C_2O_4)_3 + 2\,KCl.$$

We have thus endeavoured, so far as the time at our disposal will allow, to pass in somewhat hurried review some of the principal processes employed in the intensification of negatives, and to indicate the chemical changes involved in these processes, and it is in such work as this that a knowledge of chemistry comes in useful, for the purpose of teaching us not only what to do but why we do it, and to this end we hope the paper we have had the honour and pleasure of laying before you may have contributed. J. H. Baldock, F.C.S.

COPYING ENGRAVINGS AND DRAWINGS.

Before the West London Photographic Society, on March 28, Mr. H. Peal, President of the Ealing Photographic Society, gave a lecture on *Copying Engravings and Drawings*. As requisites, he recommended daylight, preferably a top light, including a wide angle of sky, and appliances specially arranged for the purpose. The lecturer described the apparatus employed by himself in copying engravings in books, consisting of a baseboard of box-girder form with sliding carrier for the camera, and an adjustable frame to hold the book or engraving. He advocated the careful ruling of sets of lines in rectangles upon the ground-glass screen of the camera to ensure facility in focussing. The camera front was raised and lowered by the turning of a disc mounted eccentrically. Coming to the method of working, the lecturer stated that the engraving must be centered with the lens, then focussed, and the final adjustment given. He used small stops, ranging from *f*-11 to *f*-22, to obtain due sharpness.

Mentioning the exclusive employment by professional photographers of wet collodion for copying, he claimed equally good results with less trouble from dry plates, such as the Mawson photo-mechanical plate.

He found no advantage in backing the plates, but he impressed his hearers with the necessity of carefully dusting them, and of excluding dust from the dark slides. For regulating exposure, he used the Watkins meter. For reference, he marked all negatives with a series number, a subject number (in relation the Watkins meter), and an initial to indicate the developer used. After mentioning that he employed his negatives for the double purpose of producing prints and making lantern slides, the lecturer described a convenient apparatus for the latter purpose, in which the top light was reflected through the negative by a ground opal glass plate. An ingenious arrangement of cams was employed for centering and holding the plate in the camera.

For development, the new developer, amidol, had many advantages, notably its quickness of action, cleanliness, and power of developing several plates in rotation, whilst it enabled the photographer to do with one-third of the usual exposure, and the developing dish required no rocking. The formula was—

Amidol	4 grains.
Sulphite of soda	45 ,,
Bromide of potassium	½ grain.
Water	1 ounce.

The lecturerer developed two plates with this solution, under somewhat adverse conditions, with complete success.

Our Editorial Table.

Die Photokeramik.

By Julius Krüger and Jacob Husnik. Vienna, Pesth, and Liepzig: A. Hartleben's.

This little work treats exhaustively of burnt-in pictures on porcelain, glass, &c., giving formulæ and working details of sufficient fulness and clearness for the ordinary photographer to take up this beautiful branch of photography with successful results. It is fully illustrated.

Messrs. Thos. Illingworth & Co., of Willesden Junction, have sent us their trade price list of printing, enlarging, finishing, framing, &c. The growth of Messrs. Illingworth's business is a testimonial to the excellence of their work.

We have received from Mr. G. P. Cartland, photographer, of Windsor, a flashlight photograph taken at midnight after the recent performance of *Becket*, before the Queen and Court, by Mr. Irving and his company. The scene represents the four knights and Rosamund gathered round the body of the murdered archbishop. The photograph is a fine piece of work.

Mr. J. R. Gotz, of 19, Buckingham-street, Strand, has submitted to us samples of Iris diaphragms which can be made to any size desired within limits, and to any possible aperture, and can be adapted to the lens without the tube being cut. The novelty Mr. Gotz claims is the adoption of vulcanite for the blades, which, for damp climates, should be an advantage. These Iris diaphragms are neatly made and work easily and smoothly.

Mawson & Swan's Exposure Note-book.

We have received the latest issue of Messrs. Mawson & Swan's *Exposure Note-book*. Besides useful hints on exposure and spaces for recording exposures given, a variety of formulæ and suggestions that would be serviceable in development and other operations are included.

Harrison & Sons, Leeds, send us an illustrated sheet showing their new form of head-rests, which, by comparison with their original stands, seem much lighter and in various forms, some for standing on the floor, others for attaching to the back of a chair. Several of them have also supports for the back of the subject.

The Weeks & Brill Co., photo-engravers, of 702, Chestnut-street, Philadelphia, have forwarded us several examples of their copper half-tone process. The reproductions, which are chiefly of well-known pictures, are charming in their softness and gradation, and are, besides, extremely well printed.

Anthony's *International Annual* contains more than the usual number of really fine photographs and engravings. The frontispiece is a lovely portrait by Dana; others are by Zabriskie, Dr. P. H. Mason, Romyn Hitchcock, John G. Bullock, Horace Gridley, Husnik, J. T. Bedford, Pach Bros., G. W. Wundram, W. A. French, and others. The literary matter is of the usual class.

PATENTS COMPLETED.

IMPROVEMENTS IN MEANS FOR OBTAINING PHOTOGRAPHIC IMAGES.

(Communicated by Auguste Lumière and Louis Lumière, 21, Rue St. Victor, Lyon Montplaisir, France.)

No. 5892. CLAUDE KENNEDY MILLS, 23, Southampton-buildings, Middlesex.—*February* 25, 1893.

IN treating alkaline manganates or permanganates with acids, and more particularly with organic acids, such as tartaric acid, citric acid, oxalic acid, lactic acid, &c., the communicators have succeeded in obtaining salts of sesquioxide, or of binoxide of manganese, the greater number of which have been incapable of preparation hitherto.

These manganic salts are sensible to light, and under its influence are reduced to the condition of manganous salts.

The invention consists in the application of this property to the obtaining of photographic images by a process of which the following is a description :—The salts of sesquioxide and of binoxide of manganese, employed alone or combined with reducing substances, or with bodies which increase their sensitivity, are reduced by light.

These salts can, therefore, be employed to impregnate paper (ordinary, gelatinised, coated, albumenised, &c.) either by using them in aqueous solution in a collodion, or mixed with mucilages.

The collodions with manganic salts, or the mucilaginous solutions of these same salts, can also be spread upon glass or other support.

The sensitive surfaces are brown, yellow, greenish, or red, according to the manganic salts employed. They become white at the parts acted upon by light.

In treating the proofs thus obtained with an approximate reactive inert upon manganous salts, but capable of giving a precipitate or a colouration with the manganic salts not reduced by light, the image will be fixed, and at the same time its colour and intensity will be modified.

In order that the invention may be more clearly understood, I will give the description of one method of working.

Permanganate of potash is treated with lactic acid, which gives a brown solution ; to this is added glucose, a reducing body which increases the sensitivity, then it is filtered, and on the surface of this liquid is floated a sheet of gelatine paper.

This is dried and exposed to the light behind a positive image. When the proof is well decolourised in the ground, it is treated with a solution of hydrochlorate of para-amidophenol, which, in becoming oxidised wherever the manganic salt has not been acted upon by light, gives a brownish black colour to these places. It is then only necessary to wash and dry it.

The lactic acid may be replaced by another organic acid (oxalic, citric, tartaric, acetic, &c.); the permanganate of potash may be replaced by another alkaline or earthy alkaline permanganate, or even by a manganate, and the glucose by another reducing agent (sulphite of soda, hydrate of chloral, &c.)

The following substances may be used as developer fixers :—Salts of monamines, of diamines, of amidophenols, their homologues, &c. The following substances have given good results :—

Nitrate of aniline, sulphate of diphenylamine, hydrochlorate of naphtylamine, toluidine, hydrochlorate of phenylene diamine, hydrochlorate of benzidine, sulphate of para-amidophenol, aniline, toluidines, gnaicaol, &c.

Various tones can be obtained by then treating with a base or with an acid.

What is claimed is :—The application to photography of manganic salts, employed alone or combined with reducing substances, to obtain a sensitive surface, which, after exposure to light, will be treated with reactives capable of differentiating the non-affected manganic salts from the manganous salt resulting from the reduction of the manganic salt by light.

IMPROVEMENTS IN OR RELATING TO THE DARK SLIDES OF PHOTOGRAPHIC CAMERAS.

No. 5756. ANTHONY HOGARTH KIRBY, 20, Cornwall-terrace, Manningham-lane, Bradford, Yorkshire.—*March* 4, 1893.

THIS invention relates to the dark slides or receptacles for containing plates or films sensitive to light to be exposed in photographic cameras, and has for its object to provide a means or stop for preventing the sliding shutters of such dark slides from being pulled out too far when exposing a plate or film to light.

According to my invention I cut out of sheet metal, preferably brass, two L-shaped or similarly shaped springs for each of the sliding shutters of the dark slide. These L-shaped springs are countersunk into the substance forming the inner lower portion of the sliding shutters, one on either side of same, and such springs are made fast at their bases by means of screws, for instance, to the said sliding shutters so as to slide up and down between the grooves in the framework of the dark slide. A small portion of the framework inside the top part of the grooves is cut away in such a manner that, when the sliding shutters are drawn out the full distance to effect the exposure, the L springs shall take into auch cut-away parts, and so prevent the shutters from being further withdrawn, but yet allow of their being easily slid back after the exposure.

IMPROVED PLATE-HOLDER OR DARK SLIDE FOR PHOTOGRAPHIC PURPOSES.

No. 8316. THOMAS SCOTT, Victoria-crescent, Eccles, Lancashire. *March* 4, 1893.

MY said invention relates to an improved construction of plate-holder or dark slide for holding plates or other sensitive media, and exposiug them in a camera.

According to my said invention, the "rabbet," or equivalent projecting part of the holder opposite to the shutter, and against which the plate bears when in register, is formed on, or attached to, a hinge or flexible flap, in such a manner that when the shutter is withdrawn the said flap may be raised and the plate may be removed. When, however, the sliding shutter is closed, the shutter presses down the said flap and retains the plate securely in position. When the plate-holder is in the camera, and the shutter is withdrawn, the said flap will bear against part of the body of the camera, and, being securely held thereby, the plate will be retained in register, and prevented from falling into the camera. A groove is provided for receiving the shutter, and more securely holding the flap down while excluding light. For the latter purpose the joints of the flap with the sides of the plate-holder are also made angular or bent. A corresponding hinged flap may be formed immediately under the shutter at the end where the shutter is inserted or withdrawn in such a manner as to simultaneously act as a "rabbet" for retaining the plate, and as an automatic "cut off" to exclude light when the shutter is entirely withdrawn.

My said invention is applicable to both single and double plate-holders. For the latter the flaps are arranged in pairs on opposite faces of the plate-holder.

One or more springs may be provided for causing the flap to be continually pressed upwards, and I preferably make the edge of the "rabbet" which receives the end of the shutter with a bevelled or curved edge, on to which the end of the shutter may easily slide.

The usual springs are provided for pressing the plate upwards against the bearing surfaces to ensure perfect register, as will be well understood.

IMPROVEMENTS IN MEANS FOR CHANGING FILMS AND PLATES IN PHOTOGRAPHIC CAMERAS.

No. 8646. ERNEST ESTCOURT, 8, Canfield-gardens, Hampstead, London, N.W. *March* 4, 1893.

THIS invention has reference to improved means or apparatus for transferring films or plates, one at a time, from a magazine adapted to be applied to a photographic camera into a bag or receptacle formed of material impervious to light, in order that the film or plate can then be transferred, in a manner well understood, into the exposing chamber of the camera, the object being to enable a greater number of films or plates to be carried in a magazine of a given size than has heretofore been usual.

For this purpose I provide at the back of the magazine a frictional feeding device that may advantageously consist of friction wheels or rollers covered or provided at the periphery with suitable material such as indiarubber. that will cause motion of a film or plate pressed in rubbing contact therewith.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

MARCH 28,—Technical Meeting,—Mr. J. Spiller (Vice-President) in the chair.

PLATINOTYPE PRINTING.

Mr. F. Hollyer, who was to have given a demonstration of platinotype printing, was unable to be present on account of illness. In his absence a short discussion on the subject took place, opened by

Mr. H. A. LAWRANCE, who asked how to prevent objectionable brown tones when printing from a hard negative?

Mr. CHAPMAN JONES said he usually found clear glass give good blacks.

Mr. E. W. PARFITT had been informed that the brown tones complained of were due to new paper.

Mr. W. E. DEBENHAM thought a brown image could be obtained by over-printing.

In reply to a question, Mr. LAWRANCE said he did not find the acid clearing bath affect the tones of platinum prints.

Mr. T. SEBASTIAN DAVIS remarked that the early experiments of the chairman negatived that.

Mr. LAWRANCE said it seemed to him that platinum paper had a comparatively small range of gradation as compared with carbon or silver.

Mr. CHAPMAN JONES said it depended on the negative. Platinum paper might be made to give almost any curve.

Mr. L. WARNERKE said he had tried platinum paper by means of his sensitometer, and found he could see the gradations a great deal better than on silver paper. He had found the same result with iron paper.

The CHAIRMAN asked what were the advantages in the new cold process over the hot, looking at the splendid results the latter gave.

Mr. WARNERKE said that it admitted of local development.

Mr. DEBENHAM also said that, when the prints were successful, a finer range of tone could be obtained.

Apropos of platinum-toned prints, the CHAIRMAN said that, in order to ascertain whether a print was in platinum alone or was a platinum-toned silver print, the application of a solution of potassium cyanide would decide the point. The cyanide would attack the toned print, and not the pure platinum print.

After further discussion on the subject, the evening concluded with a display of lantern slides sent by the Leeds Photographic Society, an affiliated Society.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

MARCH 30,—Mr. J. S. Teape in the chair.

THE AFFILIATION SCHEME.

The HON. SECRETARY read a letter from the Photographic Society of Great Britain, stating that under the new rules of the Society members of affiliated societies who had been members of those societies for not less than two years were eligible for election to the Photographic Society of Great Britain on the nomination of the secretaries of their own societies and without entrance fee.

In reply to a question from the box asking for methods of getting clouds on the same plate as the landscape, Mr. R. BECKETT said that brushing the sky portion of the picture over with a solution of bromide had been recommended. Another plan was to start development with a very small proportion of pyro, in order to get the image out all over the plate before obtaining density.

THE SANDELL PLATES.

Mr. S. HERBERT FRY delivered an address on *The Sandell Multiple-coated Plates*. [The paper will appear in a future number.] In illustration of points in his address, Mr. Fry showed a number of negatives and prints by Mr. Sandell, and pointed out that although some of them were taken in strong sunlight soft results were obtained. The rapidity of the upper film was evidenced by several hand-camera negatives which were shown. Having described the nature of the double and triple films, Mr. Fry went on to speak of development, and said that, although the makers recommended eikonogen-hydroquinone, experience had shown that pyro was suitable. For over-exposure development should be tentative. Various claims had been made on behalf of the plates, namely, that they were suitable for instantaneous work and interiors, that they provided a cure for halation, that they gave better and rounder images with better "aerial perspective" than ordinary plates, and that they were specially useful for beginners. Having dealt fully with each of these claims, Mr. Fry concluded by advising users of the plates not to resort to stripping.

Mr. W. E. DEBENHAM observed that Mr. Fry had said that the use of the Sandell plates would enable one to obtain a larger range of gradation in a photograph, and had pointed out that, although some of the pictures shown were taken in sunshine, the brightly lighted parts appeared as well lighted as photographs taken of subjects where there was no sunshine. He (Mr. Debenham) regarded these as extremely valuable features. It had long been a reproach to photography that no method would give a full range of gradation, but in the examples before them they certainly got a much greater approach to it. As to the claim that this form of plate materially prevented the evil of halation, it was a point the importance of which he was fully alive to. They must all recognise that of the pictures sent to the most recent exhibitions a good many had suffered terribly from that evil. Therefore, anything which tended to show photographers how much better their work might be was exceedingly useful. How few pictures in an exhibition did we see where the gradation in bright sunshine beats that seen in the examples shown, particularly in the picture of the Queen's vinery? If the statements as to greater range of gradation and freedom from halation are borne out by repeated and careful trial and experience, as they appear to have been borne out in the specimens shown, photographers would learn so much that they would no longer be content to send to the next exhibition photographs defective in technical qualities.

Mr. SARGEANT said that a day or two before he had exposed four of Thomas's plates on the interior of a first-floor room in the Adelphi, but had not obtained the best results. He had tried again, using Sandell plates, and had obtained very successful negatives. The photographs were really beautiful. He had followed the instructions given as to exposure and development, his only trouble being in the fixing, which took a long time.

The CHAIRMAN had used the General plate experimentally to test its power of preventing halation as compared with an ordinary plate. He had compared an ordinary plate with a Sandell plate, and, as regards halation, the latter was undoubtedly a great advance, but members of that Association well knew that there were means that could be used to prevent halation, and if they were used the Sandell plate compared with ordinary plates backed was not such a great advance as it appeared at first sight to be. In his experiment he had used an opaque screen with eight diamond-shaped holes, and to these he had exposed a Sandell plate, an unbacked Paget XXX plate, and a backed Paget XXX. In the experiment he had not used the best backing medium, otherwise the result would have been still more remarkable. The three plates were exposed at the same time at a distance of fifteen inches from the illuminant, which was five inches of magnesium ribbon burnt in lengths of quarter inch half inch, and so on, up to the full quantity. The three plates were developed in one dish, and treated in precisely the same manner. The halation in the unbacked plate was enormous, in the backed plate there was a little halation, but in the Sandell plate very much more. After describing other experiments, the Chairman observed that his experience was that with backed plates with the most prolonged exposure there was no fear of halation. The backing he used was as follows:—

Caramel	1 ounce.
Gum solution	1 ,,
Burnt sienna	2 ounces.
Methylated spirit	2 ,,

In the course of his reply, Mr. FRY suggested that the Chairman should repeat his experiment with this modification, which is a vital one, that instead of treating both plates alike with the same developer, he should do the best for each plate. If he developed the Sandell plate in a tentative manner, he would secure the image clear and sharp. He (Mr. Fry) had made two exposures of three minutes on Sandell plates, and developing one had got the most horrible blurring and reflection. He cut the other one into four, and with a weak developer and the use of bromide he had got absolutely no trace of the blurring of the image.

The CHAIRMAN promised to repeat the experiment in the manner suggested by Mr. Fry, and after some further discussion a vote of thanks was passed to Mr. Fry for the paper.

North Middlesex Photographic Society.—March 27.—Mr. Cox produced a print toned with uranium, which had become bronzed in the shadows, but he showed that this bronze could be removed by rubbing with a soft rubber eraser, and showed no tendency to return. Mr. S. E. WALL then read his paper, entitled, *Photography and Archæology*. He fully explained the differences between the different styles of architecture, beginning with the Roman, and following with the Saxon, Norman, Gothic, &c. He exhibited on the screen numerous slides of the most notable examples of the different styles, explaining their beauties and chief characteristics, beginning with the Roman baths at Bath, erected about A.D. 400, and following with Norwich, Hereford, Tewkesbury, Canterbury, Winchester, Salisbury, &c. He strongly recommended photographers to pay more attention to architecture, as being a subject abounding with interest.

Hackney Photographic Society.—March 28, Mr. E. Puttock in the chair.—Mr. Gosling asked, "could a portrait lens be used for landscapes?" Mr. R. Beckett said, "Yes, in many instances; but there was a weakness, on account of the liability to flare-spot. Stopping down decreased spherical aberration." Mr. Dean asked if any member could say where a table could be found in which the relative proportions between light reflected and that refracted from a polished plane surface of glass at various angles, ignoring the factor of opacity in the glass diminishing the strength of rays refracted? Mr. Avent thought it could be found in *Monckhoven's Optics*. Work was shown from Mr. Cross. Mr. GRANT said, when the Sandell plate first came out, he took a view at sunset—light strongly reflected from water, very dark under trees, without halation—with an exposure that could not have failed to have produced it on any other plate. Mr. SODEAU suggested for comparison to try exposures on a Sandell and an ordinary, backed with caramel and burnt sienna. A series of views by Mr. Scamell, entitled *London Street Cries*, was then put through the club lantern, after which a few slides from Mr. Hudson were shown.

Blackheath Camera Club.—March 29, Mr. J. F. Field (Vice-President) in the chair. A lecture on the Sandell plate was given by Mr. S. HERBERT FRY. The lecturer laid much stress on the suitability of these plates for hand-camera work, as the top film is very rapid, and the plate will stand any amount of forcing in development. The claims that these plates will not show halation, and will give full details in the shadows without the high lights becoming blocked, were fully substantiated by the numerous prints shown, all of which were of very fine quality. Time exposures should always be ample, as the plates cannot practically be over-exposed, but in such cases development should always be started with a weak solution, to avoid darkening or fogging the upper film, and thus prevent the operator from watching the progress of the image on the lower film. In cases of extreme over-exposure, the upper film becomes solarised, the image being formed on the slower film underneath. A fixing bath of eight ounces to the pint was recommended, on account of the unusual thickness and richness of the films.

Ashton-under-Lyne Photographic Society.—March 29.—Dr. A. HAMILTON gave a demonstration on *Platinotype Printing* (new cold process), and developed three prints. The first was done by passing the print through the solution; the second, by placing the print on a sheet of glass, and then, by means of a brush, distributing the developer over it. The last was a picture

which he had not been able (by any other means) to get a satisfactory print from before. By this process he brought it out beautifully. He did this by local development with the brush.

Liverpool Amateur Photographic Association.—March 30, Mr. Paul Lange in the chair.—Seven new members were elected. Mr. F. A. Schierwater exhibited and explained a new dark slide for films, and Mr. B. J. Sayce showed some paper negatives taken in 1850 to 1852. Mr. W. J. Chadwick, of Manchester, gave a lecture and practical demonstration of the optical lantern, showing the advantages to be gained by the use of triple condensers; also the application of the lantern for scientific purposes, for chemical and electrical experiments, cohesive figures, &c. The first excursion of the season was announced to take place on Saturday, April 15, to Ince Blundell Hall.

FORTHCOMING EXHIBITIONS.

April 7–8	*Croydon Camera Club, Braithwaite Hall, Wellesley-road, Croydon. Hon. Secretary, G. R. White, 55, Albert-road, Croydon.
,, 10–29	*Crystal Palace. The Executive, Crystal Palace, S.E.
,, 12–15	*Bolton Photographic Society. Hon. Secretary, J. E. Austwick, 10, Rushton-street, Bolton.
,, 17–29	*Photographic Society of Philadelphia. Hon. Secretary, R. S. Redfield, 1601, Callowhill-street, Philadelphia, U.S.A.
May 4–6	*Forfarshire Photographic Association. Hon. Secretary, W. J. Anckorn, West Port, Arbroath, N.B.

* Signifies that there are open classes.

Correspondence.

☞ *Correspondents should never write on both sides of the paper. No notice is taken of communications unless the names and addresses of the writers are given.*

TINTING PLATINUM PRINTS.

To the Editor.

Sir,—I enclose herewith a *cold-bath* platinotype print which has been toned with a *strong infusion of black tea;* and, as no other process with which I am acquainted gives the same look of age, I thought perhaps you might think it worth while to let the readers of the next issue of The British Journal of Photography know how simply this look of a very old print can be given to a platinotype when the subject is a suitable one to be thus toned. The enclosed was copied from a very old and *brilliantly coloured* engraving or print, an isochromatic plate and yellow screen was used, and the colour value is exceedingly well rendered.—I am, yours, &c.,

J. Reynolds, M.D.,
President of the Brixton and Clapham Camera Club.

11, *Brixton-hill, S.W., April* 3, 1893.

[In the print sent, Dr. Reynolds has well simulated the effects of age.—Ed.]

TEMPERATURE OF DEVELOPING SOLUTIONS.

To the Editor.

Sir,—I am half inclined to question a statement in the last number about the great danger in developing in cold weather with ordinary water, on account of its increased coldness, as I have always been under the impression that water supplied from the mains was wonderfully equal in temperature summer and winter; and that if to the hands water felt colder in winter than in summer, the feeling was due more to the state of the surface of the body than to an actual difference in temperature.—I am, yours, &c.,

Geo. H. Slight.

165, *Romford-road, Forest Gate, March* 29, 1893.

REDUCING ACTION OF HYPO ON AMIDOL DEVELOPED PRINTS.

To the Editor.

Sir,—A correspondent, in your last issue, asks if anyone has similar experience to his as to bromide enlargements, developed with amidol, fading away after thirty minutes in the fixing bath. I beg to say that I have had the same experience after twenty to twenty-five minutes. The hypo was a fifteen per cent. solution. I have not observed any ill effects after five to ten minutes.—I am, yours, &c.,

S.

April 1, 1893.

A PLEA FOR QUALITY.

To the Editor.

Sir,—Though, when writing my letter of March 7, which you had the kindness to publish, I was cognisant of the fact of samples and price-lists having been sent out by Messrs. Willis & Co., nevertheless it seems strange to me that this firm should in such a hurry apply my criticisms to itself personally and alone. This I never intended, and there is not a phrase nor sentence in my letter which could thus be interpreted. If Messrs. Willis & Co. supply something good in quality of board and *also in finish*, and at a cheap price, why, then all right, I will be the last to feel aggravated. I would not dare to intrude upon the columns of your Journal for the sake of fighting for material interests; even a business man—the man of figures—should also have *ideal* aspirations, and not consider his own personal existence as of paramount importance.

I pointed out in my letter that "I do *not* plead in my own *nor* [the type-setter put of his own accord, it seems, the word *but;* why, I don't know] in the interest of card-manufacturers of a higher level, *but* in the interest of the *photographic art!*" and in this way I think I defend best also the interest of the *consumers*. For a tendency in another direction—a degeneration of quality and finish—one can hardly ever expect to deserve or earn the gratitude of the consuming public. Finis!—I am, yours, &c.,

A Card-manufacturer.

March 30, 1893.

"ATTICUS'S" LAST WORDS.

To the Editor.

Sir,—Mr. G. Watmough Webster is mentally idiosyncratic, and "Atticus" had no desire, therefore, to disturb Mr. Webster's literary placidity. "Atticus's" first letter contained two points. First, he describes a home-made appliance for rapid solution making. Second, he owns to being amused at the "resurrection" of old methods and processes. This produced an ebullition of bile—literary or otherwise—causing Mr. Webster to reply offensively, stating that "Atticus" "was of no account, and made statements not to be found in any other copy." The succeeding letters of "Atticus" were therefore *purely defensive*, the quotations being from Mr. Webster's own articles, which your readers on reference thereto will find truthfully quoted. To insert the full text was impossible for obvious reasons.

Mr. Webster is entitled to his opinion; certainly "Atticus" has his, and Messrs. Martin & Co. have theirs. Opinions may differ, but statements and claims made in a public journal are permanent records, and open to public criticism. If Mr. Webster now denies making a claim for inventing the utensil in question, what *does* he mean when he stated, "In my own case the invention was spontaneous. . . . . Doubtless in our case the invention was original, whichever can claim priority of publication?"

Mr. Webster has objection to "covert sneers." "Atticus" don't like them—covert or otherwise. "Atticus" therefore indignantly protests against (as exceeding the limits of ordinary courtesy) Mr. Webster's "covert sneers"—under advice to the Editor—for that gentleman to be satisfied that the money is forthcoming in case of adverse adjudication against "Atticus." This request has a flavour of fishing for the verdict. "Atticus" considers this an unwarrantable impertinence and interference, and the only course open to him is to peremptorily withdraw from the controversy, which he now does regretfully in consequence.

However, the half-a-guinea promised to the funds of the Photographers' Benevolent Association, in case the award was adverse to "Atticus," is enclosed; "Atticus" requests that it be forwarded to the Secretary of the Benevolent as a further evidence of "Atticus's" interest in, and good-will towards this invaluable Institution.—I am, yours, &c.,

April 3, 1893. Atticus.

[As "Atticus" has withdrawn his challenge, we have returned Mr. Webster's letter to the latter gentleman—of course, unopened. "Atticus'" cheque for 10*s.* 6*d.* has been duly handed by us to the Hon. Secretary of the Photographers' Benevolent Association. The matter here terminates.—Ed.]

PROPOSED HAND CAMERA CLUB.

To the Editor.

Sir,—Will you kindly allow me to propose, through your columns, the formation of a Hand Camera Club. I consider the time quite ripe for such a movement, and it must be admitted that the hand camera receives but slight attention in the routine of ordinary society work. This must of necessity be so, as it only forms one branch of many. Yet I venture to think that the earnest hand-camera worker would like greater opportunity of discussing and hearing about hand cameras. Several well-known workers to whom I have mooted the idea think favourably of it, and I now ask any one interested to communicate with me direct. The proposed lines would be:—

1. A nominal subscription, say, about 2*s.* 6*d.*

2. Conducted on social lines, like the Photographic Club.
3. Confined strictly to actual workers, but no other restrictions.
4. Meetings monthly at first.
5. Comparing results, discussions upon new apparatus, and, in fact, the usual kind of society show, but confined to work.
6. Some system, perhaps, of a circulating portfolio to keep in touch with provincial members.
7. Some of the meetings, perhaps, in the provinces.

And, of course, there are other matters. If the idea meets with any kind of support, I shall be pleased to call a meeting.—I am, yours, &c.,

57 *and* 58, *Chancery-lane, W.C.* WALTER D. WELFORD.

A SOCIETY FOR CHEETHAM.

To the EDITOR.

SIR,—A new Society, open to amateur and professional photographers, has been formed in Cheetham, Manchester, and the Secretary is Mr. W. E. Hurnell, 21, Larch-street, Hightown. Next meeting, April 11, there will be a demonstration by Mr. W. T. Wilkinson (the President) on *Development*. The Society meets at 490, Cheetham Hill-road, Manchester, every alternate Tuesday.—I am, yours, &c.,

W. E. HURNELL, *Hon. Sec.*

21, *Larch-street, Hightown, Manchester.*

"A PAIR OF COMPLAINTS."

To the EDITOR.

SIR,—Whilst commiserating with Mr. John Power upon his unfortunate negotiation, I must say his sneer at "gallant little Wales" is most ungenerous. Does he think that *all* photographers on the borders of Wales are *Welshmen?* I can assure him not *five per cent.* are. Are there no *English photographers* in "Bonny Scotland?" It *may* have been a Welshman who served him the scurvy trick, but to apply the tar-brush to the *whole* borderland of Wales is a bit unjust. There are "black sheep" in most lands—Mr. Power happened to find one; but surely, having the man's address, a remedy lies in Mr. Power's hands, if it's "worth the candle."—I am, yours, &c.. J. HORTON.

26, *Caroline-street, Cardiff.*

THE CONVENTION SLIDES LOST.

To the EDITOR.

SIR,—May I ask you to give prominence to the fact that the circulating set of slides, issued by the Devon and Cornwall Camera Club in connexion with the forthcoming meeting of the Convention, has been lost in transit?

As I cannot recover any trace of them to the present, I am reluctantly compelled to provisionally cancel their engagements, but will put them on the road again as soon as I recover them, and will arrange fresh dates for those Societies that have been disappointed.

To the present I have absolutely no information as to their whereabouts, and can only express my regret to all who have been disappointed.—I am, yours, &c., B. HANSFORD WORTH, *Hon. Secretary.*

42, *George-street, Plymouth, March* 28, 1893.

"A HARD CASE."

To the EDITOR.

SIR,—Having passed through, in my early days of photography, the painful experience—or, rather, want of experience—of your correspondent in "A Hard Case," I can sympathise with him much.

Let "A. E. S." take courage from the following:—After three years' apprenticeship, which meant, in my case, a knowledge of silver printing and the art of mounting—and but little else practical photography except that gained in my back garden—I found myself expected to take a "sit." away from home. Not feeling any more confidence in myself than "A. E. S.," I took a place as assistant operator and retoucher, and managed (by hard work) to suit my employer. Leaving there, I next obtained a "sit." as operator and retoucher in a busy seaport town, and practised on the sailors, &c.; after nine months of that, during which period I had won half the battle, viz., gained confidence, I again sought pastures new, and obtained an appointment in a good-class business as operator and retoucher, which shortly resulted in my being made manager.

Therefore, my advice to "A. E. S." is to get a place in a cheap-class business first, and quietly work his way "up," and I feel sure he will soon reach his level.—I am, yours, &c., MANAGER.

March 28, 1893.

Exchange Column.

*** *No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance. The full name of the advertiser must in all cases be given for publication, otherwise the Exchanges will not be inserted.*

Will exchange whole-plate camera with three-fold stand for a cushion safety.—Address, G. CLARKE, Grove-place, Saffron Walden.

Wanted, exterior background, in good condition, in exchange for a fine-toned mandoline.—Address, W. J. RICHARD, Photographer, Fore-street, Collington, Cornwall.

12×10 camera, new, all movements, in exchange for good hand camera; also good *carte* lens, exchange for whole-plate wide-angle lens.—Address, W. G. MARTIN, 115, High-street, Merthyr Tydfil.

Will exchange a portrait lens by Lerebours (cabinet), a fine vignetted 8×6 background and burnisher, for whole-plate portrait lens.—Address, R. BROWN, Chateau Studio, Boulevard, Weston-super-Mare.

Wanted, set of Haddon Hall steps; offered, in exchange, Dallmeyer 15×12 lens, good as new, in leather case, or a midget camera for taking six on a half-plate, with six portrait lenses.—Address, A. DEBENHAM, 28, Union-street, Ryde, Isle of Wight.

Will exchange vol. xxxix. and Nos. 1618 to 1651, clean, unbound, THE BRITISH JOURNAL OF PHOTOGRAPHY, and vol. liii. *English Mechanic* (Hanover on "Construction of Microscope"), unbound, for Thornton-Pickard time and instantaneous shutter, or one of good make, size of lens-hood one and a half inches.—Address, W. H. NICHOLSON, 44, Windsor-street, Brighton.

Answers to Correspondents.

*** *All matters intended for the text portion of this* JOURNAL, *including queries and Exchanges, must be addressed to* "THE EDITOR, THE BRITISH JOURNAL OF PHOTOGRAPHY," 2, *York-street, Covent Garden, London. Inattention to this ensures delay.*

*** *Correspondents are informed that we cannot undertake to answer communications through the post.*

*** *Communications relating to Advertisements and general business affairs should be addressed to Messrs.* HENRY GREENWOOD & CO., 2, *York-street Covent Garden, London.*

PHOTOGRAPHS REGISTERED:

John Stuart, Glasgow.—*Four photographs of the Rev. Adam Cleghorn Welch, Helensburgh.*

Charles Walker Clarke, Devizes.—*Photograph of a drawing of the Market-place, Devizes, in the olden time.*

Francis Hoare, Cirencester.—*Photograph of a collection of enlarged photographs at the Cirencester Industrial and Art Exhibition, April* 3, 1893.

G. Watmough Webster, Chester.—*Photograph of the Chester Beagles, with group of people without the Master; also a photograph including the Master.*

W. BIRRELL.—Received; thanks.

F. C. GREEN (Chihuahua).—Received and forwarded.

P. BEBBINGTON.—Write to Mr. T. Samuels, Linden House, Hadley, Barnet.

J. AUSTIN.—1. Rives paper is mostly used. 2. There would not be any copyright in such prints.

F. B.—1. You will have to pay duty on taking English plates into the States. 2. Yes, 4¼×3¼ is an American size.

OUVRIER.—We cannot say whether you have a legal remedy; we should recommend you to consult a solicitor on the point.

HERR RICHARD LEO (Paulinenstrasse, 48, Stuttgart).—Mr. Gambier Bolton's address is, The Camera Club, Charing Cross-road, W.C.

DIAL (Glasgow).—In our volume for 1891 you will find a series of articles on Burnt-in Enamels, which will give you the necessary information.

A RUSSIAN READER.—The apparatus named is excellent. The makers would no doubt adapt the shutter to the camera front. A larger front could, of course, be made to take it.

B. F.—The formula will do very well. Use a gelatine similar to that employed for dry plates, say, Heinrich's. The paper must be used the day it is sensitised. In cool weather it will sometimes keep till the following day.

W. A. M.—If the lens is so firmly fixed in the flange that it defies the ordinary method of unscrewing it, run a little paraffin oil round the thread from the inside and allow it to soak for an hour or two. This treatment will generally enable the lens to be unscrewed with ease.

C. R.—If the lens is not in focus when it is set according to the scale on the mount, it is clear that the scale is in error. It may be that the camera is not the right one for that particular lens. Call the attention of the manufacturers to the matter. They can easily rectify it.

MEDAL.—The photographs in question were not taken direct from the coins. They were taken from casts in plaster of Paris specially made for the purpose. It is more than probable that the plaster was tinted so as to be more amenable to the plate; anyhow, that is the usual method.

C. WADE.—The price charged between plate glass and sheet glass, for the frame for the enlargement, is by no means "extortionate." The price of plate glass is about twelve times that of sheet glass, and as there is ten square feet of it, you can judge for yourself as to the reasonableness of the charge.

W. KERSHAW.—The pictures are a little flat, from the lighting. There is evidently too much front top light. We should advise you to have the side light in the studio made larger. That will enable you to obtain better results. A longer exposure would have been beneficial in the examples forwarded.

P. KELLY.—There is nothing in the picture to indicate that the lens is in any way faulty. But as you say the picture was taken with the smallest stop, it is scarcely a fair criterion, for a lens must be very inferior indeed that will not take a fairly good picture with a very small aperture. What will the instrument do with its full opening?

B. A. THOMAS asks how to ascertain what size condenser is required for enlarging from a given size negative, whether there is any set rule in the matter?—Measure the diagonal of the negative, and whatever that may be is the diameter of the condenser that is necessary for the work. It is always well to have it a quarter or half an inch larger, to allow for any little marginal defects.

D. CAMPBELL asks if it is possible to make a mixture of albumen and gelatine that will keep good so that it can be used as required.—Yes. The best way will be to beat up the albumen as for preparing albumenised paper, then dissolve the gelatine in the desired proportion of water, mix, and afterwards add an antiseptic, such as a little carbolic acid or thymol. When the mixture is again liquefied, it must not be heated beyond the coagulating point of albumen.

WARWICK says: "I have sent to two dealers in photographic chemicals for an ounce of cyanide of potassium, and they refuse to supply it, as they, so they say, would incur a heavy penalty by so doing, and refer me to the chemists. On applying to no less than four of them they said they did not keep it. Surely there should be some means of obtaining the material?"—Cyanide of potassium is prohibited under the Pharmacy Act to be sold by other than duly qualified pharmaceutical chemists; but, as the salt is not contained in the pharmacopœia, very few keep it in stock. It may be procured from any pharmaceutical chemist who makes a speciality of photographic chemicals, and there are many about London and the large provincial towns.

P. E. C. says: "1. I should be greatly obliged if you could answer the following:—I have found, almost immediately after sensitising, my paper is covered with metallic spots, as piece enclosed. Cannot solve the difficulty. 2. Also would you oblige by answering the following:—I work with the chloride of lime toning bath. What is the cause of it not toning rightly after addition of gold? I make every precaution not to get the bath in any way mixed up with any chemicals whatever."—1. The spots are caused by particles of foreign matter floating on the surface of the bath or settling on the paper while it is drying. 2. If the bath is rightly prepared, it will tone properly. Probably some injurious substance has contaminated it as in the case of the paper.

A. E. & Co. write: "We are desirous of building another glass house to print in, &c., during wet weather, but we wish to erect it in a way so as to be free from all risks of having to pull it down again by order of the Council. Neither do we want to submit plans, with the accompanying expense, delay, &c., to the district surveyor. Can you help us out of our difficulty? We are told, by making it a movable one, we are within the limits. Is this so?"—No. On the whole, we are inclined to think the best plan will be to consult the district surveyor. The County Council are very particular as to all buildings that are not "fireproof" under the meaning of the Metropolitan Building Act. If the work is done without the offices of the surveyor, the Building Acts had better be obtained, and their conditions duly considered before commencing operations.

H. W. L. writes: "Could you give me the cause of the spots on the enclosed print? This is only one of a number I have had like this the last few days. If I had not fixed them myself, I should have put it down to their not being moved about sufficiently; but I fixed them myself, and kept them moving the whole time, and fixed for about twelve to fifteen minutes, time that I always have given my prints, but have never had this sort of thing before. The only thing I feel it can be put to is this. On the first occasion that they appeared I opened a fresh tub of hypo, and I think that some inferior article has been sent me and charged at full price. Do you think it could be caused by the hypo? I am going to use a fresh sample to-night, when I may be able to draw a better conclusion; but perhaps you will give me your opinion on the matter."—We have seen very similar effects caused by the use of inferior hyposulphite of soda, but it is impossible to say if that is the case in the present instance. Of course, as a fresh sample is obtained the results by the two kinds can be compared and an opinion formed.

X. A. Y. writes as follows: "Last week a monument to a late very popular man in our town was erected in the public cemetery. As soon as it was finished, a rival of mine photographed it, and the following day I also took a photograph of it. Now I have received a lawyer's letter, saying that his client, the other photographer, has made his photograph copyright, and threatens me with legal proceedings if I publish my picture. Can he stop me publishing my picture? I have just learnt that the lawyer's letter was not sent from a solicitor, but was written by a friend of his, a solicitor's clerk. I fancy the whole thing is a bit of bounce, but your opinion will be esteemed."—Our correspondent cannot be prevented from publishing his picture to his heart's content. The first man can only secure copyright in his work, not in the monument itself. With regard to the "lawyer's letter," if this is written in such a way that it comes from a duly qualified solicitor, it should be forwarded to the Incorporated Law Society, who will possibly take action against the writer for penalties.

PHOTOGRAPHIC CLUB.—April 12, Members' Open Night. 19, *Cold Bath Platinotype Experiences.*

NEWCASTLE-ON-TYNE AND NORTHERN COUNTIES' PHOTOGRAPHIC ASSOCIATION.—April 11, Mr. William Parry will read a paper on *Retouching.*

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.—April 13, Paper by Mr. W. D. Welford, *The Influence of the Hand Camera.* 20, Monthly Lantern Night.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—April 11, Ordinary Meeting, a paper on *The International Congresses of Paris,* 1889, *and of Brussels,* 1891, by Mr. Leon Warnerke.

MESSRS. R. SUTTON & Co., of Ludgate-hill, have in the press a new edition of *The Microscope, and How to Use it,* by Mr. T. Charters White, M.R.C.S., F.R.M.S. It is illustrated with photo-micrographs by the author.

THE FORFARSHIRE PHOTOGRAPHIC EXHIBITION.—At the request of English exhibitors, the time for entry forms for this Exhibition to be returned has been extended to Tuesday, April 11. The Judges are Messrs. Marshall Wane, Adam Diston, and W. D. Welford.

STATUARY PORTRAITS.—Mr. C. C. Bradshaw, of 57, Market-street, Manchester, has been appointed agent for Messrs. G. B. Bradshaw & Co. of Altrincham's method of producing statuary portraits, and is prepared to grant licences to photographers desiring to adopt it.

WE are informed that Messrs. Mawson & Swan's largely increased trade has rendered it necessary for them to enlarge the size of their factory. The new buildings are now complete, and in full working order, and have doubled the size of the factory as compared with this time last year. The firm have put down new engines, electrical and other machinery.

THE SANDELL EXHIBITION.—During the week April 17 to 22 an Exhibition of photographs, chiefly those taken by Mr. Sandell (on "Sandell" plates) during a recent visit to Italy and Switzerland will be on view at 24, Regent-street, S.W. The proceeds are to be handed over by Messrs. R. W. Thomas & Co. to the Photographers' Benevolent Association, a body which, we are pleased to notice, has lately been doing such a large amount of good among needy members of the profession that it deserves on this occasion to be widely supported. Admission is by ticket only—Monday, Tuesday, and Thursday, 1*s.*; Wednesday (special ticket), 2*s.* 6*d.*; Friday and Saturday, 6*d.* Tickets may be obtained of the Hon. Secretary to the Benevolent Association, Mr. H. Snowden Ward, Memorial Buildings, E.C., or at the offices of THE BRITISH JOURNAL OF PHOTOGRAPHY, 2, York-street, Covent-garden, W.C.

THE FREE PORTRAIT SCHEME.—At Folkestone Quarter Sessions on Wednesday, George Gould was to have surrendered to bail to answer an indictment charging him with conspiracy with others to defraud a large number of persons of various sums of money by means of the free portrait scheme. There were over seventy witnesses in attendance, many having come from Ireland and Scotland, and the Treasury had retained Mr. Crump, Q.C., to conduct the prosecution. On Gould's name being called, no answer was made, and it was eventually decided to treat the defendant as an absconder. The recognisances of his sureties, two in 200*l.* each, were ordered to be estreated, and a bench warrant was issued for the arrest of Gould. The sureties stated that the defendant left the town about three weeks ago, and as soon as they learnt of his absence they followed him to London, but failed to discover his whereabouts.

PHOTOGRAPHERS' BENEVOLENT ASSOCIATION.—Meeting of Committee, held in the rooms of the Photographic Society of Great Britain, on Monday, March 27, Mr. A. Mackie in the chair.—The Secretary reported that he had just secured a permanent situation for an assistant who had received help from the Association at intervals all through the winter. There were five applications for assistance, and three of the applicants attended. In one case a loan amounting to 5*l.*, and in another case 3*l.*, was granted. In the third case, which was a particularly difficult one, owing to the applicant's inability to speak much English, a temporary grant of 10*s.* was made, and applicant was referred to a gentleman of his own nationality. The two cases in which the applicants did not appear personally were referred back to the Secretary, with instructions to make further inquiries, and to grant assistance in certain contingencies. Messrs. H. D. Miles and G. Fowler Jones were accepted as subscribers, and the Secretary acknowledged special donations from the *Photographic Review of Reviews* charitable fund, 2*l.* 2*s.*; anonymous, 5*s.*; two prize winners in photography competitions, 12*s.*

JOURNAL OF PHOTOGRAPHY.

No. 1719. Vol. XL.—APRIL 14, 1893.

LENS STANDARDS.

The chaotic state in which the spring of 1893 finds our lens standards is far from being creditable to any one concerned. Reasoning from analogy, it would be surely possible, by concentrated action, to confer an inestimable boon upon a long-suffering photographic public. The analogue is one to which we have on a previous occasion directed attention, and held up as an example—the microscope.

Many years have not yet elapsed since, when visiting an ex-President of the Royal Microscopical Society, he showed us an instrument of great excellence in his possession, and we were specially struck by the array of adapters for object-glasses which formed a part of the outfit. It appeared that only a short time previous to this each maker of microscopes was a law unto himself, and the objectives of one manufacturer would by no means fit any but the one instrument for which they were made; hence the multitude of adapters required. This evil was terminated when, by a *pronunciamento* of the Society, one standard screw was adopted by every maker, in virtue of which the objectives of A or B fit the microscope stand of C with equal facility as those sent out with it. This is the kind of thing we desire to see universally adopted in regard to the lens fittings and flanges in use by photographers.

So long a time has elapsed since a Committee appointed by the Photographic Society of Great Britain delivered their report and recommendations, that it is a matter of surprise their standards have not long ere now been adopted, and yet the number of those manufacturers who have done so is still limited.

This subject is being brought by Mr. William Taylor, of Taylor, Taylor, & Hobson, before the notice of the Camera Club Conference which opens on the Wednesday of the present week, for we write this before the meeting has yet been held. We are as yet unaware of how the subject will be treated by Mr. William Taylor, who by the way, we know to be an exceedingly expert and cultured mechanic, and one whose firm has received high medal recognition in connexion with their photo-optico-mechanical exhibits at the last Exhibition of the Photographic Society of Great Britain, but we cannot doubt that from his mechanical training he will recognise and urge the importance of absolute uniformity in lens flanges being a *sine-quâ-non*. His is one of the firms that have adopted the standards of the Photographic Society of Great Britain, which were not suggested without much care and deliberation, and, doubtless, we shall hear much concerning these standards that will interest and instruct.

For ourselves, we do not care so much about the adoption of any one species of standard over another, whether the final suggestion emanates from France, Germany, or England, as for the ensurance of uniformity that will be of an international character. That the following scene should be capable of being enacted is nothing more nor less than a disgrace. A few days ago we took to the country a whole-plate camera with three lenses of somewhat differing foci but of nearly equal flange screw apertures. But not one would precisely fit the other, and in consequence we had to take three camera fronts, with their respective flanges screwed on, these flanges differing in aperture from each other only to the extent of a sixteenth of an inch. That such could be the case is not creditable to the state of mechanical photographic art at the present day.

We can perfectly sympathise with old-established firms who, having long ago adopted certain flange standards, have stuck to them, and feel loth to make a departure; still, we consider that, in the interests of those who use lenses, a sacrifice ought to be made in the cause of uniformity.

This uniformity in apertures of diaphragms is a matter of quite subsidiary interest, because, although these apertures might be ever so antagonistic one to the other, it is a matter of trumpery moment, for one can always fall back upon the "F" or area system and name the intensity ratio for himself by a simple measurement of aperture to focus; but, in the case of flanges, it is a totally different thing. If this were once established, then could dealers all the world over keep adapters in stock in readiness to sell to any one who, on the spur of the moment, desired to adapt a small lens to the large flange screwed on his camera front.

THE CITY AND GUILDS INSTITUTE AND PHOTO-MECHANICAL WORK.

We are pleased to observe that increasing efforts are being made to place within popular reach practical instruction in photo-mechanical work, the need of which has recently been freely expressed, coupled with something like a general belief that not only are our Continental friends superior to ourselves in the quality of the results they produce, but also in the facilities they enjoy for obtaining the requisite technical and practical knowledge at comparatively low fees. A study of the advantages possessed by the magnificent photographic educational establishments at Berlin and Vienna under Vogel and Eder will demonstrate the superior position in which young photographers of Germany and Austria are placed in respect of studying photo-mechanical processes compared to those of this country.

The recent lectures and demonstrations on photogravure, organized by the Photographic Society of Great Britain, were a

step in the right direction, and, from the general interest evinced in them, we have every confidence that—at least, indirectly—they will bear good fruit by promoting increased attention to the preparation of intaglio plates for photographic reproduction.

The subject has evidently attracted the notice of the City and Guilds of London Institute, which, as our readers are aware, holds periodical examinations in photography; for we have received a notice stating that "the Council of the Institute, recognising the increasing importance in the mechanical reproduction of pictures, will, in the forthcoming examinations to be held on the 3rd and 13th of May next, give special importance to this branch, by dividing the examination in the Honours Grade into two classes—one for pure photography, and the other for photo-mechanical photography. Special examiners have been appointed for each branch, and candidates have the option of declaring in which branch it is their intention of entering. They will not, however, be allowed to compete in both branches. The certificates granted will show in which of the two divisions the candidate has passed."

We join with the Council of the Institute in the hope that the encouragement thus given to the photo-mechanical division will tend to form in this country a school of competent craftsmen in this branch of photographic work.

A Sunday Show.—Most are now familiar with the work of Mr. Burne Jones through the excellent platinotypes of Mr. Fred. Hollyer. It is interesting to know that, while the Burne-Jones Exhibition at the New Gallery was open for three hours on Sunday last, it was visited by nearly 2400 persons, who were admitted by tickets. Evidently Mr. Burne Jones's work is appreciated, and so are Sunday exhibitions of paintings.

A Gift to the City.—The Art Gallery of the Corporation of London, Guildhall, is to be further enriched. Sir John Gilbert, R.A., has intimated to the Lord Mayor his desire to present to the Gallery a selection of his works, both oil and water-colour, which have figured in recent years at Burlington House and Pall Mall. Of course, the valuable gift will be accepted. It is not generally known to many that the City Corporations possess, though not an extensive collection, some very fine works of art that will repay a visit.

Death of Mr. Vicat Cole.—Landscape painting has met with a great loss by the death of Mr. Vicat Cole, R.A. One of Mr. Cole's finest works is the *Pool of London*, which was exhibited a few years, and was purchased out of the Chantrey Fund. It is now at South Kensington. The works of this artist might well be studied by photographers, as the majority of the subjects are such as are generally dealt with by landscape photographers. We understand that the late artist's last work is to be exhibited at the Academy next month.

Recent Sunlight.—It requires no argument to prove that we have had sunlight far above the average in amount during the last month. Mr. Sowerby, of the Botanic Gardens, Regent's Park, has published the exact proportions in which we have been favoured. March 1887 had 62·55 hours; 1888, 33·4 hours; 1889, 48·3 hours; 1890, 65·5 hours; 1891, 76·35 hours; 1892, 69·5 hours; the present year, 116·16 hours! Such an amount is almost phenomenal, for this record is not the mere total of the sun's appearance, but of the hours it was powerful enough to stamp its mark on the cards of the instrument for recording sunshine used in these Gardens.

Animal Charcoal.—Few of our readers but have at one time or another attempted to use charcoal for decolourising, as, for example, with shellac varnish. It is not, however, always understood that vegetable charcoal, the kind usually purchaseable in the chemists' shops, is of no use for this purpose: animal charcoal must be used. The form in which it is usually called for varies in different countries where the main demand is for purifying sugar. Thus, in Austria, pieces the size of a walnut were used. In Germany the maximum size is a filbert. In France the size varies from that of grains of linseed up to that of a filbert. In England and America it is required almost wholly of the size of millet seed. The decolourising action is explained by one set of authorities as chemical, and by others as purely physical.

Another New Process.—It was announced some time ago that the Messrs. Lumière were experimenting with manganic salts as photographic agents. In our last issue will be found the specification of a patent they have applied for in this country for their process. From that it will be seen that it is not difficult to work, neither ought it to be costly in practice, and it is said that a variety of tones can be obtained. MM. Lumière's process will, doubtless, quickly receive attention at the hands of experimentalists. Whether silver will ever meet with a formidable rival in manganese or not remains to be seen. Anyhow, the subject is an interesting one, just now that silver printing is apparently entering somewhat on a new phase as regards commercial work, and it should receive consideration. There is one point in connexion with the manganic method that does not add to its simplicity in working, namely, that the prints are not made direct from the negative, but, as in the primuline process, from a transparency. This rather handicaps a printing process, however otherwise excellent.

Fading "Permanent" Prints.—It may seem an anomaly to speak of permanent prints as fading, yet the thing is, in a sense, of every-day occurrence. Collotypes and prints by other photo-mechanical processes may be classed as permanent, yet a considerable proportion of them undergo a very marked change with even a comparatively short exposure to light. This is not due to the processes themselves, but to the employment of fugitive pigments in the ink, and also to the frequent use of paper tinted with evanescent dyes. We have before us now some enamelled paper supplied by a Continental house for collotype work, which is as deeply coloured, and apparently with the same dye, as the rose-tinted albumen paper, and the colour is equally as fugitive by exposure to light. If these roseate pigments were simply entirely discharged, the prints would often not suffer materially; but unfortunately they usually leave an unpleasant, dirty, yellow effect behind. The marked effect of the light on this class of picture is frequently to be seen after a few days' exposure in the shop windows or at railway book-stalls.

Measuring Flasks.—Every one accustomed to exact work is acquainted with the value of flasks rather than graduated glass measures for accurately measuring liquids. For making pyroxylin, for example, it is not possible to obtain sufficient uniformity in successive products when the required quantity of water is measured with an ordinary graduate; a flask should always be used, where the liquids are not indeed weighed. In using flasks, there is some time wasted in obtaining the liquid exactly up to the graduation line, and Mr. Alex. F. Reid, in the *Chemical News* last week, has described a simple and efficient mode of facilitating the operation. It consists of a wooden or indiarubber plug, with a flange to support it, and fitting loosely into the neck of the flask, and of such size that the part of it that goes in the flask has the same volume as the part of the flask above the mark. To use it the flask is filled with water, say, past the graduation mark, and then the stopper dropped in and withdrawn. The surplus water runs out and the right quantity remains. The stopper has a tapered point, to admit of quick insertion and facilitate the running off of the water upon withdrawal.

Lens-exposing in the Studio.—We have just spoken of, as a common studio expedient, the use of an internal shutter for portrait work. It is true that it is common, but it is very far from being universal. We have been in very many studios where this primitive method—by no other less unflattering name can it be called—of exposing the plate by uncapping the lens is still employed. Yet this is very remarkable, the advantages of a shutter with pneumatic action are so patent. Take, for example, the exposing of a group. The eye of the photographer ought never to leave his subject's, yet it is most difficult to avoid doing so unless the exposure is made mechanically. The same in taking photographs of young children; ten minutes may elapse before a single favourable moment arrives, and the mere action of raising or moving the hand sufficiently to uncap the lens is enough to upset the child's face. The verdict of experienced workers with whom we have discussed this matter is, that a shutter self-setting is the best—one that is always ready for use, and merely requiring a squeeze of the pneumatic ball and a release—to expose and leave set for the next exposure; also that it is far better for it to work inside the camera, thus leaving nothing whatever that can draw the sitter's attention, be he child or adult, while the exposure is proceeding.

Photographs on Textile Fabrics.—Seeing that so many photographers are now seeking for some new or novel style or description of picture, one cannot but feel some little degree of surprise that the production of photographs on textile fabrics is so much neglected. The thing is by no means new, as we saw silver prints on silk, and really good ones too, some five-and-twenty or thirty years ago. Photographs on fabrics could be utilised in many ways, especially for decorative purposes. They can be made on a great variety of materials, and by several different processes. A few years ago we were shown a collection of photographs of fans printed on satin by the collotype process that were of very *recherché* character. Of course, instead of satin, any other fabric could have been employed, and, in place of collotype, any of the other methods of mechanical printing might have been used. Direct prints on fabrics are easily obtained either by silver printing or by the platinotype process. Fabrics ready prepared for both processes were—and, we believe, still are—regular articles of commerce. Then, again, there is the primuline process of Messrs. Green, Cross, & Bevan, which enables pictures, in a great variety of colours and almost any kind of fabric, to be obtained in a very simple manner. With so many methods of production at disposal, there is no reason why this phase of photography should have been so much neglected.

A Precaution for Continental Tourists.—The season is now coming on when tourists will be considering their holiday arrangements. Those who propose to travel on the borders of France and Germany will do well to provide themselves with passports; more particularly is this the case if they are accompanied with photographic *impedimenta*. Passports are not really necessary for either France or Germany, but we were told at the Foreign Office a short time back that it was advisable for British subjects to be provided with them when travelling on the frontiers of the two countries. Photographing in the neighbourhood of fortifications on the frontier is strictly forbidden, even though they are not included in the view, or cannot even be seen from the print. Through ignorance of this rule, foreign visitors have sometimes innocently been subjected to great inconvenience, not to say indignities. It is in such cases as this that the passport is of advantage. The holder of an English Foreign Office passport, duly *viséd*, would at once be acquitted of being a spy by either country. A passport can be obtained for two shillings by application to the Foreign Office on the proper form. When the document is obtained, it is well to get it countersigned at the Consulates of the two countries. Passports, like revolvers, are rarely required when travelling now, but when they are they are generally of great service.

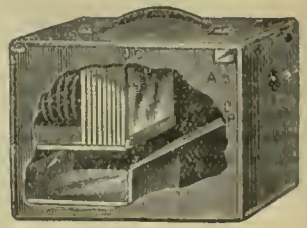
The Camera in Anthropology.—Mr. E. F. im Thurm recently gave a paper on this topic before the Anthropological Society of Great Britain. He points out that, in taking photographs of savages, special care has to be taken to avoid getting them in that "non-natural" state so often characteristic of such pictures. For example, he has seen the same savage native in a town and in the country, and he looked like two different individuals, though his costume was little more in each case than a yard of tape—literally, a single strip of cloth about a yard long and two or three inches wide. It cannot but be remarked that the lecturer himself did not go about his work in a very workmanlike manner for the end in view. Thus, instead of working a camera with an internal concealed shutter, he, in a description of a very amusing experience, tells us he simply caps and uncaps his lens. "The first time I tried to photograph a red man was among the mangrove trees. My red-skinned subject was carefully posed high up on a mangrove root. He sat quite still while I focussed and drew the shutter. Then, as I took off the cap, with a moan he fell backward off his perch on to the soft sand below him, nor could he by any means be persuaded to prepare himself once more to face the unknown terrors of the camera. A very common thing to happen to foil the efforts of the photographer at the very moment when he has but to withdraw and to replace the cap is for the timid subject suddenly to put up his hand to conceal his face," &c. It is surprising that it never occurred to Mr. im Thurm to adopt a studio expedient now common enough.

CRYSTAL PALACE PHOTOGRAPHIC EXHIBITION.

The "National" Photographic Exhibition at the Crystal Palace opened on Monday last, April 10, and is advertised to remain on view until the 29th inst. It is to be regretted that in neither the apparatus section nor that devoted to photographs does the Exhibition redeem the character of "National" that has been assigned to it, a result that must undoubtedly create an unfavourable impression in the photographic world, and at least a feeling of surprise among the general public. Taking the photographs first: the responses of exhibitors, although producing on the whole a passable display, cannot be considered at all representative of the present state of photographic art, while as regards the apparatus the exhibits scarcely exceed ten in number, and these betray an unfortunate paucity of novelties, and are, besides, of such meagre extent that the entire contents of the stalls might comfortably be placed in a shop of moderate size.

The Apparatus Section.

At four o'clock on Monday afternoon the following was the state of the Apparatus Section:—Messrs. R. & J. Beck, of Cornhill, had a handsome stand showing a series of fine enlargements from negatives taken in the "Frena" hand camera; Messrs. J. Theobald & Co., of 43, Farringdon-road, an extensive display of optical lanterns, coloured slides, limes, condensers, stand cameras and stands, hand cameras, and photographic sundries generally. Included among Messrs. Theobald's exhibit is a cheap and ingenious hand camera, the "Meteor," in which sheathed films or plates are used, the sheath with the exposed plate being released by a single turn of a screw at the side of the camera, and sliding down an incline into the back of the camera as shown in the cut. The "Meteor" has but two little brass knobs, and the handle to carry it by, projecting, and two view finders (which are let in flush with the body); is cloth-covered, has twelve sheaths carrying twelve plates or films, the special lens working with a time and instantaneous shutter inside the camera, and again worked by turning a little brass catch. It can be used for taking views or portraits both vertical and horizontal, and all for 12*s.* 6*d.*



Messrs. D. Noakes & Sons show several serviceable lanterns, cameras, with lathes at work; Messrs. T. W. Couch & Co., of 11, Bow-lane, a selection of pictures set in a variety of choice frames; Messrs. Platt & Witte, of Kingsland, cameras and camera fittings; Mr. J. D. England, film negatives and prints from them, as well as lantern slides; the Sciopticon Company, of Colebrooke-row, lantern slides of their well-known quality. The Cresco-fylma Company, of Surbiton, have a display of excellent cresco-fylma enlargements from transparencies on opal supports of various elegant shapes other than the purely rectangular, with matt and glazed surfaces. The Company are to demonstrate the process during the Exhibition.

The Welsbach light as arranged for studio portraiture, which we recently described, is to be shown in action by Mr. C. F. Treble, of Clapham Junction. The only other exhibit we observed was a mechanical contrivance for showing a number of photographs in rotation by Mr. Southward. In this a wound spring drives an exterior fan, which rotates a series of cog-wheels that actuate a series of holders upon which the photographs can be placed and inspected as they rotate. When wound, the apparatus keeps in motion for ten hours.

THE PICTURES.

In the absence of a catalogue or of any information with regard to the classification of the photographs or the competitions for which they are entered, it becomes rather difficult for us to criticise them with special reference to those conditions, and we must therefore take them *seriatim*. Inasmuch, however, as most of the pictures on view have already run through numerous competitions, and are consequently familiar to our readers either by reputation or from closer acquaintance, we are hardly called upon, in most cases, to devote a minute attention to their particular merits or demerits. There is, nevertheless, one feature in connexion with this part of the Exhibition to which we ungrudgingly accord a favourable notice, and that is the arrangement of the photographs in separate alcoves, and the capital light by which, happily, they can be inspected. In this respect exhibitions of photographs at the Crystal Palace always stand out pleasantly, as compared with the indifferently hung and poorly lighted displays it is our misfortune so often to encounter in exhibition halls of the usual type.

The "National Challenge Cup," for the best collective exhibit by a recognised photographic society, has, so far as we could discover, attracted entries from the following societies:—Birmingham, Hackney, South London, West London, Tunbridge Wells, Hove Camera Club, Brixton and Clapham Camera Club. If any other alcoves devoted to society work have been omitted from this list, the fault is not ours.

The Birmingham Society send up about eighty frames, most of them of very great excellence, and including some fine portraits. The names of the various members are not attached to the frames, so that it is impossible for us to write in detail of the pictures, but of their general good quality there is no doubt.

The Hackney Society play a strong hand with Mr. S. J. Beckett's Norwegian series, Mr. G. Hankins's hand-camera work, Mr. J. Carpenter's exquisite study of flowers, Dr. Roland Smith's technically good interiors, Mr. J. O. Grant's *Sheep Shearing* and *Adjutant*. Mr. R. Beckett shows a forcible study of a head, and Mr. W. F. Jones a clever flashlight picture entitled *A Poser*, two gentlemen seated at chess. The alcove, on the whole, is an extremely good one.

Mr. F. W. Edwards is a tower of strength to the South London, that gentleman's architectural and Tinworth work, beautifully printed in platinum, being unexcelled in the Exhibition. Other members who are particularly prominent are Mr. Oakden (with good interiors of Ely Cathedral, and a cleverly composed view of Norwich), Mr. W. Howell, Mr. H. E. Farmer (architecture, and a successful *Study of Beeches in Epping Forest*), Messrs. J. W. and W. F. Slater.

In the West London Society's alcove the eye is arrested by the President's (Mr. Hodges) very impressionistic *Drear December*, Mr. W. S. Rogers's *Coaling—Tyneside* (a small study full of life), Mr. W. L. Coll's pretty view of *Basingstoke*, Mr. L. C. Bennett's familiar *Pool* and *Rubbish Burners*, Mr. L. Selby's reposeful *Evening Calm*, Mr. Adam's *Frozen Swamp*, and Mr. W. H. Whitear's tiny, but clever, study of moon and sea, *The Moonpath;* Mr. Charles Whiting, Mr. Charles Winter, and other members, also combine to make the West London exhibit a particularly fine one.

The Tunbridge Wells Society's exhibit comprises some good cloud studies and views in Cairo by Mr. J. Chamberlain; while Mr. F. G. Smart, with a fine snow scene and an attractive view of Aberdeen Harbour, renders material support. The rich warm tones, the careful selection and exceptionally good technique of Mr. E. R. Ashton's *Monastery*,—*El Ghariani*, and a series of similar subjects, impart a distinctive charm to the Society's alcove, in which Messrs. Cassingham, Wood, and others are advantageously represented.

Mr. A. H. Webling has ably managed the lighting of a charming view, *Across the Lake at Arundel*, and also shows another clever effect in *Sunset—Shoreham Harbour*, and these, with Mr. Charles Job's hand-camera work, and Mr. J. Williamson's unforced picture, *Easy Times* (a group of fishermen gossiping), are perhaps the most noticeable exhibits of the Hove Camera Club.

Dr. Reynolds, the President of the Brixton and Clapham Camera Club, in the Club's alcove, shows a realistic tea-tinted platinum copy of an old print, *Smoaking*, and several evenly rendered interiors obtained by exposures of five, six, and seven hours on asphaltum-backed plates. Mr. C. F. Archer's delicate and well-lighted study, *Grandpa*, Mr. W. Thomas's small sheep studies, Mr. J. A. Butler's well-chosen, bustling *View in Amsterdam*, the charming lady in Mr. Archer's harmoniously lighted *Interested*, and excellent pictures by Mr. Bartrop, Mr. Kent, and Mr. Golby, are conspicuous in the Club's exhibit.

On the whole, the competition for the challenge cup among the competing societies is so keen that we do not envy the Judges the task of coming to a decision.

Coming now to the other exhibits, Mr. W. M. Warneuke, of Glasgow, has a series of masterly direct portraits of Toole, Miss Kingsley, Wilson Barrett, Miss Johnson as Desdemona, Vezin as Shylock, together with half a dozen comparatively small landscapes. We have so often complimented Mr. Warneuke upon the excellence of his large work that criticism becomes superfluous; but, if there is one picture more than another in his present exhibit that we prefer, it is the Vezin picture, which is full of the freest, boldest handling, and conveys an effect of massiveness not often seen in character portraits. Mr. H. Hallier, of High-street, Upper Sydenham, shows about forty frames of portraits and interiors, his pictures of children betraying great skill in juvenile portraiture. In Messrs. Morgan & Kidd's alcove are some very refined examples of carbon, platinum, and collotype, but interest must undoubtedly centre in the fine big bromide enlargement (from a negative by Mr. Van der Weyde) of Miss Mary Anderson, in which the softness and gradation are perfect. A scene from *Hypatia* (from a negative by Alfred Ellis), enlarged to 8 × 4 feet, and another enlarged portrait, are of equal excellence. They are splendid examples of bromide enlarging.

Messrs. James Robinson & Sons have some very fine portraits, notably one, *An Irish Beauty*, which has a character and vigour not always to be discerned in ladies' portraits. *Miss K. Oram*, *The Earl of Aberdeen*, and *Marie Roze* give Messrs. Robinson an opportunity of showing the possession of high artistic skill. The beauty of the sitters in *An Irish Lady* and *The Countess Annesley* make us almost forgive Messrs. Robinson the slight unevenness of tone apparent in the gelatino-chloride pictures; but otherwise they are of high merit. In another alcove Mr. P. Lange is represented by some capital hand-camera work, and, passing by some clever pictures of turkeys and pigeons by Mr. P. Parsons, we come to a number of pictures of ironclads and kindred subjects by Mr. J. E. Goold, with which, technically, no fault can be found. One of them represents an instantaneous photograph of a torpedo leaving the ship's side at a speed of forty feet a second, and showing the angle at which it strikes the water. As a photograph it is a marvel of sharpness.

Mr. F. T. Palmer has a numerous collection of portraits, and Mr. F. Fitzpayne shows a capitally exposed *Nave of Wells Cathedral*. Hereabouts, too, are Sir Henry Roscoe and Mr. Lunt's *Bacteria from Sewage;* a series of views by Mr. P. Welch illustrating the North of Ireland tourist district; Diston's humorous *Rehearsal*, *Soldier's Return*, and *Highland Smugglers;* Mr. Lord's *How's that!* some animated illustrations of *Golfing* by Mr. Lange; and a selection from Mr. Sandland's lion, tiger, and buffalo pictures, and his excellent horse picture *Unyoking*. May we suggest to Mr. Sandland that he is less successful with his composition subjects including the human species than with his animals? Messrs. S. B. Bolas have some good examples of collotype; Messrs. Poulton, a selection from their well-known series; Messrs. Gregory, of the Strand, coloured types of the British army.

Mr. W. P. Marsh, of Bognor, has rarely shown better seascapes than those he has here, both small and large. He seems to have studied the sea in nearly all its moods, and the result is a fine collection of wave pieces, all cleverly caught. A blue carbon print, *After a Sou'-Wester*, is especially good in its realism, and a study of *A Breaker* not less so.

What soft, evenly lighted work can be produced by flashlight, Mr. R. Slingsby, of Lincoln, shows by several very fine examples. Mr. Douglas Pym's touched and untouched portraiture are both noticeable for their good qualities, and in *Dad's Pipe*, a boy in three stages of a bout with the paternal calumet, there is considerable quiet humour as well as great photographic merit. We do not like Mr. Pym's *Repose*, however. This shows a very lightly clad, finely limbed young lady, simulating sleep in a recumbent position, with so little relief in the face that the result is not convincing. Mr. Dresser has a screen filled with his well-known works. Mr. E. M. Stone shows three small views, *A Yorkshire Coble*, *Filey*, and *On the Thames*, with nice sepia tones, sharp, crisp, and well printed, which are certainly amongst the finest things of the kind in the Exhibition. Mr. Court Coles's interiors, the Hon. S. Bethel's *Shipping at Guernsey* (a freely handled picture), and the same gentleman's *Clouds*, with Mr. T. Scotton's *Musselburgh Fishwives* and cathedral studies, are safe to hold the attention of even the non-photographic visitor to this part of the display.

Examples of statuesque portraits of a high degree of skill are shown

by Mrs. Frank Holmes, of Bristol. We would recommend professional photographers to study them. *Steady*, two men fishing, and in the act of getting a bite, is a clever bit of work by Mr. H. Young, the effect being perfect.

Mr. T. M. Brownrigg's *Winter Sunset, Derwentwater*, and *Morning on the Wey* are especially evident in an Exhibition singularly free of impressionistic pictures. Messrs. Alfred Werner & Son show a few large portraits of a superior quality, pose and lighting being exceptionally fine. Finally, Mr. Goodwin, of Anerley-road, makes a highly meritorious display of portrait work—indeed, the Exhibition is commendably strong in professional portraiture—and Mr. C. F. Treble, of Clapham Junction, besides exhibiting some examples of portraiture by the Welsbach light, which show perfect tone rendering and freedom from harshness, includes a varied collection of large and small portraits of great beauty in his alcove. Mr. Treble's examples in sepia platinotype are remarkably engaging in their compromise between critical sharpness and diffusion; and, indeed, the exhibit as a whole is a fine one.

It should be mentioned that the Judges only met for the purpose of making awards on Thursday (yesterday), and that while the Exhibition is open there will be nightly lantern entertainments.

AMERICAN NOTES AND NEWS.

The Smartness of the "Heathen Chinee."—It is pretty evident that the mental or, rather, the moral characteristics of the Celestials in America have not suffered any change since those days when Ah Sin, the gentleman whose "smile was so childlike and bland," engaged in the ever-celebrated game of euchre with truthful James and Bill Nye. In May next the Chinese Registration Act comes into force. This necessitates each Chinese labourer in the country presenting himself at the office of the Collector of Inland Revenue with proper vouchers from the Chinese Consul, on which certificates are to be pasted a photograph of the bearer, a duplicate of this being returned to him, which he is compelled to show on demand to any United States official as his authority. Here, now, comes the smart part of it, for which information we are indebted to Mr. Julius F. Sachse, Editor of the *American Journal of Photography*. The photographic part of this certificate is in reality the only means by which it can be determined whether the holder is the same individual to whom it was granted, as the description given would in most cases fit ninety-five out of a hundred Chinamen. But a photographic chemist in Philadelphia has been teaching the Celestials how to produce photographs which, within a few months, would so fade as to fail in the identification of the individual, while the written description would still remain. The authorities are taking steps to circumvent and punish the conspirators.

Cleaning and Photographing Old Oil Paintings.—A writer in the same journal, who has had experience in copying oil paintings, gives the following as his mode of cleaning old paintings previous to their being photographed:—After dusting, wash the painting by a sponge and rain water, and then sponge over the surface the following:—The white of two eggs, beaten up and cleared, a tablespoonful of glycerine, and half a litre of water. The object of adding the glycerine is to prevent the albumen from drying in spots, which would appear dull, and prove of injury to the reproduction.

Focal Plane Shutter.—The employment of this class of shutter is strongly advocated in our Philadelphia contemporary. It is constructed in the same way as the Thornton-Pickard shutter, but its position, instead of being close to the lens, is situated in front of, and as close as practicable to, the sensitive plate. The roller blind composing the shutter has a narrow slot in it, and travels rapidly across the plate. We are personally aware that some bicycle scenes, of exquisite sharpness and well lighted, were taken by Mr. James Inglis, formerly of Montreal, by a metal shutter constructed on this principle, and working at the focal plane. These were exhibited six years ago at one of the London societies. It was estimated that the exposure was about the thousandth of a second.

Requirements for Success.—Mr. Xanthus Smith lays down as conditions of success in the studio or portrait branch of photography, perseverance, good business ability, a large amount of good address and tact, and, highest of all, artistic taste or good judgment in matters of art. The special qualifications for outdoor photography are, in his estimation, good general artistic sense, quickness of perception, rapid and sound judgment in selection and timing, this last being necessary to cope with the changes in the conditions of lighting, of subject, and of exposure.

Animal Life.—In the portrayal of animal life, Mr. Smith holds the utmost pains should be taken; in the first place to acquire a knowledge of the poses in which different animals show their good points to the best advantage, the best lighting and accompaniments, chiefly as to background, for the success of a great part of animal photography is marred by carelessness about the backgrounnd. In addition, great patience and perseverance are required in the management of animals in photography; but, when success is attained, we have in refined pictures of handsome animals one of the most interesting phases of the photographic art.

Miss Barnes's English Trip.—In the *American Amateur Photographer* Miss Barnes continues the account of her camera trip in Great Britain, illustrating her paper with several views, mainly of archæological subjects in Yorkshire, such as *Fountain's Abbey* and *Old Remains in the City of York*, very nicely phototyped on stout calendered paper.

Coincidence or Plagiarism?—Knowing the honesty of the American journalists, and their promptness in acknowledging the sources from which their reprint articles are taken, we are the more surprised at Dr. John H. Janeway making himself, in his *Index Rerum Photographie*, an exception to this well-recognised rule of courtesy. Interested in seeing what he had to say on the flare-spot or ghost, we read his (?) article on that subject in the last-named serial, and found it to be a reproduction, *verb. et lit.*, of what we published a few years since, without the slightest acknowledgment. While we feel it a compliment to have articles from this journal reproduced by American friends, we must certainly draw the line at such appropriation as that just indicated.

DETERMINATION OF PLATE SPEEDS.

[London and Provincial Photographic Association.]

Before commencing my paper, a few words are necessary to explain the reason of my appearance before you this evening. Those of you who read The British Journal of Photography may have noticed that, on January 27 and February 3, there appeared two articles over my signature, headed, "Determination of Plate Speeds." Immediately following publication, there also appeared a mass of correspondence, some of it of a very violent tone, and most of it irrelevant to the question at issue. To this correspondence I replied briefly, to the effect that I should abide by my experiments; and such was my courage of my own opinions that I offered to submit *everything* to a disinterested jury, and I further offered to repeat any individual experiment such jury might select. To this challenge none of my dissentients have responded. It might be thought that, in making such offers, I would be pretty safe, by reason of the disinclination of any of these parties to try conclusions with me, especially when so wide a chasm separates us in the views we hold of the theory involved in the matter; but, as I was not disposed to allow this subject to rest where it was, it is with full belief that I shall be fairly dealt with at your hands that has prompted me to lay before you an account of *my* "investigations," accompanied by examples. I thereby constitute the London and Provincial Photographic Association my jury, and I shall be glad if you will accord me a patient hearing.

In bringing this subject before you, I am assuming that most present will have read my previous remarks in The British Journal of Photography of January 27 and February 3. In case any have not, I will endeavour shortly to outline them.

Messrs. Hurter & Driffield's Investigations and the Speeds of Plates.

You may be aware that some three years ago Messrs. Hurter & Driffield published their "Investigations." Beyond creating some

surprise in photographic circles, I am not aware that their remarks produced any further effect than what might have been expected from the publication of matter of so distinctly controversial a character. Many of their conclusions were so totally at variance with the preconceived notions of most photographers, including myself, that, like other things, one might have expected the subject would be a nine days' wonder, and then fall into oblivion; but, for reasons best known to themselves, certain manufacturers of dry plates have thought fit to adopt the system introduced by these gentlemen, and have issued boxes of plates marked on the outside with speed numbers in accordance with the method of Messrs. Hurter & Driffield. I, like others, have been a purchaser of these plates. Without recapitulating much that has already been published in my previous articles, suffice it, perhaps, to say I think it is beyond controversy that, if we purchase plates bearing speed numbers according to *any* method or system, we have a right to demand that the goods so sold shall be what they are represented. From the dealers and from the makers direct I purchased many boxes of plates, bearing speed numbers of 37, 80, 95, 100, 135, and 140. I tried a variety of experiments in different ways, to ascertain whether the relative speeds, as indicated on the boxes, were borne out in actual practice, and I finally adopted the method of exposing two competing plates side by side in a stereoscopic camera. I need not dilate upon the accuracy of this method beyond any other known method of competitive camera comparisons of the sensitiveness of different plates. Supposing the possibility of error, the method I adopted of making duplicate, and even triplicate, tests, and thereby reversing the positions of the plates, at once serves to expose any error, and enables one to judge with accuracy any difference in results.

As you will see by the examples I will hand round, the subject was one well calculated to test the rapidity of plates against one another, and very fine shades of extra sensitiveness in one or the other of any given pair of competing plates could be readily observed. I must point out to you where the variations in sensitiveness are chiefly to be detected. The stove you see in the negatives is dead black, and stands within the recess of a dead black grate. You will detect differences, where it exists, in the sensitiveness by closely examining all around these dark parts, and in the relief ornament of the grate, the horse-shoe form of which is visible in some plates and not in others. Another point for the detection of sensitiveness will be found in the detail, or the absence of it, in the clothing hanging in the corner in the shade of the chimney-breast. When examining each pair of negatives, I must ask you to read the explanations written at the foot of each, and also to bear in mind the conditions involved in producing each pair. Since I mounted these examples, I have gone over them and marked in red ink my estimates of the percentage differences in their sensitiveness, together with other remarks, in accordance with my published list of experiments on pages 69 and 79 of THE BRITISH JOURNAL OF PHOTOGRAPHY, copies of which are on the table.

Messrs. Hurter & Driffield have said that I cannot estimate differences of ten per cent. If I tell you that in several instances, in order to check my estimates, I gave the additional exposure to the slower plate, and thereby obtained identical negatives, as far as two different emulsions will yield two similarly exposed negatives, I think you must give me credit for knowing what I am talking about; and I shall leave you to judge of the general accuracy of my estimates, of which a large number are submitted to your inspection.

THE METHOD OF DEVELOPMENT EMPLOYED.

Now let me add a few words of explanation of the method of development employed. I have previously stated that the plan on which I proceeded was to give such exposures as would leave me the shadows—even the very deepest shadows round the stove—clear up to the end of prolonged development. The plates were developed by the formulæ of the manufacturers, and development was, in every instance, carried on until no further detail would come. Any attempt to ascertain differences of sensitiveness by developing for any arbitrary length of time must, in my opinion, result in unfairness to one or other of the plates under trial, and especially so if they are of different makes. I maintain that by the treatment I adopted can we alone discriminate differences of sensitiveness between competitive plates without favouring or prejudicing either one or another. If, with a given exposure of identical duration for a pair, one plate shows, under prolonged development, greater detail in deep shadow, I should certainly say that plate is the more rapid of the two. If I verify this result by making a repeat, or yet a third test, no room for doubt exists. I must point out in connexion with this, that if we expose so as to get a pair of *fully* exposed plates, on development the pair, even if of different makes and sensitiveness, will frequently appear almost identical, and I must insist that full exposures or over-exposures are no tests whatever of the rapidities of plates. In all experiments of this class some little heed must be given to the thickness or thinness of the coating, which does influence the result, but least of all in those parts the least exposed, viz., in the deepest shadows.

NO GRUDGE AGAINST HURTER & DRIFFIELD'S METHOD.

Judging from the tone of the correspondence I have alluded to as following my original articles, one might imagine that when I wrote them I had sat down with the deliberate intention of demolishing the Hurter-Driffield theory, or that I had some especial grudge against plates "speeded" in accordance with that method. As a matter of fact, I had no such idea, and I disclaim any intention other than that of putting to the test of actual use the plates so marked, to ascertain whether they bore out the theory. This they failed to do; and I am left to adopt either of two conclusions:—

(*a*.) If these plates had ever been submitted to examination in an instrument of precision, such as we are led to believe the Hurter-Driffield modification of Bunsen's photometer is, then I say, if the system is right, the plates are wrong, and the examiners either do not understand the system or they have blundered.

(*b*) If, on the other hand, these plates have been accurately examined and "speeded" by the system, then the system is wrong, for the plates most certainly are incorrectly marked, and do not carry out the system.

I have already alluded to the tone of the correspondence, I don't know that I should have noticed it but that the damning admissions made by one of the writers affords me the opportunity to expose what is either gross ignorance or a wilful perversion of facts. This brings me to another branch of my subject not previously dealt with.

Just let me read you two extracts from letters already published. The first is from a letter in *Photography*, 26th January last, page 63, and is signed "Platemaker." He says:—

"So little does the question of daylight *versus* candle-light come into practical effect that Mr. Driffield tells me that even ortho plates, as far as he is able to observe, are correctly read by the candle for ordinary daylight exposures."

The next is from a letter in THE BRITISH JOURNAL OF PHOTOGRAPHY, February 10 last, page 94, and is signed by James Cadett. He says:—

"I now come to the candle question. It is manifest that, provided that all makes of plates obey the same constant in the relative sensitiveness to candle-light and daylight, it does not matter a fig what that constant may be. Do plates obey that constant, generally speaking? All that I can say is this, that, after hundreds of tests, neither Messrs. Hurter & Driffield, Mr. A. Cowan, nor myself, are able to say that plates vary in this respect. Even orthochromatic plates for ordinary landscape work obey the same constant very well, though, of course, it is easy to see that under certain conditions of screen and light such plates would require a different constant."

Now, gentlemen, I am not quite so intent upon pointing out to you the strong family likeness that exists in these two letters (which may possibly be the result of accident) as I am anxious to inform you that the statements there made are absolutely incorrect and untrue so far as orthochromatic plates are concerned. Whilst I am sorry that such erroneous dogma should get publicity, I feel compelled to adopt the only course open to me, which is that of giving it a deliberate contradiction, and now I am going to prove it to you.

PROOF TO THE CONTRARY.

The pair of specimens (mounted on opal glass to make them very easily judged) which I shall place in the Chairman's hands were produced in the following manner. Taking a box of "Ordinary" plates and another of "isochromatic medium" plates, we shall find their rapidities to daylight very nearly equal, and these will enable us to make a most conclusive experiment. I cut two plates down the centre, and take half of each to an experiment. I place a simple graded screen in an ordinary printing frame, and put half an "ordinary" plate and half an "isochromatic" plate thereon, and expose briefly to usual daylight at midday. The result of this exposure, developed to completion, will be found on the right hand of the specimen, and is marked "*daylight*." You will probably agree with me that their sensitiveness to daylight as read by this means will be about two points in favour of the isochromatic plate, viewing the densities as transparencies.

I then take the other two halves of these plates, and place them just as before, but instead of daylight I submit them to candle-light. As a matter of fact, the pair at the left hand had ten C.M. seconds. You will see that even ten C.M.S. impress the "iso" plate to such an extent as to reveal the last grade of the screen (16) with great force, whilst the "ordinary" plate responds in a remarkably feeble manner. A longer exposure, such as fifteen C.M.S. or twenty C.M.S.,

will give you a better reading on the "ordinary" plate; but so sensitive are the "iso" plates to candle-light that great density results up to the full scale of the screen, and the comparative readings are valueless. As it is, and viewing these results by transmitted light, I think you will allow that there are from ten to twelve points in favour of the "iso" plate, and to verify this the Chairman shall be at liberty to cut the specimens off the opal glass after they have been all round, and then compare the relative gradations. Viewed by reflected light, the difference is even greater.

Now, gentlemen, how do you find it? On the one hand look at the two letters of "Platemaker" and Jas. Cadett, and, on the other hand, weigh these experiments! Please accept my assurances that these experiments have been repeated over and over again, and always with a like result. Do you find that ordinary and isochromatic plates obey the same constant—the candle, or do you think with me that any one who could be rash enough to make such an assertion must surely have forgotten the very *raison-d'être* of isochromatic plates?

If I needed confirmation of the results I place before you, I need but refer you to an article bearing strongly on this very subject, by Mr. Debenham, and you will find his experiments recorded on the very same page of THE BRITISH JOURNAL OF PHOTOGRAPHY (page 69) as my own. As this page is before you, please refer to Mr. Debenham's figures. He gives you for camera exposures with daylight, "ordinary" and "isochromatic instantaneous," equal periods; but for lamp-light you will see he fixes the rapidity of the "isochromatic" plate at no less than *eight times* that of the ordinary!

With no intention of either attacking the system nor yet of interfering with any man's trade, I repeat that my object has been solely to ascertain whether and how far the theory and the practice of determining the speed of plates would accord, and in the alternative as to whether the theory could be of any assistance (or otherwise) to practical photography. If time permitted, I should like to have read to you a leader from *Photography*, signed "A. P.," and dated March 2. As it is, I must content myself with a short excerpt therefrom. Alluding to Messrs. Hurter & Driffield, the writer says:—

". . . . If they mean that, after all, we can materially control our practical results by controlling the developer and the following operations, then no more need be said; but, with their writings before us, we must say that it is by no means clear what they do mean in the matter."

As I have not found that the theory of these gentlemen has been borne out by the plates issued in conformity with their system, I decided to place my findings on record; hence all this storm, and hence, also, my appearance before you this evening, which I determined upon even if it involved further encounter with my cavillers, or entailed a recital of the tenets of my photographic creed.

I trust that the subject may have interested you sufficiently to induce discussion whereby we may gain photographic knowledge, and endeavour to arrive at perfection and the truth.

G. F. WILLIAMS.

NATURALISTIC PHOTOGRAPHY.*

AND now we will return to the main subject, which I shall lay before you in a series of *propositions only*, for psychology has not yet become a science in the *true sense:* psychological work is merely in the working hypothesis stage, though by no means at the worked-out hypothesis end.

Proposition I.—That the material universe may be regarded by us as eternal (though varying in aspects), and the fountain-head of all our *sensuous* impressions.

Proposition II.—That accepting the doctrine of evolution the mind has evolved from the merest crude sensations of the amœba to the complex and subtle sensations of the master artists of to-day.

Proposition III.—That in the course of this evolution there arose the sensation and perception of the beautiful,† and this emotion was followed by acts intended for ornamentation of their persons or homes.

Proposition IV.—That from this germ developed the sense of the beautiful, until in civilised man this appreciation of the beautiful may be divided into three steps:—

1. That of sensation. 2. That of perception (intellectual). 3. That of emotion.

That these three be three distinct processes, yet they are one—indissoluble.

Proposition V.—That the appreciation of the beautiful is thus *subjective*, an ideal existing in the minds of men in varying degrees of development; and that, though Nature (by which the objective world is meant) has probably produced at various times exquisite harmonies, it took man to recognise these as beautiful, and so it has been said the artist is the master of Nature.

Proposition VI.—That, as the NERVOUS system developed, these appreciations became more delicate and subtle, and so a man with a naturally delicate sense of vision gradually purges himself of the coarser emotions, and his perceptions are more purely cerebral acts. A master artist regards first of all by mere *acquaintance* the decorative harmony of a picture or natural scene, *then* by previously acquired knowledge he *knows* why it is lovely, fit, true in sentiment, and *distingué*, and that knowledge gives way to the emotion of joy, which is expressed physically by his smiling face.

That the *reverse* is the process with the Philistine; the crude and tawdry appeals first to his emotion, hence the popularity of the sentimental subject; of the anecdote; of "literature in the flat."

Proposition VII.—That we have physiological proof that men's sensitiveness varies in degrees of fineness; thus a *virtuoso* in flour knows samples grown in different countries by their feel, a *virtuoso* in wine knows a glass of port taken from near the bottom from one taken from the top of the bottle, and the blind Laura Bridgeman knew purely *by touch* the clothes of all the inmates of a workhouse. From which it is self-evident that in all persons the boundary of their appreciation is hard drawn; in some cases, therefore, fatally limited by their very organization. A man whose vision is not delicate can *never see* the delicacies of line, colour, and tone patent to a more delicate nervous organization. Such a limited person is for ever doomed to be outside the pale of the pictorial art world, as the man with no ear for music is for ever doomed to be an "outsider" in the musical world.

Proposition VIII.—That, as the sense of beauty is a human ideal, this ideal will vary with individuals and *in* the individual from day to day, nay, from hour to hour. Indeed, so complex are the brain processes, and so dependent upon each other, that an artist may begin a picture with one ideal and finish it with quite a different ideal. Indeed, it is one of the great difficulties of the artist to keep steadily to his original ideal throughout the work. A glass of wine, a santonine powder, may completely change his ideal or power of execution. From which it is plain how delicate a thing is a work of art, how thoroughly *personal* is every touch in a work worthy the name of art, what a perfect index of the creator's mind.

Proposition IX.—That the ideal existing in any given brain at any moment is a complex and refined essence, the result of the man's whole previous life up to date; wherefore this ideal is no mere reflection of Nature, but a result of imagination, or the selection from various ideals or parts of ideals; and thus man may go beyond Nature and conceive things that do not exist in the world—such as the vase, the phonograph.

That fine art is the artistic expression of this ideal by a *personal* method, and that no man is an *artist* who has the ideal and can see the beautiful if he have not the power of execution as well. Art is therefore achievement. By their *results* alone are artists to be judged; as thus a very inferior *technician* may be a very delicate seer of the beautiful, but the world rightly only gives him credit for his picture—*his result*—and if that be poor, if his hand cannot express his ideal, he does not rank highly, nor often does he get credit as a seer. "Art is therefore with the man," as Mr. Whistler has said.

Proposition X.—That Nature sometimes sings in tune, or succeeds in producing glorious and exquisite harmonies, harmonies fully appreciated by the seers of the beautiful, for many more may appreciate than can depict; hence the rarity of real artists. Whence also a layman may be a far keener seer than most painters; but seer *and* masterly executant is genius itself.

Again, that the harmonies of Nature are altogether different from the harmonies of art—are dependent on different phenomena, and that Nature and art are different worlds. That Nature sometimes sings in tune Mr. Whistler himself has allowed, but I submit that it is absolutely impossible to reproduce that harmony on a plane surface; it is a thing by itself, a thing apart; though a number of unphilosophical painters *think* they do reproduce Nature, but they do not. Here is a very simple proof suggested to me by my friend Mr. Havard Thomas, a sculptor. Let the observer look at a distant landscape behind some reed-stalks in the foreground. The reed-stalks in Nature, under certain conditions, do not blot out *any* of the background, *we see round them*, and see the *whole* landscape beyond. In art the reed-stalks would always *blot out* part of the background. I think our sense of the third dimension of space or "distance" arose first through this peculiarity of vision. For further and deeper proofs of the utter impossibility of *reproducing* Nature as we see her I must, in a brief paper like the present, refer you to Professor Hemholtz's *Scientific Lectures*, to Mr. Rood's *Chromatics*, and to our *Perspective Drawing and Vision*. A careful study of these publications, aided by a few

* Concluded from page 213.

† According to Darwin this is a fact first noticeable in birds.

experiments made for himself, will convince the veriest neophyte that it is *impossible* to reproduce Nature or make a "mere transcript."

Proposition XI.—That in photography we are confronted with a new phenomenon, in that we find some of the results of a *machine* give true pleasure to master artists which has never hitherto been the case with machine-made works.

Proposition XII.—That photography is not art because a machine comes between the man's ideal and Nature, and the result is *machine-made*, the trapping of a sunbeam. Say the photographer, like the painter, goes to Nature with certain ideals—we will, for illustration's sake, assume that two men have exactly similar ideals of the beautiful (which is, of course, impossible). They go together to Nature, and find a beautiful natural harmony in a lovely stretch of purple sands by the sounding sea. The photographer at once sets up his machine, focusses, and exposes; but in these very processes *his* ideal has *gone*. What results *may* be beautiful, but it is no more the representation of his ideal, the vision he first saw. It is something else, for the machine imposes certain conditions which were never in the photographer's mind at all. How often has the most experienced of us been disappointed with the photograph of what was fine in Nature—fine to our eyes that is, and sometimes *vice versâ?*

The painter, on the other hand, begins, and if he be an expert each touch helps to his desired or ideal end; this wavelet is delicately put in, that breaker strongly and broadly, and so on; everything is done unto one end, and all is certain from the first—whereas the photographer has boxed a maimed and contracted reflection of what he saw. True, it may be a beautiful reflection; but, after all, it is *Nature's drawing*, and not the man's. Still such machine-drawn pictures may in certain cases satisfy, or rather harmonise with, the photographer's ideal of beauty, or, indeed, with the master painter's, as does a beautiful natural landscape; and yet, again, the beautiful photograph is not *art* any more than the natural scene of which it is a reflection.

Proposition XIII.—That, though the machine draws the photograph, yet in the production of a photograph there are a few (very few) very limited *incalculable* elements, as there are in organ-grinding and engine-driving.

These are—(1) Selection of view. (2) Selection of lens. (3) Selection of focus. (4) Selection of developer. (5) Selection of printing method.

These limited incalculable elements give a man a very limited opportunity of blending his materials to his ideal, and though, by taking advantage of these *with knowledge*, he may surpass other photographers in decorative work, still they are too limited for him to express to any degree of certainty or fulness *his ideal;* and, since the drawing is mechanical, these few very limited incalculable elements cannot enable a man to express his ideal in anything like the same degree as does a personal art. Indeed, photography is not nearly so *personal* an art as sailing or rifle shooting, both of which have very little of the mechanical about them and much of the personal.

In photography man puts the machine under certain physical conditions, and the machine will always (under these same conditions) bring about the same result; therefore the process is logically mechanical. On the other hand, a personal art is one in which the results would differ again and again under the same physical conditions, for the *mind* would work differently on each so-called "replica" of the original—*no artist could paint two pictures exactly alike.* A photographer might take fifty views of a subject exactly similar, from which it is self-evident that photographs are not works of art in the sense accepted by artists, though photography may be an art or craft in the old sense of the word art, as surgery is an art; but such a use of the word "art" as applied to photography would not satisfy the *dilettante*, for the word used so would include *every* photographer as an artist, which is not what the ambitious amateur means at all.

Proposition XIV.—That therefore it would be wiser for all photographers to drop the use of the words "art" and "artist" in connexion with photography (photography is a science, or hopes to be some day), and classify exhibition works as—

(1) Decorative or pictorial (when the *intention* is merely and purely to produce a beautiful thing). (2) Scientific (accurate mathematical reflections).

By using the terms "decorative or pictorial photographs" and "scientific photographs" we should, I think, allay all opposition from artists—not to say painters—and critics (who are right in refusing to call photographs works of art), and should be at the same time working in a less pretentious way and in a legitimate pursuit, humble as compared with painting, 'tis true, though the best results surpass all but the masterpieces of art in beauty. And I would suggest that this Society sets the example at their forthcoming Exhibition and describes the works submitted into two classes, scientific and "decorative or pictorial," for works should be classed according to their intention.

Proposition XV.—That decorative photographs are worth doing (if well done) because they give us certain beautiful qualities art cannot give, hence their *raison-d'être.* That the producers of such may prove themselves as keen seers (not artists) of the beautiful as the master artists themselves. They may have art knowledge too; yet, if they be no creators by personal method, I submit they are not "artists." But, then, this does not mean, on the other hand, that mediocre draughtsmen, whose vision is vulgar or obtuse, are to crow over these seeing photographers, for such mediocrities are not "artists" and, indeed, seeing photographers have far more claim to the title, as the masters would allow.

Proposition XVI.—That, though photographs are sometimes more beautiful than art, they never equal Nature when she sings in tune. Indeed, I submit than when Nature "sings in harmony" she is more beautiful than photography or art, unrivalled in her delicacy, fineness, and distinction.

Proposition XVII.—That "idealism" and "impressionism," if used in connexion with photography, are mere contradictions of terms, and used by slovens in thought—or worse.

Gentlemen, let us conspire *not* to be called by any false or vain names such as "artists," but to produce beautiful decorative work, each of us in his own way. Let us in friendly and unselfish spirit band together for the furtherance of this end, and let the too eager or ambitious (I will not say vain) neophyte remember that the proof of his delicacy of vision is in a measure what he shows us *of his own*, and that, as there are few Laura Bridgemans with perfect touch, so there are few seers of the most delicate beauties, because few organisms have delicate vision. Let the neophyte and others remember that the seers of the beautiful are as rare as the limners of beautiful scenes; that physiology proves that most are for ever fatally limited to remain *without*, and no disgrace either, if such have but the honesty and pluck to own it; the disgrace is pretentiousness and imposture—in *pretending* to see.

Amongst these blind have been the vast body of persons who have ridiculed Mr. Whistler; indeed, nearly the whole press has ridiculed him, and yet, gentlemen, to-day his pictures hang in the most honourable position in Paris, the city at present the Queen of the Arts, and so it will always be, for I for one believe that truth is great, and will in the end prevail over obtuseness and dishonesty, for I am optimist enough to think the majority of men are fair-minded, honest, and manly, and that, though they may for a time let the rogue and the cad live their little days, they will in the end arise and put their houses in order and turn the unclean from their temples.

As for these propositions, gentlemen, I do not intend to fight over them, for they are *propositions*, and therefore no fighting matter, but provisional until psychology shall either prove or disprove them.

I offer them to you frankly and trust you will deem them worthy your consideration, after which I leave you to accept or reject them, as your honest judgment dictates. At any rate, they may prove interesting to some of you, at least I hope so, for they are an attempt on my part to solve what has long been a vexed question, a problem to which no satisfactory or *rational* solution has hitherto been offered.

P. H. Emerson, B.A., M.B. (Cantab.)

PHOTOGRAPHIC INDUSTRIES—THE OPTICAL WORKS OF W. WRAY, HIGHGATE, LONDON.

For many years has the name of Wray been associated with the construction of astronomical, microscopic, and similar achromatic object-glasses for high-class instruments of precision. It is only within the past six or eight years that the firm has been indnced to add to the above departments the sister branch of photographic lenses, which has already developed into one of great magnitude and importance. In the belief that our readers would like to know something, however little, of the inner life of a recognisedly high-class lens-making establishment, we visited the place one afternoon, note-book in hand.

The premises are situated on that suburban slope known as North Hill, Highgate. This locality was originally selected as being on an elevation considerably above the lower parts of London, in which smoke and fogs find a congenial resting-place not conducive to the testing of object-glasses for large astronomical telescopes. There is no shop or anything else visible from the adjoining public road which would lead any one to the belief that just inside of the gate, and within a hundred feet or so of it, were quite a number of workshops, forming the elementary parts of a great factory, the lathes and other mechanical forces in which were in direct communication with a Crossley gas engine, which the Messrs. Wray find more convenient than steam as the motive power.

Entering the first of these workshops, we observe four rows of turning

lathes extending from end to end. Some of these are elaborately fitted with slide rests, face plates, and similar belongings incident to such machines. At one end we observed an elaborate mechanical appliance which we could not relegate to the department of either lathe, planing, or shaping machine, being unlike anything we had previously seen made use of in connexion either with the construction of lenses, telescopes, or microscopes. This, Mr. Wray informed us—demonstrating its *modus operandi*—was an entirely new machine they had made for the production of Iris diaphragms, it being used for cutting and drilling the slots and holes which form a portion of their internal mechanism. This machine, when once set for any special size of tube, did its work with a degree of perfection quite impossible to be attained by the most careful and skilled hand-work. The mechanical resources of the establishment are such as to have enabled them to construct this useful machine on the premises. The blades used range from twenty-four in number downwards, according to size of tube, and are made of steel about one two-hundredth of an inch in thickness. These are cut out in a screw press, and we saw a large rack full of the steel-cutting tools, one pair of each being used for each size of diaphragm. The blanks for the Waterhouse diaphragms are also cut out in the same way, the apertures being turned in special chucks in the lathe, hard steel gauges being used for the purpose. Close by is the riveting machine for fixing the pivots into the blades of the Iris. It is driven by a strap from the shaft overhead, and delivers something like sixty blows a minute, each one, of course, with absolute precision, and is under perfect control, instantly stopping or starting with a slight pressure of the foot. By an ingenious device the pivot is withdrawn from the bed plate after the operation of riveting is completed. So perfect is the working of this machine that Mr. Wray informs us that he has never heard of one of the pivots becoming loose.

In the lens-grinding department we saw much to interest us. Commencing with the raw material, the glass: this, we learnt, is obtained from Chance, of Birmingham, and Mantois, of Paris, and, in order not to waste any time in grinding any piece containing an imperfection, each was critically examined previous to being placed in the hands of the roughers, who, with coarse emery and iron curve tools, ground it to the semblance of a lens. The way we saw one disc examined will serve as a general description of all of them. This was to form the "flint" element of a rectilinear of four and a half inches diameter, thirty-two inches focus, and to work with an aperture of *f*-8. It was a disc of considerable thickness, and had been polished not only at repeated intervals on the edge, but also on both sides, all this being done solely for the purpose of enabling the internal structure of the glass to be critically examined. The indices of refraction and dispersion having been ascertained and noted, the body of the glass is then examined through the edges and sides by a magnifying-glass for the discovery of such defects as tears, striæ, or mechanical disturbances of like nature. But an examination extending only so far would not be complete, for there is a powerful factor still to be determined, which is the homogeneity of the glass. Owing to some imperfect carrying out of the annealing process in the glass works, there might be present strata or patches of unequal density. This is tested for by polarised light, which instantly reveals the slightest departure from perfect homogeneity. Not until the glass satisfies all the conditions implied by the tests mentioned is it sent down to the roughing shop to be ground approximately to such curves as have been determined by the circumstances of each case. Such an examination as we have described is, we are aware, practised by all high-class opticians, and here comes in one point of difference between what we have termed "high-class" lenses and those pretty, low-priced productions redolent of polish and lacquer, which come to this market in such shoals from abroad. Such makers could not possibly afford, even if they possessed the knowledge, to make a selection or examination of the glass, but take it as it comes from the glass works, soften it by heat, and, by discs, press it into the curves required, finally grinding and polishing the surfaces. When done and placed in their mounts, some by a fluke may be passable, while others are —well, not so. With our *best* opticians, both at home and abroad, each lens forms a matter of individual study from beginning to end.

But we must follow the fortunes of the particular lens which we left in the hands of the roughers. When it has been brought into shape, it goes into the grinding and polishing shop, where it is ground and smoothed on a tool of the exact radius of curvature necessary, emery of various grades of fineness being used in succession. With each change of emery the workman washes the surface of the glass, and examines it through a magnifier to see that no grits from the penultimate grinding have been left unground out, and that the surface is that due to the grade of emery last employed. The final grinding leaves the surface in a state of extreme smoothness, although still grey. The lustrous polish is imparted by a tool from which every trace of emery has been removed, and a fresh surface of pitch or some unyielding cement of a similar nature has been given. To this, while still warm, a tool the exact counterpart of the other is applied, by which the true curve is imparted to the cement surface, to which is now applied the rouge or putty powder requisite in the imparting of the highest polish capable of being attained by the glass. This being the way in which the astronomical lenses for which this firm is celebrated, are polished, its use has been continued in the construction of their photographic objectives. In the olden times, and even still yet in some cheap factories, the lenses were polished on felt or textile fabrics; but this causes a rounding of the margins, and is apt to change the figure of the lens. But the lens is not yet finished. It has next to be centered. To this end it is cemented on the face of a chuck in a lathe of special construction, and, before the pitch or other cement has set, the lens is moved by little and little from one side to the other until the reflection of a gas flame in front is seen to be stationary and free from wobbling when rotating the lens in the lathe. When this has been done, and the cement is quite cold, a plate of metal charged with emery is by slow degrees and by screw adjustment brought to bear upon the edge, and continued until the lens is ground circular and is of such a diameter as is required.

After cementing with Canada balsam the component parts of an achromatic lens, blackening the edges to prevent light from being reflected, and placing the lenses in the cells of the mount, the combination is ready for being tested. Several tests are employed in Wray's establishment, one being the examination of an artificial star formed by a thermometer bulb filled with mercury. Several of these bulbs are used, the nearest being fixed at a distance of probably 150 feet from the lens to be tested, and it was astonishing to note the rapidity with which the trained eye of Mr. Wray could almost in an instant note anything connected with the correction of the objective and give directions for alteration, should such prove necessary. Flatness of field and covering power were ascertained by attaching the lens to a camera much larger than the effective covering power of the lens demanded, and to this end trees and the general scenery at a distance, not omitting to mention houses at no great distance, the black windows of which bore small white enamel letters, lent invaluable aid, especially to any one unversed in the values of the higher optical tests and who desired to see how a lens would perform on an average landscape subject.

One of the sons of the founder of the establishment ensconces himself in a quiet corner, surrounded by the other members of the working staff, who devote themselves to the microscopic object-glass department. Another son is at the head of the photographic lens department, while still another member of the family takes cognisance of the astronomical object-glasses, and all that appertains to them, yet is the training of these chiefs of departments so complete that any one can interchange with another. Incidentally, we noticed that the smallest of the photographic objectives—those of the wide-angle class—were being made by workmen engaged in the department devoted to microscopic lenses.

An inquiry as to the relative demand for lenses with Iris diaphragms contrasted with Waterhouse and others, revealed that the Iris is preferred in the ratio of three to one. There is a fully equipped dark room on the premises, and the actual working of any lens can be practically demonstrated in a camera which always stands ready for use. In the brass-turning shop we observed what seemed to us some hundreds of mounts of various dimensions in every stage of progress, there being a preponderance of small ones intended for hand cameras.

Standing in the grounds, and at a little distance clear of the workshops, are two equatorial telescope stands, having all the fittings for the testing of astronomical object-glasses. One of these receives all objectives up to five inches in diameter; in the other, and larger, objectives from six to twelve inches diameter are finally tested on celestial objects, after having passed the preliminary optical tests.

Apropos of charges we and others have occasionally brought against artists for the untruthful drawings often indulged in by them, more especially in the case of the sun or moon, we were shown, by Mr. Harry Wray, a couple of photographs that demonstrated the truth of this charge in an effective manner. Placing a lens of fifteen inches focus in a camera, and selecting a time when he knew that the full moon would that evening be within the field of view, he exposed a plate during the day, and left the camera undisturbed till evening, when the moon was in the scene, when he exposed a second plate, on which he got an instantaneous view of our satellite. On carefully comparing the relative angles subtended by the objects in these two negatives (now in our possession), and contrasting these with a picture of a similar scene drawn by an artist, we find that we understated the case when we said that some artists made the moon four or five times larger than it appeared in nature.

This business was established in 1850 in Windmill-street, Tottenham-

court-road, and was removed from thence to Highgate for reasons already hinted at. Beginning in a small way, it has grown, until it now gives employment to about two dozen hands—all expert workmen.

CENTRAL PHOTOGRAPHIC CLUB.

As already announced, a meeting of intending members and those interested in the Central Photographic Club will be held on Monday evening next, April 17, at the Memorial Hall, Farringdon-atreet, when the chair will be taken at eight o'clock precisely.

The principal object of the meeting will be to receive the report of the Executive Committee appointed on March 6 to

(1) Select suitable premises.

(2) Decide upon what financial basis the Club should be conducted.

(3) Draw up a set of rules for the government of the Club.

In regard to the first, the Executive Committee immediately appointed a Premises Sub-committee to seek for suitable premises within a limited area which might fairly be considered central, and, after considerable trouble and investigation, the Sub-committee recommended the Executive Committee to decide on premises in Fleet-lane, Farringdon-street, as being in every way suitable for the purposes of the Club. The Executive Committee have endorsed the recommendation, and the meeting on Monday next will be asked to adopt it.

As to finance, the Executive Committee unanimously agreed that the Club should be administered and carried on by a limited company, so that the liabilities of members might be restricted to the amount of their annual subscription, the profits, if any, after five per cent. has been paid to the shareholders, being devoted to the benefit of the Club. A considerable proportion of the capital haa already been subscribed by the members of the Committee and friends.

After careful consideration, the Committee hava adopted the following rules for the government of the Club :—

Rules of the Central Photographic Club.

1. The title of the Club shall be the Central Photographic Club.

2. The object of the Club is to provide a central meeting-place for those interested in photography where they may enjoy social and technical advantages.

3. All gentlemen interested in photography shall be eligible for membership.

4. The annual subscription for town members shall be 1*l.* 1*s.*, and for country members 10*s.* 6*d.* For life membership a payment of 10*l.* 10*s.* shall be required. The first 500 members will be admitted without entrance fee. Those joining after that number haa been reached shall pay an entrance fee of 1*l.* 1*s.* for town members, and 10*s.* 6*d.* for country. Gentlemen residing within a radius of twenty milea of Charing Cross shall be deemed town members.

5. The management of the Club shall be veated in a Committee of twelve, six to form a quorum, consisting of an equal number of shareholders and ordinary members, to be elected by the members in general meeting annually. The Committee shall have power to fill up vacancies during the current year.

6. An Hon. Treasurer and Hon. Secretaries and an Hon. Librarian shall be elected by the members annually in general meeting, and shall be *ex-officio* members of the Committee.

7. Candidates for membership must be proposed and seconded by two members of the Club. The name and address of the candidate, and the names of the proposer and seconder must be aent to the Hon. Secretaries at or before the stated meeting previous to the one at which it is proposed to snbmit such candidates for election. Snch names shall be read by one of the Secretaries to the meeting, and posted on board till the next meeting.

8. The election of members shall be by ballot at any stated meeting of the Club, and a vote of fonr-fifths of the members present and voting shall be necessary to elect a new member.

9. Every candidate on his election shall be notified in writing with a request for payment of his subscription and entrance fee.

10. No member ahall be entitled to use the Club until his aubscription for the current year has been paid.

11. The annual subscription shall be payable in advance on the first day of July in each year. Subscriptions to be paid to the Club Company.

12. Members joining the Club before September 30 shall pay the full subscription. After the end of September and before January 31 the payment shall be two-thirds; after the end of January and before May 31, one-third; the subscription of any member elected after May 31 ahall be considered payment for the following year.

13. Any person who shall by any means cease to be a member of the Club shall, nevertheless, remain liable for and shall pay to the Club Company all moneys which at the time may be due from him to the Club.

14. Any member making himself obnoxious to the members of the Club shall be reported to the Committee, who shall investigate, and, if necessary, call a special meeting of the Club to discuss the matter; then, if the majority so decide, the offending member shall be expelled the Club, and lose all interest and benefit in it, auch decision to be taken by ballot.

15. An annual general meeting of the members shall be held in the first week in July to receive the report of the Committee, to pass the accounts, to appoint officers for the ensuing twelve months, and to elect members of the Committee to supply the places of those retiring. The newly elected officers and members of the Committee shall come into office at the conclusion of such meeting.

16. Ordinary meetings of the members shall be held weekly.

17. The Committee may, whenever they think fit, and they shall on a requisition made in writing by ten members, convene an extraordinary general meeting. Any such requisition ahall specify the object of the meeting required, and ahall be aigned by the members making the same, and shall be delivered to the Secretaries.

18. Every member of the Club shall be entitled to one vote only. The Chairman shall have a casting vote in addition to the vote to which he may be entitled as a member.

Bye-laws for the Club House, and such other rules and regulations as may be found necessary when the Club premises are opened, will be drawn up by the Committee, and submitted to the first general meeting of members for approval.

It is hoped that as many as possible intending members of the Club will attend the meeting on Monday next. The Hon. Secretary *pro tem.* (Mr. Thomas Bedding, 2, York-street, Covent Garden, W.C.) has already received a very large number of applications for membership from all parts of the country, and from both professional and amateur photographers, and the Executive Committee anticipate that the adoption of the above and other recommendations to be made will enable them to approach all classes of photographers in London and country with the certainty of obtaining such a numerical support as will result in the formation of the largest photographic club in the world—a club that shall be at once a home, a rendezvous, and resort for all those interested in photography, whether residing in London or the country—a powerful agency in furthering photographic progress, and a representative force in each of the many branches of modern photography.

CROYDON CAMERA CLUB EXHIBITION.

This Exhibition was held on the Wednesday, Thursday, Friday, and Saturday of last week, when, besides the pictures on the walls, the now customary evening attractions of music, lantern displays, and technica demonstrations were included in the programme. A display of some sixty or more of the most successful photographs of recent years, by such men as Ralph Robinson (whose loan collection included his fine *Sir Frederick Leighton*), Brownrigg (*Winter Sunset*, &c.), Byrne (direct portraits and studies of children), Karl Greger, Colonel Gale (*An East Country Quay*, &c.), H. P. Robinson (*Carolling*), Seymour Conway, T. J. Bright, and Adam Diston (about twenty-six examples of this master's work, comprising the ever-delightful *Gloaming*), lifted the Exhibition, as a whole, to a point of excellence which the non-competitive exhibits did little to support.

The Judges were Messrs. J. Gale and Thomas J. Bright, and the mention of their awards in Classes A and F must suffice, inasmuch as the classes were small and poor. In Class C, for outdoor views (members only), however, some really meritorious work was shown, Mr. C. E. Whitaker's picture of *The Gateway, Hever Castle*, catching the eye as a technically well-rendered photograph. Mr. William F. Frost's views on *The Mole*, Mr. G. R. White's series, and *A Study of a Mill Pond* by Mr. A. E. Isaac, as well as the same gentleman's clever bit of realism in the effects of *Winter*, being conspicuously prominent. To our thinking, however, the beautifully crisp definition, relief, and panoramic-like effects of Mr. Hirst's *Deepdene* and *Arundel* constituted the pick of the class. We hope that so manifestly a good and careful worker will be content with effects like these, and turn a deaf ear to the pipings of the foggy school. In Class D (*genre* or figure subjects, members), a group of *Three Fishermen* easily and naturally posed was, perhaps, the best; but the work in the class was not good. In Class F (any subject) Mr. A. J. Sargeant had some capital interior work (*Langton's Chapel*), and Messrs. W. J. Wright, George Corden, H. E. Holland, and G. R. White were represented by excellent landscapes.

In the class for members' exhibits not for competition, Mr. B. G. Wilkinson was a tower of strength with several of his famous studies, and the President (Mr. Maclean) had a good selection, of which we preferred a little picture *The Causeway*, a waterside study, in which the arrangement of land and water was accomplished with the happiest

artistic effects. In the same class, Mr. G. R. White had a series of interiors of dwelling rooms, difficult subjects successfully handled.

Useful exhibits of photographic apparatus, &c., were shown by Messrs. Hurst, & Co., of St. Michael's-road, West Croydon, and D. P. Roberts, 120, North-end, Croydon. The Exhibition must have given great gratification to local photographers. It was small, but well arranged.

The following were the judges' awards:—

Class A (Best prints illustrative of hand-camera work).—No. 9 (first award), George R. White.

Class B (Lantern slides).—No. 22 (first award), H. E. Holland; No. 25 (commended), George Corden.

Class C.—No. 48, to 50, Series (first award), William F. Frost; No. 63 (commended), George R. White. No. 67, 69, 70, Series (commended), A. E. Isaac.

Class D.—No. 79, *Fishermen* (first award), C. E. Whitaker; No. 81 (commended), H. E. Neeves.

Class E.—No. 105 (first award), Miss J. R. Fooks.

Class F.—No. 148 (first award), A. E. Isaac.

WEST SURREY PHOTOGRAPHIC SOCIETY'S EXHIBITION.

The fifth annual Exhibition of this Society was held during the week at the Public Library, Lavender Hill, S.W. The competitions were restricted to members, and about one hundred and sixty photographs were placed on the walls. If we remember aright, the Exhibition of last year had the advantage of including a number of Colonel Gale's and Mr. Davison's pictures which added materially to its average of excellence. This year no such assistance is forthcoming; but, as if by way of compensation, the members' work is undoubtedly superior to that previously shown, although, perhaps, numerically smaller.

Naturally an exhibition of members' work is only of confined interest, and therefore, criticism of it in detail is superfluous. Some of the pictures, however, well deserve commendation by name—notably an enlarged study of the *Waterfall*, Battersea Park, by Mr. E. Pointon, possessing great softness and naturalness; two large platinum views of the choir and nave, *Lincoln Cathedral*, by Mr. F. P. Smith, capital pieces of interior work; a delightful view of *Eynsford*, by Mr. Winsford, and a triptych by Mr. P. Martin, *Seeing the Show*, children all agog with expectation in the street, waiting for a Lord Mayor's procession or something of the sort and held back by a man in blue. Mr. E. Calland showed a portrait, which, in the way of "diffusion of definition," would have been bad to beat, supposing the use of a lens. Two tiny views in carbon, on very large mounts, by Mr. G. H. James, were reminiscent of Mr. Davison, and the same exhibitor's portrait of a lady, a gracefully posed warm-toned picture, was undoubtedly the best picture in the room. We liked Mr. J. S. Bond's well-printed platinotype view of Melrose, and a plough horse piece, *A Surrey Team*, also by Mr. Bond; Mr. E. Swingler's river scene with shipping, *A Still Day*, a refined tender view; and Mr. W. Graham's minute crisp studies of *Caistor Beach* and *On the Bure*. Mr. J. L. Lyell's capital studies of *Indian Architecture* agreeably diversified the Exhibition, which contained much other really meritorious work.

We may note, in conclusion, that the West Surrey Society has its own journal *The Photographic Gazette*, edited by Mr. G. H. James. The April number, containing the catalogue of pictures, includes well-written and practical papers on "Enlarging" by Mr. Agars, "Autotype Printing" by Mr. Calland, "The Dominant Factors of Exposure," by Mr. G. H. Seward, and other instructive photographic matter. The *Gazette* is a credit to its Editor and the Society.

THE INFANTS AND THE PHOTOGRAPHER.

In the Worthing County Court last week, the Judge delivered judgment in the case of Simmons *versus* Edwards, which was an action to recover 10*s.* 6*d.* paid to defendant, a photographer, under circumstances which we referred to a few weeks back. Two sisters, both under age, paid, one the sum of 7*s.* 6*d.*, the other 3*s.*, to defendant to photograph a family group. Defendant expressed himself prepared to fulfil the contract, but the plaintiffs' father forbade the photographing of the family, and, at his instigation, the girls sought to recover the money from Mr. Edwards. His Honour, while pointing out that one action should have been brought, and not two, confessed that he did not pretend to understand the father's reasons for forbidding the photograph. His Honour said that in his opinion the case fell within the Infants Relief Act, 1874, and the contract was void; and, if not so under the Act, still he thought that the plaintiffs, being infants, were entitled to void or rescind the contract. Further, there was the question whether they could get their money back, and whether they had derived any benefit from the contract. Defendant, in his opinion, was in the same position as he was before the contract was entered into, and he could not treat the making of an appointment as work done. There would therefore be judgment for plaintiffs, but without costs. He thought it would have been much better if defendant had been allowed to carry out the contract. Defendant: "Thank you, sir."

Our Editorial Table.

Elementary Photography.

By John A. Hodges.

In this work, which forms No. 7 of the "Amateur Photographer's Library" (Hazel, Watson, & Viney), all the various processes of practical photography are described in such simple language as befits a teacher who is imparting his knowledge to young and inexperienced aspirants after the photographic art. In recommending the selection of a camera, he give preference to one of the half-plate size on the score of comfort and convenience. After describing the special features of some of these, and of some of the lenses in common use, the author describes non-actinic lanterns and the fittings of a dark room, the preparation and uses of the various solutions, and, in short, goes through all the processes of making negatives, printing and enlarging from them. The manual will be useful for beginners—the class for which it is intended.

Photographs by H. Yeo, Plymouth.

A series of photographs of children—or more correctly of a child—attests the skill of this artist. The story is in reality the history of a soap bubble illustrated by a small series, from the cradle to the grave sort of idea, which tells its own tale. But, quite apart from this, the pictures as a whole and the poses of the chief actor—a pretty little girl—are admirable. The prints are in platinum, and as pictures are charming productions, the expressions on the face being natural and in keeping with the stages of progress of the soap bubble, from its birth at the pipe to its collapse in mid air.

PATENTS COMPLETED.

Improvements in Photographic Hand Cameras.

No. 8324. John Skynner Baily Bell, 3, Wentworth-place, Newcastle-upon-Tyne.—*March* 4, 1893.

My invention relates to and is for improvements in apparatus for photographic hand cameras, and I carry it out in the following manner:—

The camera case may be of the usual shape or form, or otherwise, and with any additional or necessary adjuncts if required.

Within the camera, and immediately behind the lens, I have the exposure chamber, and behind this chamber, and divided from it by a suitable partition, there are two chambers, one above the other, and divided by a horizontal plate or partition at or near the middle of the height of the camera. The upper one of these chambers is the unexposed chamber for the reception of sensitised plates, and the lower one is the exposed chamber, to receive the sensitised plates after being operated upon in the exposure chamber, the back end of this chamber being the usual light-proof end cover.

In these two latter chambers there is a cage having a horizontal top plate of thin sheet iron or other suitable material. The bottom plate is similar to the upper one, and they are connected together with small rods passing through the horizontal partition and let into grooves in the camera sides or otherwise, the whole being free to slide up and down in the two chambers, the downward motion being actuated by the weight of the cage or otherwise.

The cage being, say, at the top, the upper part is in contact with or contiguous to the upper part of the unexposed chamber.

There is a horizontal slit or opening in the unexposed chamber at the bottom in the vertical partition dividing it from the exposure chamber. This slit or opening is just large enough to allow one sensitised plate with its sheath to slip out into the exposure chamber, and there is another slit in the upper part of the partition of the exposed chamber dividing it from the exposure chamber sufficiently large to allow a plate operated on in the exposure chamber to pass into the exposed chamber.

Immediately in front of these slits there is a shutter kept close by a suitable spring or springs.

In the exposure chamber there is a tumbler or pivoted plate of suitable shape to receive the sensitised plate, having its edges turned up at the two sides and at one end. This plate is pivoted on a horizontal axis at or near its centre, and having spindles or pivot pins let into the sides of the camera case. One of these pins is continued outwards, and on its outer end there is a suitable milled head or other device or contrivance so as to give the tumbler the necessary amount of motion, and having an index finger to show the position inside. There is a stop piece below the slit in the partition of the exposed chamber for the edge of the tumbler plate to rest upon when it is at its lowest position, that is, in a position to deliver a plate into the exposed chamber.

There is also a stop piece at the top of the exposure chamber, so that the tumbler may rest in the vertical position, that is in a plane at right angles to the axis of the camera, when a photograph is being taken. At one side of the exposure chamber there is a thin strip of metal as a spring or other contrivance which the tumbler plate presses against in its rotation which steadies the tumbler and arrests unnecessary motion. This spring has a projection or knob at such a point that the tumbler is arrested in its motion when in a position suitable to receive one of the sensitised plates from the unexposed chamber on to the tumbler plate.

There may be an index and register, actuated by the cage, so that the descending cage, acting on a hinged lever inside the exposed chamber, communicates motion to an axle, which axle is continued to the outside, and an index finger fixed on it there will show the number of plates operated upon—or other form of index and register may be used if desired.

The method of working is as follows :—

The cage in the unexposed chamber is charged with sensitised plates up to its highest point, the top of the cage being above the highest of these plates. The tumbler plate is in the vertical position or plane, at right angles to the camera.

The first operation is to rotate this plate the necessary quadrant of a circle or so by the milled head, until it is in a position to receive the sensitised plate from the unexposed chamber. In its downward motion it has pressed the shutter downward before it, so that there is a clear opening for one sensitised plate. The camera is slightly tilted forward, and the plate slides out on to the tumbler plate in the exposure chamber. Secondly, the tumbler, with the sensitised plate upon it, is now rotated into its proper position to receive the impression. The photograph is taken, and the tumbler, with its plate, is brought down to the lower stop, carrying the shutter before it. The camera is slightly tilted backwards, and the plate slips off the tumbler through the slit on to the bottom plate of the cage in the exposed chamber. The tumbler is now slightly rotated, and is checked by the knob at a position to receive a fresh plate from the unexposed chamber, and so the operations are continued as before until the supply of plates is exhausted, the cage dropping down as each separate plate is removed from the unexposed chamber.

It will thus be seen that the plate is moved into its various positions without violence or risk of breakage.

The various parts may be of any suitable shape or material.

The claims are:—1. Self-acting apparatus for supplying the unexposed plates from the unexposed chamber and returning them again into exposed chamber, and method of retaining unexposed and exposed plates in separate chambers. 2. The method of changing the plates by the revolving tumbler—in bringing unexposed plates into "register," and returning them after exposure into exposed chamber. 3. The whole arrangement substantially as described in specification and drawing, having the whole of the mechanical operations of changing the plates actuated from one finger-piece.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
April 17	Camera Club	Charing Cross-road, W.C.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

April 11,—Ordinary Meeting, Mr. W. E. Debenham in the chair.

The attendance numbered fifteen, which was considerably reduced before Mr. Warnerke had got half way through his paper.

Mr. Hubert J. Elliott and Lieutenant H. Wood, R.E., were elected members.

It was announced that the following presentations of pictures shown at the last Exhibition had been made to the Society: *Aylesford*, by Mr. A. R. Dresser; a series, *Blowing Bubbles*, by Mr. H. Yeo; and *Sunset in Winter*, by Mr. Cembrano.

The South London Photographic Society were admitted to affiliation.

The Chairman stated that Mr. W. England would, in May, demonstrate the Daguerreotype process, upon which occasion there would be an exhibition of specimens, to which members were invited to contribute.

The Paris and Brussels International Congresses, 1889-1891.

Mr. Leon Warnerke read a lengthy paper on this subject, describing the origin and labours of the two Congresses, and concluding with a detailed account of the decisions arrived at with regard to photographic standards and units. He mentioned that the next Congress would be held at Geneva in the ensuing summer. [We shall make extracts from the paper when it is published.] Mr. Warnerke said that Captain Abney wanted him to make a critical report, but all he would then say was that the work was conscientiously done. At the same time the decisions of the Congress were such that they could not be adopted in this country, particularly with regard to the size of plates, screw threads, and flanges.

Mr. Chapman Jones said that photographers had not troubled much about these congresses, but they had not had till now any connected account of them. With regard to a standard light, it seemed to him that they would, after all, have to go back to standard candles; but he would like to ask Mr. Warnerke whether the congresses had got us any nearer a standard light of any other kind.

In the course of his reply, Mr. Warnerke admitted that this question as well as that of the determining of the sensitiveness of plates, was yet unsolved.

Mr. G. Scamell said that, as regards delegates to future conferences, the affiliated societies should be invited to act in the matter.

The Chairman, in closing the discussion and moving a vote of thanks to Mr. Warnerke, said that Mr. Warnerke had gone to very great labour in drawing up the paper, but it was unfortunate that photographers would not trouble about the work of the congresses. One of his (the Chairman's) objections to the decimal system was the difficulty there would be in abolishing it in favour of the duodecimal, which he thought would ultimately be adopted. The inch and the foot were more convenient than the metrical measure, as they were so easily appreciated by people in this country.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

April 6,—Mr. E. J. Wall in the chair.

Determination of Plate Speeds.

After the disposal of other business, Mr. G. F. Williams read a paper on this subject [see page 229].

Mr. A. Cowan said he would like to have the chance of meeting some of the points in Mr. Williams' paper. In his (Mr. Cowan's) opinion Messrs. Hurter & Driffield were not such fools as platemakers seemed to think. It was impossible to judge of exposure by eyesight. Messrs. Hurter & Driffield's test enabled one to obtain the exact rapidity of any plate of unknown rapidity. The exposures could just as well be made to daylight as to candle-light, and he (Mr. Cowan) would undertake to prove that to whichever light an exposure was made the results would be identical.

Mr. W. E. Debenham agreed with Mr. Cowan as to the general similarity of the behaviour of plates to candle-light as well as to daylight, with the exception of orthochromatic plates. The difference in results given by Warnerke's sensitometer to daylight and candle-light was much exaggerated.

Mr. J. Sterry said there were four factors in the Hurter & Driffield system which were estimated separately. These were, relative exposure, relative degree of developer, the character of the plate itself, and the chemical fog, which varied in different plates, and which, if we estimated it simply by the eye, made it necessary that we should eliminate the action of the other three factors. But chemical fog did not affect the matter at all. His chief point, however, was as to the relative amount of developer to use, and in that connexion he would like to ask Mr. Williams how to distinguish between the effects of twenty-five per cent. extra exposure and twenty-five per cent. extra developer, as both increased density, but in a different manner? It was distinguishable by the photometer numbers, the speed showing by the relative position of the curves, and the developer by the angle which the straight lines made with the base lines. Fog was estimated by direct measurement. It was impossible to make two plates which were identical, and thus judging results by the eye was an extremely fallacious plan. To estimate density by this plan it was easy to go utterly wrong, as the surroundings upset the estimation.

Mr. James Cadett observed that Mr. Williams had asked the supporters of the Hurter & Driffield system to go before a jury of practical photographers to judge a question which they knew nothing about. He could hardly expect that system to be accepted by the people who had no practical experience of it. Mr. Williams had called the system a *fiasco*, and plates tested by it utterly worthless, and in that he had shown bias. We had been in the habit of reading the speeds of plates by what we observed in the shadows. The action of light was to produce density on development, and density must therefore hold some relation to speed. It was the object of Messrs. Hurter & Driffield's system to show that relation. He (Mr. Cadett) had given plates which yielded different densities to different photographers to test with various exposures, and errors of about 300 per cent. were obtained by the camera. It was in confusing density with speed that Mr. Williams condemned the system, basing his condemnation on what some platemakers had put on some boxes of

plates. He, however, should have tested his system against the photometer. He admitted that his own plates had been in one instance marked too high; their speed, instead of 130, should have been 108. As regards orthochromatic plates, an enormous difference in their orthochromatic effects to candle-light and daylight had been noticed, but with his own plates, which were not orthochromatic, Mr. Driffield had found that they obeyed the same constant. Mr. Driffield had also found plates tested by candle to give exceedingly good negatives in daylight—he had, in fact, not observed any difference in their qualities in that respect.

Mr. COWAN observed that he had tested plates by the candle, and was able to tell the maker of the plates what amount of exposure he could give.

Mr. CADETT (continuing) put in a plea for the use of the photometer, saying that they were unable to judge of density by the eye, whereas the photometer showed it instantly. Taking the case of two plates which had received identical exposures, the only difference might be that one would have a higher density than the other. One would look under-exposed, and the photometer would indicate a lower curve. The same detail would come out with a slower plate, but measurement of the density with the photometer would at once show the difference. In one case a difference of 300 per cent. had been found. If density was not related to speed, how was it to be made use of? He (Mr. Cadett) thought Messrs. Hurter & Driffield's principles should be attacked. Alluding to Mr. Cowan's experiments, he said that, under the conditions, he was a far better judge of the system than Mr. Williams, who had simply based his experiments on the numbers on makers' plate-boxes. There was another point. Thickness of coating had an enormous influence; but by cutting a plate in halves a mean reading between the two should be obtained.

Mr. W. J. WILSON said that his impression of Hurter & Driffield's system was that, within its own limits, it was perfect—that is, within what was called the period of correct exposure with a certain developer at a certain temperature, and excluding the question of the spectrum altogether. It was a question how far the spectrum question came in. No two makes of plates would act in the same way as regards the spectrum. In most ordinary circumstances we had to deal with white light, and practically the spectrum did not give any. They had heard it stated that two plates of different makes might have the same relative speeds in different lights—that is, they might be equal in speed at one o'clock and different at six. As to the developer question, he believed Messrs. Hurter & Driffield started by asserting that a photographer had no control over gradation by varying his developer, but he (Mr. Wilson) had some reason to believe that Messrs. Hurter & Driffield had since modified their statement. He (Mr. Wilson) had found that rodinal sometimes showed a plate to be three and a half times as quick as one developed with pyro and ammonia, and if that was admitted it needed investigation, and the speeds of plates according to certain developers should be recorded. It came to this, that one developer acted better with one plate than with another. Another point, as to temperature of developer. Messrs. Hurter & Driffield had tried development at a certain temperature, but, had they developed two plates of different makes with the same developer at, say, forty degrees Fahr.? There might be a variation with the same make of plates at different temperatures. In conclusion, he thought that within certain defined limits and conditions the system was a perfect one; but whether, where all the conditions did not come in, the other conditions were vitiated was an open question.

Mr. CADETT thought that Messrs. Hurter & Driffield had corrected their remarks in their original paper as to a plate being found more sensitive to one developer than another, inasmuch as they had stated that they had found no difference worthy their notice. Those who were using Hurter & Driffield's system had learned that the speed of a plate could be altered by a developer. The photometer enabled them to observe the periods of over and under-exposure. Before the Hurter & Driffield system came out, we were content with 100 per cent. errors in the speed of plates; now, ten per cent. was looked upon with horror. The time of development did not alter the speed of plates very materially, but density was widely different.

Mr. P. EVERITT pointed out that, in two of Mr. Williams's results, there was a difference, whereas, according to the speed numbers of the plates, they should have been exactly alike. The difference was possibly due rather to the delicacy of the plates rather than to the opacities. Alluding to the actinograph, he said that, with different speeds of plates, and working strictly according to exposure, he found the speeds practically correct.

After further observations from Mr. Haddon, Mr. Cowan, and the Chairman, Mr. Williams briefly replied to some of the criticisms on his paper, and the discussion was adjourned till Thursday, April 20.

Holborn Camera Club.—April 7, Annual General Meeting, Mr. Fred. Brocas in the chair.—The Secretary read the annual report of the Committee, which was adopted. The Treasurer presented the balance-sheet, showing a balance in favour of the Club of 14*l.* 18*s.* 8½*d.* The following officers were then elected:—*President:* Mr. A. Horsley Hinton.—*Vice-Presidents:* Messrs. Fred. Brocas, S. T. Chang, and R. D. Lowe.—*Committee:* Messrs. J. H. Avery, E. H. Bayston, J. Bush, T. O. Dear, A. T. Ebsworth, A. W. Miller, and J. Stevens.—*Librarian:* J. Brittain.—*Lanternist:* Mr. E. Benest.—*Treasurer:* Mr. Albert Bell.—*Hon. Secretary:* Mr. F. J. Cobb.—*Assistant Hon. Secretary:* Mr. Herbert Thompson. Several alterations in the general arrangements and rules were made, and the meeting separated. The first official outing was held on Saturday last at Hampstead Heath in excellent weather. A copy of Mr. J. A. Hodges' "Elementary Photography" has been presented, by the publishers, to the Club library.

Harringay Photographic Society.—April 6, Mr. C. Watson presided.—A practical demonstration of *The Frena System* was given by Mr. Bynoe, and illustrated with diagrams on the screen. The demonstrator first showed the new and improved system of changing films, the use of the swing back, and, the patent and very ingenious time and instantaneous shutter. Some pictures taken with the "Frena" were shown on the screen, and were much admired.

Hackney Photographic Society.—April 4, Mr. F. W. Gosling presiding.—Members' work shown, Mr. Dean and Mr. Nunn. Question: "Is there a limit to length of time between printing and developing the cold-bath platino paper without deterioration?" Reply: "It is always advisable to develop at once. Paper absorbs moisture; even when under mackintosh, the edges will. Undeveloped prints were put away for six, four, and two months, and recently, and, although all care was taken, the last only were good. When the paper is dry, it curls film side outwards, and, when damp, the opposite. It is not generally known that, if the negative be very thin indeed, a good print can be obtained by printing under light blue glass; also, if a print be very much over-exposed, so that all the details are out, a good result comes by fixing in the acid bath without developing." Question: "What is the relative exposure between limelight and daylight portraiture?" Reply: "For portraiture the light must be diffused, either by several lights or white paper reflectors, hence limelight is not satisfactory. Magnesium ribbon for high lights and gas for shades recommended." Mr. Dean then read Mr. Dawson's paper on *Photogravure.*

South London Photographic Society.—April 5, Dr. T. G. Munyard in the chair.—The Committee presented their fourth annual report, which showed that the Society was continuing to progress, and that the number of paid-up members was 105. The proportion of working members had, during the year, largely increased. At the bi-monthly meetings demonstrations and papers of great interest had been given and read. The Club camera (12×10), lantern, and slides had been in much request. Several valuable contributions to the library were made during the year, and the demand for the loan of the various works had been good. The Committee tendered their thanks to the editors of the photographic papers for copies of their papers. An excursion secretary was appointed at the beginning of the year, and endeavours were made to put the outings on a better footing, which had met with much success. An exhibition on more extended lines was held in November last, and favourably commented upon by the photographic press. The Treasurer's report showed that the members had obtained the maximum benefits for their subscriptions, a considerable amount having been expended in apparatus, which left the accounts just balancing. The report and balance-sheet were adopted, and the election of officers proceeded with, which resulted as follows:—*President:* F. W. Edwards, Esq.—*Vice-Presidents:* Messrs. Maurice Howell, Dr. T. G. Munyard, W. Rice, and H. G. Banks.—*Committee:* Messrs. Boxall, Buckle, Claridge, Esler, Fellows, Greaves, Lester, Lyon, and Miller.—*Curator:* Mr. G. H. Moss.—*Treasurer:* Mr. E. A. Whitby.—*Hon. Secretary:* Mr. Charles H. Oakden, 51, Melbourne-grove, East Dulwich, S.E.—*Hon. Assistant and Excursion Secretary:* Mr. W. F. Slater, 169, Southampton-street, Camberwell, S.E. The Affiliation scheme was discussed, and it was decided to join the Affiliation Committee.

Lewisham High-road Camera Club.—April 7, Annual General Meeting.—The following gentlemen were elected:—*Vice-President:* Mr. A. H. Miles.—*Committee:* Messrs. M. Stodart, B. Davidson, E. Eastwood, R. W. James, M.I.C.E., C. Churchill, W. C. Chaffey, Professor Lambert, M.A.—*Hon. Treasurer:* Mr. E. B. Eastwood, 26, Breakspears-road, Brockley.—*Hon. Secretary:* Mr. H. M. C. Sprunt, 192, New Cross-road, S.E.—*Hon. Assistant Secretary:* Mr. H. L. Davis, 95, Cranfield-road Brockley.

Croydon Microscopical and Natural History Club (Photographic Section).—April 7, Mr. J. H. Baldock in the chair.—Mr. S. H. FRY discoursed on the "Sandell" plate. These, he explained, differed from the ordinary plates in being coated with two or three emulsions of different degrees of sensitiveness, the most rapid being on the top, and resulted in several great advantages, enormous latitude in exposure, freedom from halation, &c. Proceeding to the development, he laid special stress on the adoption of a tentative system, using a weak developer when the exposure given was longer than the normal for the top film, and he attributed the want of success experienced by some to their not having so treated them. The stripping of the top film was strongly deprecated; if veiled, it should be cleared. A series of very fine 15×12 prints, taken by Mr. Sandell, showed the great success with which Alpine scenes, irregularly lit interiors, and other strongly contrasted subjects could be photographed on these plates. A number of snap-shots, taken by the lecturer, were also shown.

Leeds Photographic Society.—April 6, Mr. J. H. Walker (President) in the chair, Lantern Night.—Many lady friends were present. The Indian and Colonial set of slides belonging to the Photographic Society of Great Britain and affiliated societies and a set of prize slides were exhibited. Both sets were much admired, many of them receiving hearty applause, and the Society feels deeply indebted to the Photographic Society of Great Britain and affiliated societies, the slides being only one amongst other sets they distribute amongst their affiliated societies. Such, amongst other benefits, only requires to be known to induce other societies to join.

Photographic Society of Japan.—March 3.—Some very fine photographs were exhibited, sent by Messrs. B. J. Edwards & Co., London, showing the difference between the photographs taken on ordinary plates and on their isochromatic plates; the contrast between these was very striking, especially in the photographs of flowers. Mr. Kajima Sebi then exhibited an extraordinarily large bromide print (36×42) taken direct on a negative in his big camera exhibited at a previous meeting. Some views taken by the Dallmeyer telescopic lens were sent to the meeting by Mr. W. K. Burton, he himself not being able to be present. The telescopic lens was again shown, this time fitted with gear to enable the focussing and spherical aberration adjustment to be made more readily. Mr. Beilter showed a new lens by Carl Zeiss, of Jena, called the apochromatic triplet. It is claimed that this is more complete and correct for spherical and chromatic aberration than any lens which has hitherto been produced, and certainly some extremely beautiful views of cabinet size taken with the lens were exhibited, as also some larger views on aristotype paper taken by the same instrument; these were much admired.

FORTHCOMING EXHIBITIONS.

April 14–29	*Crystal Palace. The Executive, Crystal Palace, S.E.
,, 14–15	*Bolton Photographic Society. Hon. Secretary, J. E. Austwick, 10, Rushton-street, Bolton.
,, 17–29	*Photographic Society of Philadelphia. Hon. Secretary, R. S. Redfield, 1601, Callowhill-street, Philadelphia, U.S.A.
May 4–6	*Forfarshire Photographic Association. Hon. Secretary, W. J. Anckorn, West Port, Arbroath, N.B.

* Signifies that there are open classes.

Exchange Column.

*** No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance. The full name of the advertiser must in all cases be given for publication, otherwise the Exchanges will not be inserted.*

Exhange eight-inch gas burnisher, 5×4 bellows camera, and silver Albert chain for whole-plate camera.—Address, J. BENNETT, 38, James-street, Swansea.

Exchange Dallmeyer *carte* lens, splendid definition, for good-make half-plate bellows camera lens, and three dark slides.—Address, W. MELLING, 147, Newport-street, Bolton.

Doublet lens, by A. Ross, 18×16, has been used regularly for plates 24×18; exchange for 15×12 wide-angle tourist camera, half-plate.—Address, A. Cox & Co., Tavistock-chambers, Nottingham.

Will exchange Emmerson's head rest for two backgrounds, one in-door and one out; or half-plate camera and lens, for out-door work; must be perfect.—Address, F. MOORE, 36, Wollaton-road, Beeston, Notts.

Will exchange a heavy burnisher, by Richardson, eighteen-inch bar (oscillating), perfect condition, and with gas burner; wanted whole-plate wide-angle lens, any make.—Address, C. BENNETT, 104, High-street, Lymington, Hants.

Correspondence.

☞ *Correspondents should never write on both sides of the paper. No notice is taken of communications unless the names and addresses of the writers are given.*

MR. PRINGLE AND THE SANDELL PLATES.

To the EDITOR.

SIR,—Although Mr. Pringle has confined his reply to my letter of the 17th ult. to another journal, I think the matter of such universal interest that it should get directly into the hands of your readers, and so you will oblige by inserting the following contribution to it. I hasten to reciprocate Mr. Pringle's kindly feelings. Mr. Pringle has been a friend to ourselves, speaking for my Company, and to myself, and trust he may ever remain so; but there happens sometimes in human experiences a period when it is well to be saved from one's friends, and this I have taken to be one of those interesting occasions. Mr. Pringle expresses regret that I did not attend at the meeting of the Camera Club. Well, I thought the matter was so simple that, in the hands of such an expert, the subject was quite safe; secondly, I disliked the appearance of "exploiting" at scientific meetings; and, lastly, I did not think it consistent with my *amour propre*, inasmuch as I had some time previously been advised by Mr. Pringle that I should not be considered worthy of the Club membership. Of the first idea I have been altogether disabused, and it is entirely due to Mr. Pringle's handling of the subject that it has been thought desirable to give instruction in the uses and capabilities of the plates by demonstration at the Societies.

Mr. Pringle seems to wish to represent my former letter as dealing "mainly with opinions." Nothing is further from my desire. I want facts, and facts only; and I maintain the facts of the case are so easy of proof as to be within the reach of all.

Mr. Pringle objects to my use of the adjective "preposterous." I can only repeat that the idea of stripping the films in practical negative making is preposterous, and consider I was justified in being so emphatic on the point when a gentleman, Mr. Gregor Grant, who admittedly had received instructions from Mr. Pringle on the proper use of the plates previous to starting on a trip, is reported to have said at a meeting of the West Kent Society that he gave enormous exposure, developed, and stripped off the top film; but I understand even then nine good negatives were secured out of twelve, the remaining three being under-exposed. I take it the latter were the cause of Mr. Grant's adopting Mr. Pringle's notion, that a little over-exposure produced a failure with the plates.

In discussing the question of rapidity, I contend I am entitled to have from Mr. Pringle some suggestions as to why he should go out of his way to represent the plates as slow, in order to release him from any suspicion of being disingenuous. Either he must imagine I cannot make a fast emulsion, or must have an idea that the successive coatings interfere with one another.

Mr. Pringle must surely know there is every inducement to put the most rapid emulsion on the surface, for, with the increase of rapidity, halation is increasingly troublesome in the single film. As a matter of fact, the plates are as rapid as any plate of any make I have ever tested, and I am more than sanguine of soon being able to provide a plate of much greater rapidity still.

Mr. Pringle's assertion at the Camera Club, "I found that in a view with trees in it, the normal exposure to get a good negative on the top film was ten seconds at *f*-32," if unaccompanied by an extempore explanation, was an outrage. I will here point out that the questionable advantage possessed by the ordinary plate of the supplementary exposure from reflection (which I maintain is stupidly called halation) is absent. Why I think the term halation stupid is, because it detracts attention from the undue density, and what may be called the inner effect of the reflected rays when not sufficiently strong, or the angle of reflection is not large enough to produce the halo.

Mr. Pringle, in his use of the adjective "absurd" in connexion with my assertion as to the practically unlimited latitude of the plates is, I submit, somewhat unscientific. If it is possible to do, as I have done, give an exposure on an open landscape of half a second, and another of one hour with the same stop (and, in all probability, six hours would have answered equally), is my claim unjustified? I should be glad to know who requires greater latitude. Mr. Pringle says he has not found the plates an absolute cure for halation. I shall esteem it a great favour if he will furnish me with details of the alleged failure, and will guarantee, if the exposure is within the province of what can be fairly described as practical photography, to make a negative free from it.

On the question of quantity of light passing a film, Mr. Pringle appears to give himself entirely away, or I cannot understand his language. He says, "I think under-exposure is one of the most certain ways to produce halation." Now, taking it for granted that the halation meant is reflection, and as the reflected rays are only a small percentage of those transmitted, it stands to reason that a large quantity of light has passed the film even in the cases of under-exposure. Then, am I right or wrong in claiming a great advantage for the double films in cases where one wishes to develop up all that is possible?

Now on the question of amenability to development.

I have not the advantage of a knowledge of the results obtained by the *savants* referred to as having "studied the subject."

It has been a matter of daily, almost hourly, study to me for the past fourteen years, and this is the only way in which I can account for the fact that a weaker developer is necessary for a slow plate than for a rapid one, and also for another fact, that a weak and restrained developer with a rapid plate will furnish a finer-grained negative than a strong one. Why this, unless it is that the finer grains are more easily reduced? This, in my opinion, also furnishes the correct answer to the Rev. F. C. Lambert's question as to the appearance or non-appearance of the positive effect in negatives, propounded at the Camera Club on the same evening. Mr. Pringle, I expect, will agree with me that light and heat are only different manifestations of the same natural phenomenon. Now, in sensitising an emulsion, heat is as necessary as light is in making a negative. We know the effect of light is, up to a certain point, to facilitate or render possible the development to maximum density; beyond that point it renders it more and more difficult, and at last it makes development by any known method an utter impossibility; in other words, the salt of silver is what is termed perfectly solarised.

Then I suggest the action of light and heat being similar, that in the more highly sensitised emulsion we have an approach to the effects of solarisation, and consequently density is less easy of achievement, as it is well known to be with the most rapid emulsions.

I can assure Mr. Pringle there are many items to be found in the philosophy of a dry-plate maker, which are not to be found in the philosophies of the majority of our handbooks; neither is it fair to expect it. We, as emulsion-makers, make thousands of gallons of emulsion of different kinds during the year, whereas our authors may make their few half pints.

In conclusion, I can only beg of Mr. Pringle not to fail to pay a visit to the Exhibition which is being held during next week at 24, Regent-street. If he cannot there find that I have more than proved my case to the hilt, I shall be surprised.—I am, yours, &c., J. T. SANDELL.

Thornton Heath, April 10.

REDUCING ACTION OF HYPO ON AMIDOL-DEVELOPED NEGATIVES.

To the EDITOR.

SIR,—The reducing action of hypo on amidol-developed images is not confined to bromide paper. A few days ago I developed in amidol and fixed in a somewhat strong bath two hand-camera exposures. The negatives produced were fairly strong and of good gradation, without fog, and fixation appeared to be complete. I rinsed them under the tap for about three or four minutes, and placed them in a draining rack, intend-

ing to finish washing them as soon as I had developed the remainder of the exposed plates in the magazine.

I was then called away for two or three hours, and, as soon as I returned, at once proceeded to complete the washing of the negative. To my consternation, I found only the merest ghost of an image left. There was no sign of fog, and the gradations had not suffered.

It has long been an article of my photographic faith that negatives underwent merely apparent reduction in the fixing bath, and that prolonged fixation did not perceptibly increase this apparent reduction. An exception must evidently be made in the case of images produced by amidol.

I would recommend a comparatively weak fixing bath for both plates and paper when this developer is used.—I am, yours, &c.,

54, *Loftus-road, W., April* 7, 1893. L. CROSSLE.

To the EDITOR.

SIR,—In the last two issues of THE BRITISH JOURNAL OF PHOTOGRAPHY I have read letters on the above subject, and write these few lines to inform your readers that, having used the above developer upon several different brands of dry plates for negative work, I have noticed that when the negatives have been left in the fixing bath for, say, two hours, their density appeared to be reduced a little as compared with their density after about half an hour's stay in the fixing bath, which for all ordinary plates is the length of time I consider necessary in order to thoroughly fix the image. I may also mention that I have even left negatives developed with amidol for at least twelve hours in the fixing bath, and, although they have been a little more reduced in density, none of the finest details appeared to have suffered in the least, *and in no case did the image entirely disappear.*

It will be interesting to many of your readers to know that negatives developed with pyro, hydroquinone, eikonogen, and rodinal will be reduced a little in density if left in the fixing bath for several hours; *but I do not think that amidol-developed negatives* are reduced to a greater extent than those developed with the other developers above mentioned—at least, this has been my experience. An ordinary, and not an acid, fixing bath is always used in my dark room; therefore I cannot say what effect the latter or any other kind of fixing bath may have upon the image.

The foregoing facts may set many of your readers' minds at rest as regards the permanency of their negatives—from this cause, at least; indeed, this is the only reason why I wrote this letter.—I am, yours, &c., J. T. HACKETT.

Fleet, Hants, April 7, 1893.

CYANIDE OF POTASSIUM.

To the EDITOR.

SIR,—May I be allowed to correct a statement you make in answer to correspondents, re cyanide of potassium? You say this is only sold by "qualified pharmaceutical chemists." All *registered* chemists can sell it; but the latter are *not* pharmaceutical chemists, although both are registered as duly qualified to sell poisons. At the same time, you will find it in the British Pharmacopœia method of making its characters and tests.—I am, yours, &c., J. W. WRIGHT.

141, *St. James's-street, Burnley, Lancs, April* 7, 1893.

ALBUMENISED PAPER *VERSUS* P.O.P.

To the EDITOR.

SIR,—As so much has been written upon the superior permanence of P.O.P. paper over albumenised, there is one test I have never seen mentioned, viz., hot water. Our old friend will stand boiling; the other—well, try it.

I should recommend amateurs to be wary of discarding old and tried friends.—I am, yours, &c., AMATEUR.

April 8, 1893.

[Our readers will be amused to be told that the "permanence" of gelatino-chloride prints is open to question because they will not resist the application of boiling water! Our correspondent's test is such a ridiculous one that it obviously explains why he has never seen it mentioned.—ED.]

TRADE DEPRESSION—THE CAUSE AND THE REMEDY.

To the EDITOR.

SIR,—Your valuable JOURNAL, ever alert to the interests of those who seek a livelihood by, and are entitled to a position in, our much-abused profession, will gladly entertain the above—the burning photographic question of the day. The thorough practical remarks of "N'Importe" in your issue of March 24 are a step in the right direction. So let us proceed to consider the facts. When circumstances are adverse to progress, we must understand the cause thereof, and what is conducive to improvement; in our case, this is not difficult. While we submit to incompetents usurping the rights of genuine aspirants, the present state of matters will prevail, to the discredit of a nation whose boast is, "Liberty and the suppression of all unrighteousness." Let us follow the expedient adopted by other trades and professions, and prove our genuineness by technical examination and registration. Those unable to survive a test would find their proper insignificance seeking pastures new, while those who proved their superior claims for a position in the photographic world would no longer incur the sceptical view, as one of the many sheep in the fold (black included), but as a distinctive class. To further our interests we have established our National Association of Professional Photographers, Photographic Society of Great Britain, and others. If they wish to uphold their profession as an honourable one, will they not endeavour to suppress the existing evil? In this advanced age, when competition is so keen, we must establish measures for the protection of a genuine business career. Then, and not till then, can photography maintain the high position which it is destined to, and deserves to occupy, as one of our many arts and sciences.—I am, yours, &c.,

April 10, 1893. ONUS PROBANDI.

PROPOSED HAND CAMERA CLUB.

To the EDITOR.

"The cry is still they come."

SIR,—I note in your last impression a proposal for a Hand Camera Club. As there is now a Photographic Society in most parishes, I should have thought that the hole cut in the stable door for the fowls would have been large enough for the chickens; however, I may be wrong, and the new Club may fill a long-felt want, after all.

Should the proposal succeed, I would suggest a "Half-plate Club," a "Seven and a Half Five Association," and a "Whole Plate" Society (with power to add to their number), the subscription to be in proportion to the size of the plate adopted, thusly, quarter-plate, 2*s.* 6*d.*; half-plate, 5*s.*; 7½ × 5, 7*s.* 6*d.*; whole plate, 10*s.*; and, when these are all in good working order, an "Iris Diaphragm" Society, a "Portable Symmetrical" Club, a "Tele-photographic" Association, and a "Concentric" Union might be started. I was going to add an *Eccentric* Club, but possibly, by the time the others are in full swing, there will be several of these under other titles.

I would also suggest that, if these Societies are formed, some of the meetings should be arranged for the daytime, as at present there are only six *evenings* in the week available for those who make either a hobby of, or a living by, photography.—I am, yours, &c., DROP SHUTTER.

April 10, 1893.

THE GENESIS OF THE GAS REGULATOR.

To the EDITOR.

SIR,—Allow me to say that Birrell's Gas Regulator was patented and used on his automatic oxy-hydrogen apparatus on July 25, 1875, seven years earlier than 1882. His regulator is different from all the other regulators, his is a Bellows and Stud Acting by means of a lever and Connecting Rod on a Keyed Cork.

The latter is a more certain form than a valve as any dust between it and its seat regulator renders the regulator entirely useless. His has one of his Anti-friction Keyed Cork which reduces the friction of the key to a minimum.—I am, yours, &c., WILLIAM BIRRELL.

109, *Graham-street, Airdrie, N.B., April* 10, 1893.

Answers to Correspondents.

*** *All matters intended for the text portion of this* JOURNAL, *including queries and Exchanges, must be addressed to* "THE EDITOR, THE BRITISH JOURNAL OF PHOTOGRAPHY," 2, *York-street, Covent Garden, London. Inattention to this ensures delay.*

*** *Correspondents are informed that we cannot undertake to answer communications through the post.*

*** *Communications relating to Advertisements and general business affairs should be addressed to Messrs.* HENRY GREENWOOD & CO., 2, *York-street Covent Garden, London.*

PHOTOGRAPHS REGISTERED:

John Anderson, Dalry, Ayrshire.—*Photograph of the Mother Lodge of Scotland.*

Mackintosh & Co., Kelso.—*Four photographs of the grave of the late G. A. Baird.*

R. DAVIS.—The prints will not curl if they are well rolled.

HERMANN SCHNAUSS.—We shall be pleased to receive the article.

BRUTUS.—Your post-card was quite inexplicable, please write more fully.

JOHN A. LLOYD.—Sharland, Thavies Inn, Holborn-circus, is the address you lost.

B. O.—We have no information as to any imminent scientific Exhibition at Islington.

XXX.—Try the effect of refixing the plate in an acid (bisulphite of soda) hypo fixing bath.

H. W. H.—The tincture meant is the compound one in which water is the solvent.

COLLOTYPE.—Apply to Messrs. Waterlow, Messrs. Bemrose, or the Loudon Stereoscopic Company.

A. E. PLATT.—The negatives are out of our possession. Try either daylight or magnesium, whichever is most convenient at the time.

J. W.—Practical information on the subject of process-block and collotype work is given in the Editorial article of the last ALMANAC.

JOHN BUCHANAN.—1 : 15 and 1 : 6 in the formula mean solutions containing respectively one part of gold chloride to fifteen parts of water, and one part of hypo to six parts of water.

E. H.—Hydroquinone, as well as eikonogen, may be obtained from all the dealers. Neither article is, or ever was, kept by ordinary druggists. You are misinformed as to its being withdrawn from the market.

T. G. SHAPE.—If the seller says the rose tint on the albumen paper is permanent, it ought to be. The thing is easily tested. Expose a piece in a pressure frame to the sun for a few days, part of the paper being shielded by a mask.

COMPARE.—1. No bag is needed for changing the plates, the reservoir being complete in itself. It is adaptable to any camera. 2. The lens mentioned will, when stopped down to *f*-8, do all the work that can be done by a lens in which thia is the maximum aperture.

A. E.—The combined toning and fixing bath, at one time universal, was abandoned for albumen paper prints some thirty years ago. The theory of its action will be found in some of the earlier editions of Hardwich's *Photographic Chemistry;* see the sixth and seventh.

SEPTIMUS.—Any of the wholesale stationers who supply enamelled paper for lithography will also supply paper suitable for collotype. Sometimes the plates have to be modified to suit any particular make of paper. But the makers can modify the surface of the paper to order. Of course, they will only do this when a sufficient quantity is ordered at a time.

W. HOBBS.—We cannot hazard an opinion as to the safety of the mounts. Methods for ascertaining the influence of the mount upon the photograph have been published in the JOURNAL. In the meantime you may plaster, by means of water, a print face down upon a mount, and place under pressure for a fortnight. You will then see whether any signs of spots or other imperfections are apparent.

T. ROWE says: "I always see it recommended for the photo-lithographic and other mechanical processes that wet collodion be used for the negative. Will not dry collodion do as well? Surely a negative may be as good by one process as it is by another?"—It matters not by what process a negative is made, so long as it is of the kind suited to the work. Wet collodion yields negatives of the character best suited to most of the photo-mechanical processes. It is for that reason that it is almost universally employed.

A. MOUNTER.—If eight girls are employed in the establishment you are engaged in, we should certainly say that it comes within the Factory Act, and that the employer is not justified in keeping the hands employed for so many hours a day, particularly with only three-quarters of an hour for the three meals. You are certainly entitled to the Saturday half-holiday according to the Act. Communicate with the factory inspector of the district, or write direct to the Home Office, Factories Department, Whitehall. According to your account, you are all being "sweated."

C. FERMER.—We are not familiar with the "liquid gum" named, and do not know its composition. Many of the cements sold ready for use, though excellent adhesives, are quite unsuited for photographic mounting purposes, by reason of the injurious action they would have on the print. Some of these liquid cements, we are told, contain bichloride of mercury as an antiseptic. We need not say the effect such a one would have on a silver picture. As a mountant, nothing is better than starch, or gelatine, and either is easy of preparation as required.

E. W.—When a youth is apprenticed, the indentures, whether a premium is paid or not, should be properly drawn out and duly stamped, otherwise they are not binding on either party. It should also be clearly stipulated as to what the youth is to be taught; otherwise the apprentice, at the end of his term, may find that he has wasted his time to no purpose, unless he obtains redress by legal proceedings. In the indentures have it stipulated the time he is to serve in each department, so that the whole of his time is not expended in mere drudgery. See letter and comment in our penultimate issue.

D. MCMAHON.—1. If the collodion you have made peels off the glass while the plate is in the silver bath, it shows that it is not suitable for negatives. In a first essay of the wet-collodion process, a beginner had better purchase his collodion of one or other of the well-known makers, he will then be sure of obtaining what is necessary. 2. The "metallic markings" on the glass are due to its not being perfectly clean. 3. In working the collodion process, the plate is not placed in a dish for development. Why not get a lesson or two from an old hand, as you wish to work the process for commercial purposes? you would save much time by so doing.

J. R. WILLIS writes as follows: "I often see it mentioned, in connexion with the stability of some of the old silver prints, that they were made on slightly albumenised but heavily salted paper—fifteen or more grains to the ounce—and sensitised on a hundred, or stronger, grain bath. Can you tell me who supplies such a paper, ready sensitised, as I should like to give it a trial, for all my prints show signs of deterioration after a year or two?"—Such paper, either sensitised or unsensitised, is not a commercial article now. If our correspondent requires such a paper, he will have to prepare it himself.

PHOTOGRAPHIC CLUB.—April 19, *Cold Bath Platinotype Experiences.* 15, Saturday Outing, Hadley Wood; meet at Hadley Wood Station at three o'clock.

MESSRS. MARION & CO. write: "It may be interesting to you to know that the successful group taken at Windsor by Mr. Cartland was with Slingsby's flashlight apparatus."

BRIXTON AND CLAPHAM CAMERA CLUB.—At the next meeting on April 18, Mr. T. C. Hepworth, F.C.S., will lecture on *Photography applied to Journalism,* with lantern illustrations.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.—April 20, Adjourned Discussion, *Determination of the Speed of Plates.* 27, *The Influence of the Hand Camera,* W. D. Welford. May 4, *Developers,* Technical Lecture of the Series, E. J. Wall.

THE London Sensitised Paper Company writes: "To meet the demand for our albumenised and matt-surface sensitised paper, 'Sans égal' brand, also to provide accommodation for machinery and plant for two new brands we are going to introduce at an early date, we have found it necessary to acquire new and spacious premises—Caversham Works—which we are fitting up for the production of silver printing papers. Our new office address is 2A, Caversham-road, N.W."

THE Bradford Amateur Photographic Society hold their annual Exhibition at the British Art Gallery, on May 1, 1893. The form of entry to be returned on or before April 28, to the Secretary, 15, Beech-grove, Pollard-lane, together with a postal order for entrance fees, payable to Mr. F. B. Pickles. The entrance fee is 2*s.* 6*d.* for each class.

RECEIVED.—An Amateur; T. H. Faulks; Morgan Backus, many thanks. We shall probably utilise.

MR. W. M. WARNEUKE, of Glasgow, occupies a considerable space at the Chicago Exhibition with several large direct portraits, some of them about 40 × 30 inches, in sepia platinotype.

MR. S. HERBERT FRY writes: "I shall be much obliged if you will permit me a little of your space to add the following remarks to your report of the meeting of the London and Provincial Photographic Association for March 30. The Chairman of the meeting, Mr. J. S. Teape, showed some comparative results upon a 'Sandell' plate and one of another maker. If the result appeared somewhat to the disadvantage of the multiple-coated plate, it was only because it was not given the treatment which would develop its qualities. A multiple-coated plate can be spoiled in use. In this case it was. Given an exposure which is longer than what I may describe as a normal exposure, development must always be tentative. By this I mean development must be commenced with a solution which is both weak and restrained. If this be done, and the developer strengthened only sufficiently to produce an image of the same character as the image upon an ordinary dry plate, then the inherent advantages of the multiple-coated film will be utilised to their utmost. Backing, judiciously done, does in a large measure prevent halation, but the advantages of multiple-coated films are not confined to this one point. They are also practically over-exposure-proof, a quality which is by no means bestowed by backing."

*** *Owing to great pressure on our columns this week, we are compelled to hold over several interesting articles and other communications that we have in type.*

No. 1720. Vol. XL.—APRIL 21, 1893.

THE CAMERA CLUB CONFERENCE—VAN DER WEYDE'S PHOTO-CORRECTOR.

It is difficult at first sight to account for the lamentable falling off that this year characterises the gathering of the members of the Camera Club at the annual conference which was held on the Wednesday and Thursday of last week. The attendance altogether was meagre in the extreme, and, but for the presence of the press and a few others belonging to the outside world—at the second day's proceedings six of the press in an attendance of eighteen—it would have been simply appalling.

We have said that at first sight it is difficult to account for this, but imagine that a factor towards the solution of the problem is to be found in the attitude lately taken by the Club in its relation to the public by interdicting the outside press from publishing any of the papers which from time to time are read, or the communications made at the meetings.

It is only in accord with human nature that those who have anything valuable to say would prefer to have their *dicta* presented to the whole world rather than be confined to the limited number of the Club members who may happen to be present on the occasion of such communication being made, and thus be inclined to select some other wider channels for the dissemination of their ideas. In adopting this new exclusive course, the executive are acting quite within their rights, but they might consider whether it would not be a kind and graceful act to open their doors, so far as publication is concerned, to their professional and less favoured brethren throughout the world.

It seems we were not wholly right in our surmise last week when indicating, as we did very briefly, the direction which Mr. William Taylor (not Thomas, as we had it) would take in his paper on the *Establishing of Standards* in photography, for this paper was of wider scope than we had anticipated, and not merely embraced the screws and fittings of photographic lenses, but every point on which there was likely to be a divergency of opinion, such as the metre or the yard; the centimetre or the inch; the gramme or the grain; the sizes of plates and films, &c. His paper, however, was not so much practical as philosophical.

The knowledge that Mr. Henry Van der Weyde was to disclose the secret of his so-called photo-corrector on Thursday evening brought a larger attendance than had hitherto been the case. Pending the time when in another week an exhaustive paper is to be read on the subject before the Society of Arts, and which we will publish in due course, we may here give the following brief explanation of what an artist might call the photo-corrector, but which would be designated by a scientist as a photo-distorter, each of them being right from his own particular point of view. Let us suppose that the hands, or the feet, the nose, or, in short, any part of a sitter were, from the nearness of the camera, represented in the photograph on a scale somewhat larger than was quite satisfactory to the fair sitter, the question arises how are these individual portions to be reproduced photographically on a less accentuated scale, and so as to be in harmony with the desires of the sitters, if not of their actual measurements?

In addition to the ordinary or primary lens in front of the camera, and by which the image is formed, there must be interposed in the path of the rays coming from the lens to the ground glass one or more other lenses having a peculiar form, and mounted so as to be adjustable directly in front of the offending hand, nose, or foot, or, for that matter, of the whole head, for Mr. Van der Weyde is of opinion that many heads are, speaking artistically, formed on a scale too large for the body, and should therefore be curtailed in dimensions in order to fulfil or satisfy the conditions of art. By the interposition of the lens referred to, the focus of such rays is virtually shortened, and the size of so much of the picture as is produced thereby is reduced.

The form of the lens required to effect this is peculiar; it is not plano-convex, but as if a plano-convex lens were cemented to a disc of flat glass, and made to rise almost imperceptibly from the surrounding plane instead of suddenly—very much, in short, as a gently undulating hill would rise from a level prairie or plain. This would undoubtedly reduce the dimensions of the portion acted on, but it must do so at the cost of magnifying all the surrounding parts. This will be apparent if, instead of a lady's hand or her nose, or any other part of her figure, the central spots on a chess-board be selected for this class of remodelling or reducing in dimensions, leaving the margins unaltered. Just try to imagine how this could be done.

The law of compensation demands that the space vacated by the diminution of one part must be added to its immediate surroundings; that the reduction, say, of the mouth, must be attended by the enlarging of the muscles or space in its vicinity. Mr. Van der Weyde admits that photography cannot lie, *optically;* but he says optical truth is not visual truth. As far as photography is concerned, optical truth is the result of a mere mechanical impression on a plate, which, while sometimes wonderful and beautiful, is sometimes so brutal in its fidelity, and microscopically vulgar, as to give a disagreeable surprise. Visual truth, on the other hand, depends for its appreciation on the artistic sense and power of observation on the individual, which he claims to be hereditary. Whereas in

the former the camera focusses every spot at the same moment without favour or prejudice, in the latter they have to please the family relatives and friends of the subjects who are most familiar with their appearance, and in this case the visual truth is the outcome of loving and friendly contemplation.

Mr. Van der Weyde is undoubtedly a clever artist, and produces admirable work; but we shall prefer waiting before writing more until he further promulgates his ideas before the larger world of the Society of Arts, for which, we observe, he is down for the 26th inst.

Before quite leaving the subject at present, we may notice that artists are and have long been in the habit of improving upon nature, especially as regards the human figure. We have heard Sir George Harvey, President of the Royal Scottish Academy, speak in approving terms of the action of the late Kenneth Maclea, who invariably when painting a photograph or using a photograph to mak an oil painting from it, drew the eyes larger than nature had represented them. Possibly it was this craze, so prevalent in former times, that accounts for the large goggle, saucer-like eyes to be found in so many of the ivory miniatures of by-past times. Whatever artists may say, and however much they may decry optical truth, there is no doubt that photography has conduced to a more accurate and healthy tone in their drawings.

LENS SCREENS.

It has been objected by thoroughly practical men that our recent suggestions as to the need of lens screens, especially in studio work, err on the side of unnecessary precaution, the ground our objectors take being that in their own personal experiences, covering long periods of time, they have produced thousands of negatives without taking any such care as we have stated to be needed, and yet have had no negatives spoiled by "lens fog." Quite apart from the legitimate argument that a number of negative results do not necessarily invalidate an apparently sound logical predicate, it is enough to say that the particular conditions of every individual studio have to be taken into account before forming a judgment upon the subject at issue. Now, it is very easy to show that the position and construction of the studio itself may be such that a natural screen, if bricks and mortar may be so called, may exist. Thus, take in the first case a studio built upon a roof-ridge roof, lean-to, or other style, a lens screen is a *sine-quâ-non* to the production of uniformly good results, for under many conditions of lighting the light must enter the lens from the sky or clouds, and frequently under such conditions will mar the otherwise attainable perfection of result. Let, however, as is often the case, a studio—one worked from one end only—be built against a lofty building, say, on the ground level in the gardens of a square, the sitter being so placed that his back will be against the outer building, there will be practically no need for the precaution of a lens shield, seeing that the building itself intervenes between lens and sky and so shuts out objectionable outer rays.

We have thought it well to allude again to this subject and the objections brought against it, seeing that it affords an opportunity of emphasising our advice and further pointing out conditions that may render them unnecessary. That under the majority of circumstances a screen is highly desirable our arguments conclusively show, and we cannot too strongly or emphatically recommend every photographer not using one to look around and see whether he cannot better his results by adopting some plan of screening. If we thought our argument needed fortifying, it would be enough to point out that it is no new theory, for such screens are by no means uncommon among professional portraitists, though we laid stress upon the recommendation, knowing that they might with advantage become far less uncommon. Their forms are very numerous, every user of them having his particular views as to the most suitable construction. One of the most elaborate we have seen is the patent Lafayette camera stand, fitted with curtains and blinds. So complete are the arrangements in this that the camera itself is screened from the light, while provision is made for the lens itself to be hidden from external useless rays of light by the curtains of the stand, further aided by a spring-roller blind in front, which may be drawn down to any extent required to shut off sky light; and this blind is still more increased in protecting power by two hanging side pieces for cutting off side light that might offend.

The simplest form that has been brought before our notice is a provision for hanging black velvet over two projecting arms, swinging in sockets attached to the camera itself. Another good plan is a light wooden skeleton framework lined with velvet, and attached to a wooden support, which slides under the camera in grooves cut on the under side of the stand. This can be pushed in or out according to the conditions of light and the particular lens used. To describe all the expedients we have seen would need far more pages than are to be found in a whole number of this Journal. We have said enough to show the need, and to impress on those who have not before felt it the desirability of adopting some one or other plan to meet it.

The same remarks apply to cameras for outdoor use. It may here be said that, seeing the great want of some plan of this kind for outdoor use, it is very unfortunate that we now never see lenses provided with the attached shutter, such as were fitted to the original Ross doublet lenses. These, it may be remembered, had an outside flap for use as a screen, and an exposing arrangement inside the lens. This use of the flap was little understood, and we have frequently seen the inner exposing arrangement always set open, and the shutter or flap used for making the exposure. It answered for that end, of course, and occasionally, at the same time, subserved its original purpose. But with the advent of dry plates and instantaneous shutters the sky shade seems to have dropped out of existence, the more the pity. Then, again, before the elaborate cameras of modern days, it was no unusual mode of construction to have them with a sunk front, which served both to protect the lens when the whole apparatus was folded and put away, and for use as a sky shade when landscape work was going on. It needs no instruction for any one to devise an arrangement, economical or elaborate, to provide a screen. There are abroad contrivances as numerous as those used by portrait photographers. All we say is, let every one give careful thought to our arguments and carry into his daily practice the adoption of some scheme or other in which these recommendations will be embodied.

The Photographic Society and Affiliated Societies.—The recent revision of the rules of the Photographic Society of Great Britain has resulted in the adoption of a rule which should greatly facilitate the ingress of members into the Society. In future, members of affiliated societies, who have belonged thereto for a period of two years, may be proposed for membership of the Parent Society on the nomination of their own Secretary, and will be admitted without entrance-fee.

Water-colour Exhibition.—The Exhibition of the Royal Water Colour Society, which opened on Monday last, is one that photographers, particularly those devoted to landscapes, will do well to visit. A large proportion of the pictures are just that class of subject that the majority of amateur photographers delight to render. A visit cannot fail to be profitable, as the photographer will see much to imitate, and, in a few instances, what to avoid.

More Photographs for Chicago.—English photography in its various phases will, apparently, be well represented next month at the World's Fair. At the last meeting of the Astronomical Society it was mentioned that Dr. Ainslie Common had, at the request of the Council, produced a fine series of astronomical photographs for the Exhibition. The series includes a number of diagrammatic enlargements of different solar eclipses with corona that will prove highly interesting to Transatlantic scientists. Every one is familiar with Dr. Common's astro-photographic work, so there is no question that this branch of English photography will be represented at its best.

The Photographers' Benevolent Association.—It is to be hoped that this institution will receive a good benefit from the Sandell Exhibition. It did from Mr. Fred Hollyer's recent Exhibition of platinotype reproductions of Mr. Burne Jones's and others' works. The Photographic Society of Great Britain annually gives the Association a benefit night, and the Photographic Club did so once, and it is somewhat surprising that other Societies have not followed the example; for, by this means, the funds of the Association might be considerably increased. By the way, could not the Benevolent Association get up one or two entertainments during the winter season, as it once did, on its own account? There is considerable talent, both vocal and instrumental, in the photographic world, most of which would be forthcoming gratuitously for so deserving an object. We commend the idea to the Committee, although it would be too late to carry it out this season.

Success of Societies.—Notwithstanding the number of Photographic Societies that have sprung into existence during the past few years, the majority of them are in a flourishing condition. The annual report of the South London Photographic Society shows that it has 105 paid-up members. This is many more—probably double—the number that the original South London Photographic Society possessed in its palmiest days. Yet the old Society preserved an active life for more than a quarter of a century, and its meetings were well attended by experienced workers. The roll of members cannot be taken as a criterion of the activity of any Society—it is by the attendance at the meetings, and the business transacted, that an opinion must be formed. For example, the original North London Photographic Association, if we mistake not, had something like 120 paid-up members at the time of its decease. It died of inanition—the members took but little interest in the meetings. The new South London Society is to be congratulated on its membership and the attendance at its meetings.

The Eclipse of the Sun.—The total solar eclipse was observed at Para Cura, on Monday, under favourable conditions by the British astronomical expedition under the charge of Mr. Albert Taylor, assisted by Mr. William Shackleton. The clouds were heavy shortly before contact, but afterwards dispersed, leaving a clear space for observation during totality. The photographs taken are not yet developed, but are believed to be satisfactory. Professor Pickering, of Harvard College, states that the atmospheric conditions prevailing at Minacaris during the solar eclipse were perfect, and that the results of his observations were very satisfactory. Professor Pickering says that he observed four streamers proceeding from the corona, two of which stretched over a distance of more than 435,000 miles. Several dark rifts were also visible, extending directly westward from the moon's limb to the utmost limit of the corona. Several solar prominences attained great distinctness and brilliancy. During the eclipse the surface of the moon appeared almost of an inky blackness by contrast with the dazzling brightness of the inner corona. The observations, Professor Pickering remarks, showed very conclusively that the present condition of the sun is one of great disturbance. There were very distinct evidences of a large number of spots, and of the presence of faculæ. The corona was whitish rather than red in tint. The results obtained may be said to be a combination of the observations, as drawn by Liais, of the eclipses of 1857 and 1871. The photographs taken on the present occasion, Professor Pickering concludes, were both numerous and satisfactory.

Richmond Heads—a Novelty.—Just now portraitists are on the alert for anything in the form of novelty to give a fillip to business during the coming season. We were recently shown some portraits that possessed great artistic excellence, and, although the style was by no means new, it, under its present aspects, was certainly novel, hence our allusion to it. The portraits were vignetted heads, cabinet size, by the platinotype process, but, instead of the figure being merely shaded off in the usual way, some delicate hatched lines were introduced in the vignetted portions of the figure and the background after the manner of Richmond's celebrated heads. This destroyed much of the photographic appearance of the picture, and gave ita close resemblance to a chalk or crayon drawing, particularly when it was on moderately rough paper. As we have just remarked, the style is not new. It was introduced by Mr. N. Sarony for *cartes-de-visite*, and patented by him something like thirty years ago. It did not take then, probably because the crayonlike hatching on such small pictures on highly glazed paper was quite out of keeping. But with larger sizes on a matt surface, as in the platinotypes referred to, the effect is widely different. There are many ways by which the hatching can be introduced, such as that of Sarony by a double exposure in the camera, first to the sitter and then to a hatched background, double printing, using a vignetting glass upon which the lines are etched by fluoric acid, or with the lines scratched on a plate coated with black varnish. In the present example, the hatching was introduced by a second printing from a negative made from some artistically hatched lines of larger size; indeed, from one of the lithographed backs that used to be supplied for the old photo-crayon portrait.

Graver versus Process.—It is always well to look an adversary squarely in the face. This is the attitude that was only slightly taken last week at the first annual dinner of the International Society of Wood Engravers by Mr. W. L. Thomas, R.I., who presided. While it is quite true, as he observed, that the much-threatened art of wood-engraving has never been more worthily upheld than by the engravers of the present day, and that a fine engraving of this class has an inexpressible charm about it, still we know that process work has made fearful havoc among the ranks of wood-engravers—a havoc that is constantly increasing, witness the numbers that are being compelled to retire from that profession in consequence of the rapidly advancing tide of "process." But since the times of Palmer, who was the first to strike a blow at wood-engraving, process work has undergone a revolution, which dates from the time that photography has been impressed into the service, for not till this was done was there any real danger to the profession. Over a quarter of a century has elapsed since, *àpropos* of the Graphotype process, which was then being introduced, we published an article entitled "A Blow at Wood-engraving," which led to some far-seeing engravers taking just alarm at the prospects of their profession, and providing against a possible further development of that encroachment; yet did the danger from the source named pass away with the failure of the Company that worked it and controlled the patents. It is really the Gillotype, or its congeners, for line work, and the grated screen system for half-tone that have imparted the most severe blow yet given to the wood-engraver, and these processes have come to stay, and will eventually oust skilled hand work from its strongholds, at any rate, from the important position it has so long occupied in relation to serial and book illustration. The time has now passed when wood-engravers can afford to treat photo-process work as "a foeman unworthy of

their steel." We know of numerous draughtsmen who are producing their drawings with special reference to their being engraved by process, and the encroachment cannot afford to be ignored. It may be remembered that a hostile attitude was taken against portrait photography by miniature painters some forty or fifty years ago, but photography eventually proved to be too strong.

RESTORING FOGGY PLATES.

A short time back, in turning out a box that had not been unpacked for several years, and which was supposed to contain only books and papers, I came across a packet containing some dozens of dry plates, which had been entirely forgotten during all that period. From the memoranda on the various packages I found that the plates were all over ten years old, some of them nearer twelve, having been made at various times for experimental purposes; and from other data I have to go by I know that most, if not all of them, contained a certain proportion of chloride in their composition, while many also contained iodide. I had, however, nothing to guide me, except in one or two instances where the information was pencilled on the packet, as to their precise composition, but I take it that they were all either bromo-chloride or bromo-iodo-chloride films.

An examination showed that they were all more or less—some very badly—affected by iridescent markings round the edges, a fault which has been said, with what truth I cannot decide, to be a necessary concomitant of the employment of chloride. On submitting some of them to development, the worst cases were found to be hopelessly ruined by fog, while others, though comparatively free from heavy fog, fell far short in quality of what a modern plate of even moderate character is expected to be. The greyness and veiling of the image was in all cases accompanied by a poorness and difficulty in obtaining density that rendered the plates quite useless for practical work even when giving a fairly clear image.

I tried every possible means, by ringing the changes on modifications of development, to overcome the tendency to thinness, but without any great degree of success. But I may say here, in passing, that our old friend, pyro, once more proved itself a more trustworthy servant than any of its newer rivals, for no modification, either in strength or otherwise, of hydroquinone, eikonogen, amidol, or para-amidophenol, produced the slightest improvement. With pyro, however, on increasing the strength to about six grains to the ounce, printing density was obtainable with some of the better samples; but this, unfortunately, was accompanied by an increase in the veil or fog that practically nullified the advantage gained.

It so happened that I ran out of plates of a particular size for some work I was doing at home, and, as there were some of that size amongst the defective ones, I resolved to try if they could not be restored to workable condition. From the fact of the plates having been packed away, instead of going to the "wash-tub," I conjectured that they had at one time been of good quality, and indeed, except for the iridescent edges, they appeared all right even now, being rich and dense in character; indeed, from a knowledge of the formulæ I was in the habit of employing, I knew they contained a liberal quantity of silver, if it could only be brought into available condition for use.

The first attempt at renovation was made with a plate of medium character, neither one of the worst nor one of the best, but picked out almost hap-hazard, since I concluded that, if the treatment answered for one, it would for all, in which it subsequently turned out I was correct. A solution was made as follows:—

Bichromate of potash	2 drachms.
Bromide of potassium	1 drachm.
Water	10 ounces.

In this the plate was immersed in a dish for five minutes, and then it was carefully rubbed over, especially at the edges, with a fine and very soft Turkey sponge, rinsed with water, and returned to the bichromate solution for another two or three minutes. It was then copiously washed from a jug and left to soak afterwards for an hour, face downwards, in a basin of water, the latter being changed some half-dozen times during the interval.

It was then taken out, drained, and exposed wet, a comparatively long exposure being given, and on development it turned out as good a quality of negative as could possibly be desired. The loss of sensitiveness brought about by the treatment, too, had been over-estimated, for, though not over-exposed, a shorter time would have sufficed.

The next experiment made was with a view of improving the sensitiveness, for which purpose the plate before exposure was immersed for three minutes in a weak solution of ammonia—three minims of strong liquor ammoniæ to the ounce of water; but, though this had the desired effect so far as it brought the sensitiveness back to about that of an "ordinary" gelatine plate, it reintroduced a slight tendency to fog, which without the ammonia treatment was conspicuous by its absence. As the work I required the plate for did not necessitate any great rapidity, the ammonia was relinquished for the time, though as I shall show, I later on succeeded in securing the extra rapidity without the addition of fog.

The process of restoration as thus conducted was all very well under the circumstances, where the plates were wanted, and it was the only way of getting them; but it was an eminently tedious one for ordinary use, and, of course, entirely out of the question for outdoor work. So I set to work to improve upon it by removing the fog and restoring the plates to the dry condition, so that they might be available for any purpose whatever.

The films as they stood consisted of gelatine with a mixture of silver haloids and probably some unremoved soluble matter that had assisted in bringing about the deterioration, though, no doubt, the silver chloride they contained contributed more than anything else to the result. The action of the bichromate solution is primarily to remove the fog and next to convert the chloride of silver into bromide, while the various washings the film has to undergo further bring about the removal of any soluble matter. Therefore it seemed reasonable to anticipate that, if the plates were treated as already described, washed with sufficient thoroughness to remove every trace of bichromate and dried, the result would be not only films that were usable, but that would keep owing to the elimination of the deleterious agents that had led to the previous deterioration.

I need not enter in detail into the various experiments that led up to the final method adopted, but will briefly describe the process as completed:—The plates were treated eighteen at a time in rack, holding that number, being dipped first of all into a tank containing the bichromate solution, in which they remained five minutes. The sponging of the individual films may be resorted to, but I came to regard it as an unnecessary refinement, and relinquished it. The racks were transferred one by one to a large tub of water, each receiving the contents of a large jug of water to remove the large excess of bichromate solution from the plates and rack. Living, as I do, in the country, though I have unlimited water supply, I have not the facilities for keeping up a constantly changing current, and must therefore rely upon periodical changes, which necessarily prolongs the time occupied in the process. However, by drawing off and replacing the water once every half-hour for a couple of hours, I found, with the volume employed, that the bichromate was practically eliminated: but, with a constantly changing stream, it would be, no doubt, removed in a much shorter time.

As the treatment with ammonia for restoring sensitiveness had proved a failure, or partially so, I cast about for a better plan, and succeeded at last by imitating as nearly as possible the condition that prevails in the sensitising of an emulsion by the "ammonia process." Here the silver haloids are subjected to the action of ammonia, not alone, but in the presence of excess of soluble bromide and of the by-products produced in the act of sensitising, in other words, nitrate of potash or of ammonia, both of which act as fog-restrainers. This gave me the "tip" for the next part of the process.

After a couple of hours washing the plates were transferred for half an hour to a solution composed as follows:—

Liquor ammoniæ	2 ounces.
Bromide of potassium	1 ounce.
Nitrate of ammonia	2 ounces.
Water	40 „

This, while adding to the rapidity of the films, further ensures the total removal of the bichromate, the slightest trace of which allowed to remain would be fatal to sensitiveness, and, if present in any quantity, to development, except in the best lighted portions of the

image. Although for actual working purposes it is not so absolutely necessary to remove every trace of the above solution, still it is most desirable it should be done; and, indeed, if the plates are to be kept for any length of time, it really is needful. A preliminary rinse, followed by a soaking of half an hour in three or four changes of water, will do all that is necessary.

All that remains now is the drying, which may be effected by simply resting the plates on end on a few thicknesses of blotting-paper in a dark cupboard or a large packing-case. Films of ordinary thickness will thus dry perfectly in less than twenty-four hours. But to ensure perfect regularity of drying, and also to materially hasten it, I prefer to remove the superfluous moisture from each individual film by one or other of the following means:—I prefer to use a sort of roller squeegee, formed of a wooden roller mounted in a handle in the usual way, and covered, first of all, with several thicknesses of blotting-paper, round which is finally wound, for two or three times, a short length of soft, *old* linen, neatly sewn, so as to leave as little ridge at the edge as possible. Before using this, the plates are allowed to drain for a few minutes until they become nearly surface dry; they are then taken singly, laid on a flat surface, and the squeegee passed over them with considerable force or pressure, which will squeeze a good deal of moisture out of the film, and leave the surface perfectly even.

Failing the squeegee, a thick pad of blotting-paper faced with soft linen, free from "fluff," will answer the purpose very well; it is simply laid on the plate on a flat surface and rubbed with the hand with considerable pressure. After either of these methods of treatment, the films will dry with great evenness in a few hours.

I have mentioned this method of restoring plates, firstly, because by its means or similar I have not, for the first time, been able to utilise otherwise useless films; but, secondly, because it may frequently prove of value to either amateur or professional who may have the misfortune to light upon a bad lot of plates. I have, for instance, only to-day made a good negative on one of a batch of commercial plates that have hitherto puzzled me entirely. The trouble involved is really very little, although it may seem so in description, for, with fairly convenient washing arrangements, three or four dozen plates may easily be treated in an evening and left until next day to dry. The quality, moreover, is scarcely to be surpassed by the best commercial plates now on the market.

I omitted to say in connexion with the sensitiveness that, although I have not obtained—for I have not really tried—the rapidity of the quickest commercial plates, yet the films I have restored are quick enough to be used for groups and animal pictures, using *f*-11, and taking the cap off and on as rapidly as possible. No doubt still shorter exposures would do, but I have not tried them.

W. B. Bolton.

JOTTINGS.

The weather recently has been phenomenally fine and genial in this country—except in the vicinity of Sydenham, where, according to all accounts, it has developed Siberian severity since Monday week. The wintry visitation gives every indication of lasting till April 29, when a change for the better may be expected, consequent on the closing of the National Photographic Exhibition on that date. The photographic press is unanimous in characterising the apparatus section of the Crystal Palace show as a fiasco. On the principle of evil coming out of good, the trade, the dealers, and the manufacturers are to be congratulated at standing aloof from the Exhibition, and the moral of their action, it is to be trusted, will not be lost on organizers of future exhibitions who may be blind to the fact that they do not possess the confidence of those they aspire to represent, or who shut their eyes to their own unfitness for the task they undertake. Such is the vanity of photographers, that it is not difficult in these times to get up a large and fairly good exhibition of photographs, but business men do not as a rule give way to the pleasant vice unless there is money in it, so that it is becoming increasingly difficult to get up a good apparatus show. I throw out the suggestion, that any future exhibition of photographic apparatus, on a large scale, should be managed by the trade, and for the trade. It is a matter that might well have fallen within the province of the defunct trade association, in collaboration with a small committee of photographers charged with the care of the pictorial department.

I read in an American photographic journal that the Camera Club have forbidden the English photographic press from reproducing papers read before the Club and published in its *Journal*. Strange to say, in others of the American papers issued at about the same time as the one I have referred to, I came across several Camera Club papers printed in full. The Club, I suppose, can do what it likes with its own, but I wonder whether the ukase meets with the approval of readers of papers who are thereby prevented from addressing on occasion the photographic world at large, of which the Camera Club, much as I respect that body, is, after all, only a trifling fraction? The action of the Club, which finds no parallel in any learned Society, from the Royal Society, of which the Club's President is a Fellow, down, is explicable on two grounds alone: First, that the photographic pabulum served up at Charing Cross-road is too intellectual for the vulgar photographic public, in which case I hope the legislature will at once pass a Bill making it penal for anybody not a member of the Camera Club to pretend to know anything at all about photography; or, second, that the said photographic pabulum has got too ridiculous for reproduction at the hands of charitably disposed editors anxious, as far as possible, to give everybody a hearing in their pages, so that the Club are simply protecting the readers of papers against themselves. In this case, let us be grateful for small mercies, and say, The Lord be thanked!

I see it stated "that, if a platinum print be very much over-exposed so that all the details are out, a good result comes by fixing in the acid bath without developing." Granting the accuracy of this, have we not here the germ of a simplified process for platinum printing? I draw the attention of Mr. Willis to it in the hope that he will make a note of it. I suppose the presence of moisture would be essential for obtaining the necessary quantity of reduction product, unalterable in dilute hydrochloric acid, and that it would consist of a mixture of platinum and iron. It is a great pity that when these interesting communications are conveyed to us they are not accompanied by some attempted explanation of the phenomena observed and the conditions prevailing. I have tried platinum printing according to the method described, and could get nothing but a faint image, looking more like a stain than a deposit.

I beg to ask Mr. H. W. Peal, the President of the Ealing Photographic Society, who read a paper on *Copying Engravings and Drawings* before the West London Society on March 28, and which is given in the Journal of April 7, upon what experimental evidences he bases the statement that amidol enables a photographer to do with one-third of the usual exposure? I am well aware, from practical observation, that a plate is frequently found to be faster to one developer than another—a fact which is easily conceivable by any one having the slightest acquaintance with the physics of emulsion-making—but, until it is proved to be the case, I refuse to believe that there is any known developer combination in current use which, all else being equalised, will allow of the photographer reducing his usual exposures two-thirds. Think, Mr. Peal, how nice and convenient for the portrait man it would be if he could give studio exposures of two and three seconds instead of six and nine, simply by substituting amidol for pyro! He can't; take my word for it.

Ditto to you, "Drop Shutter!" What possible object a Hand Camera Club can serve, beyond contributing a more or less appreciable addition to the pretty little game of you-scratch-my-back-and-I'll-scratch-yours, which is such a marked feature in photography nowadays, I'm afraid very few people could tell, even in a prize-guessing competition. There are too many photographic Societies as it is. Every parish, as "Drop Shutter" points out, possesses one; and to ask us to believe that adequate facilities are not afforded in the broad kingdom of hole-and-cornerdom which those Societies occupy for talking about the hand camera and all that appertains thereunto,

is to draw an uncommonly big bill on the credulity of the photographic public; for, after all, I fear the hand camera "is a thing of beauty and a toy for ever" with most of those who use it, and who have neither the capacity nor the desire of completing their photographic education. It will be found, I believe, that the few good hand-camera workers we have are in other respects capable photographers, and for them there are plenty of Societies where they can secure opportunities of listening to their own voices. According to the published reports, that is about all for which most of the photographic Societies are useful.

"Sweet Spirits, hear my Prayer." This would have been an appropriate sentiment for Mr. Traill Taylor when that gentleman was making his now famous experiments in psychic photography. I wonder if, in the midst of the subsequent alarums and excursions which his paper has provoked, he has been inclined to parody the line and mutter, "Sweet Spirits, hear me swear?" Whether they heard him or not, you couldn't blame him if he *did* use a big, big D or two, could you?

COSMOS.

RETOUCHING.

[Newcastle-on-Tyne and Northern Counties Photographic Association.]

I FEEL I must not begin to-night without offering a sort of apology for the brevity and the incomplete state of this paper. I would fain have got off altogether, but have not dared again to mention it to the Secretary, as he has already let me off once before. It was my intention to have prepared examples and slides to illustrate it, but I have really had no spare time to devote to slide-making, having been so fully occupied with business lately. On some future occasion I hope to be able to give a more complete and comprehensive paper, with lantern-slide illustrations.

Retouching is the art of improving or doctoring a negative or positive by the aid of a lead pencil, or by the use of a sable brush, and not, as a certain writer on so-called naturalistic photography would have it, when he says it is a process by which a good, bad, or indifferent photograph is converted into a bad drawing or painting. Now, I cannot agree with that in the slightest degree. I do not mean to say but that there are many instances where a good negative, without any retouching whatever, would give a finer print than if it were given into the hands of the most competent and experienced retoucher. Retouching, like many other things, is an operation which is very much abused, and has been overdone to an alarming extent. It has been said many times that some operators depend entirely on the skill of the retoucher, caring very little whether his subject is well or badly lighted, thinking all will be put right by the retouching. Now, this is perfect nonsense, for, unless a good and well-lighted negative is put into the retoucher's hands, all the skill and artistic knowledge he possesses will not enable him to make it into a perfect negative. Certainly a badly lighted and defective negative may be considerably improved by judicious retouching and careful printing. Some recommend thin and weak negatives as being the best; others, again, strong and denser ones; but from experience I find that the best results are got from negatives that are all round good, both in lighting and everything else. It is, no doubt, true that retouching—that is, a certain kind of the work—has done much harm to photography, and, unless the operator and retoucher work in harmony together, each striving to get the best possible results, the standard of retouching is considerably lowered.

Retouching is a branch of photography which an amateur does not often attempt. In working upon the negative with the pencil, one of the greatest difficulties to amateurs and beginners is to be able to obtain texture, a process by which much time is generally wasted, and the result very often disappointing. He tries to get a good result, but without knowing how to go about it. I think amateurs are often much puzzled by a too elaborate description of how to do this and how to do that; whereas, if the thing was put in a more practical form, many would be better able to accomplish more in the way of such operations as retouching and improving the printing qualities of their negatives generally, than they would with such impractical instructions.

It must not be supposed that retouching can be learnt easily by taking a course of lessons, no more than drawing or painting can, but can only be attained by careful practice and experience, and the examination of good examples by first-class men. I just intend giving a few verbal instructions to amateurs present, which are in no way tended for any professionals who may be here to-night. The simplest method of all is the working on the back of the negative and often a very great improvement can be made by doing so, especially in the case of much heavy shadow and want of detail. There are various methods of preparing the back of the negative. A fine quality of tissue paper or, better still, an oiled paper called *papier minérale*, pasted carefully on the back, and, when quite dry, worked over lightly with the pencil on the parts that are too transparent, at the same time cutting out those parts that may be already too dense. I have seen a harsh printing negative yield a very good print after such treatment. This answers as well for a landscape as a portrait, and is what I frequently do in practice. If a negative is too weak and wanting in contrast, the high lights can very easily be strengthened by stronger lines with a soft pencil, or crayon can be used.

I believe, some years ago in America, the use of both black and red crayons was recommended for certain kinds of work, but I do not think with much success. Crayon powder is sometimes useful, but more difficult to work. I find, if there is only very little work required on the back of a negative, it is quite sufficient to give a light wash of madder brown in water colour, with a little gum added, on the glass itself. It may seem a difficult operation to spread an even wash of colour on glass; but it is not so, requiring very little practice, only the glass must be perfectly clean and the colour free from grit or dust. In a landscape clouds can sometimes be worked over a thin sky so as to be passable, but I would rather recommend blocking out the sky entirely and printing from a cloud negative. Working with a pencil on the film side is not such an easy matter for the beginner. For this a retouching desk is necessary, which is a piece of apparatus needing little or no explanation. It must have a piece of very finely ground glass, or the coarseness of the grain will be visible through the negative, and will confuse the retoucher. I also would explain that, if the negative be raised up from the ground glass to the extent of about an inch, leaving a little space between the negative and the glass, the grain is destroyed when the eyes are focussed on the part to be worked upon.

I may here give a word of caution with reference to the eyes. On no account practise retouching if your eyes are not strong or suited for it, as the injury done to weak eyesight by persistent retouching, with a strong light on them, is considerable. A good plan, if the eyes are weak, is to cover the reflecting mirror with white paper, which gives a very soft and pleasant light to work by, unless, of course, the day is dull. Some use a magnifying-glass for small heads, but that I don't recommend, as the point of the pencil is also magnified, and very awkward to use in consequence; the natural eyesight is preferable, if the eyes are strong enough to bear the strain. With regard to the surface for retouching upon, it is necessary to roughen or abrade the bright surface, so that the pencil will bite. There is great difference of opinion with regard to the proper kind of surface; some prefer using a matt varnish, others prefer rubbing the part with turpentine or powdered cuttlefish bone. There are many other methods of preparing the surface so as to give a tooth to the pencil. I have tried almost all, but cannot find anything better or simpler than powdered resin, applied to the part with the tip of the finger and dusted off with a flat camel's-hair brush. In the days of the collodion negative, a little very fine coal ash, rubbed on very carefully, gave an excellent surface for working on, but great care was required to avoid damaging the delicate film; with gelatine plates it is quite different, as it is surprising what an amount of rough handling they will stand without damage.

The pencils are an important item in the retoucher's outfit. The best for the purpose are either Faber's or Hardtmuth's; HB, HH, and F are the most suitable, although I have known four and six H's to be recommended, which is very absurd. The pencil must be sharpened to a fine point, and, as it wears away quickly, it must be kept in condition by rubbing it gently on very fine emery cloth. The best way to use the emery cloth is to glue a narrow strip on a piece of flat wood.

In beginning work at the desk, sit in an upright position; do not bend or stoop over the work, do not look too closely at the negative, unless you are short-sighted; a far better effect is got by working at a little distance; you will find it more comfortable, and not so tiring.

Before commencing to retouch a head, it is advisable to take a rough print from it, although it is rarely done by the profession. Now comes the most difficult part, the actual retouching. If the negative has been properly lighted, a correct exposure, and carefully developed, the work will be quite easy, unless the subject is much marked with freckles, in which case it requires a certain amount of skill and patience to remove them. It will be best seen from an examination of the rough print what is required. Many spots and blemishes will be seen which really are in the subject's face, but considerably exaggerated in the photograph; to get rid of these and

soften strong shadows, without in any way losing the likeness, is the work of the retoucher. Different faces require different treatment; old faces may be worked over without in any way altering the character, but still may be improved. Some faces are patchy, which would be unwise to leave so; the patchiness must be removed, which will not affect the likeness, but will give a more pleasing expression. Children's faces require very little work, unless much marked with freckles. In the faces of young ladies and gentlemen there should be no very strong lines or wrinkles. About the most difficult faces to do, to give satisfaction, are those of middle-aged ladies. The majority of lady customers say nothing about wanting to be flattered, but it seems to be an understood thing that the photographer is to do his best in that way. Of course, there are exceptions. One lady gave me special instructions to touch out all lines and wrinkles, and to make her look as youthful as possible. Only once, I think, have I been asked to do it, and only once have I been requested by a gentleman not to touch up his photograph at all—he wished to come out just as he was, as Oliver Cromwell said, warts and all. But I did touch him up, and he was perfectly satisfied.

When commencing a head, the better plan is to give it a general clean up, get rid of all the defects first, and soften shadows and lines that are too strongly marked. Do not fill in all shadows alike, or a flatness will be the result.

Rules cannot be laid down as to the movement of the pencil. Almost all workers have a different style of their own, some working with certain comma-like strokes; others, again, in small circles, in straight lines, in cross hatchings, and a variety of other ways. I prefer partly cross hatching and a sort of zigzag rubbing motion as being as good as any other. Delicacy and freedom of touch can only be acquired through practice and experience; strokes of the pencil should run in the direction of the muscles as much as possible. I remember many years ago, when retouching first came into general use, some of the heads done in the "Berlin" style, as it was then called, looked more like a person who had had a very bad attack of small-pox, so coarse was the grain on the face.

There are many who condemn retouching altogether, and no wonder when we see such attempts as we often do in every-day work. Some faces are covered with white spots, others are like sand-paper; children, old men and women are all made alike. Others, again, are in favour of it, and, I think, rightly so, many photographers using it only as a necessary continuation of good and careful work. I think a good retoucher is as useful a member of the photographic profession as any other, and I think, if amateurs would devote a little time to retouching, their negatives would be sometimes much improved by it.

William Parry.

SOME NOTES ON NATURALISTIC PHOTOGRAPHY.

[Photographic Society of Ireland.]

My excuse for giving a paper to-night on a subject so much debated already, and one having given rise to so many violent and wordy contests, is the fact that Dr. Emerson has come forward once again from his retirement as the champion of his old ideas on art and their adaptability to photography. In fact, in his recent paper read before the Photographic Society of Great Britain, he takes up, with very slight modifications, the doctrines he taught in "Naturalistic Photography." There can be no doubt that the first feeling his reappearance gave rise to was one of genuine pleasure at his return to the photographic fold. I must confess that I strongly feel what an advantage it is to have on the side of photography one so enthusiastic on the theories of art, and possessing a large amount of artistic taste combined with a practical knowledge of photography. There can be no doubt that "Naturalistic Photography" has done an immense deal of good to photography; there are certain principles laid down in it, there are ideas suggested that have revolutionised our art, and, in fact, have created a new school; and it is a strange fact that in several instances the pupils have produced very superior practical results to their master in carrying into effect his principles.

Having thus freely expressed how much I appreciate the teaching, theoretical and practical, of Dr. Emerson, I will now, with equal liberty, say how thoroughly I am at variance with many of his theories, assertions, and criticisms, which are marked with an extraordinary narrowness of view and an absolute want of appreciation of the position taken up, or of the arguments advanced by, any one holding views opposed to his own. Nothing is more conspicuous in his writings than his absolute want of judgment. He poses above all as a critic, and yet he cannot even correctly judge his own productions.

In his book, *Naturalistic Photography*, his first and truest merit is, that he saw clearly and boldly advocated the high position that photography had a right to claim amongst the methods of pictorial representation. Could this be better expressed than when he says: "Photography may be, and is, in the hands of an artist, a method of expression producing works of fine art, because no such works can be produced in photography by a man who is not an artist." And, again, "Photography stands at the top of the second or tone class of methods of expression, so nearly perfect in its technique that in some respects it may be compared with the third or colour class. The scale here, too, is limited, but less so than that of any other black and white method. Its drawing is all but absolutely correct—that is, if the lenses be properly used. It renders the values relatively correct if orthochromatic plates are used, and it renders texture *perfectly*." The first passage occurs at page 17 of the work, the second at page 277, so we may say that, from beginning to end, his book is an eloquent pleading in favour of the claim of photography to a high place in pictorial art. In this respect the only fault to find with the author is that perhaps his enthusiasm makes him go a little too far, for, much as I love and appreciate photography, I feel that it has serious limitations which can never be removed.

It was, no doubt, the consideration of these limitations, and particularly those connected with perspective and the altering of ratio in development, that brought about Dr. Emerson's renunciation, which renunciation is, however, for all practical purposes, itself renounced in his latest paper, for there we read: "I may now say the methods of practice I advised in naturalistic photography I still advise, and the artists I held up for admiration in that work I still hold up as the best examples of their various crafts; but my art philosophy is different, and I do not consider photography an art." The difficulty about perspective is settled by the admission that the opticians are right from the mathematical standpoint, and he was right from the physiological and psychological standpoints. Of Messrs. Hurter & Driffield's theories on development, on which he laid so much stress in the renunciation, there is not a word in his latest utterance. Dr. Emerson's art philosophy, when it deals with pure theory, is often very hard to follow; it consists too often, as Mr. A. Pringle aptly said in the discussion that followed the paper, "of a number of truisms as old as the hills and a certain amount of extremely debatable matter clothed in high-flown and enigmatical language." The principal point where his latest theories lead him to differ from his former opinions is the denying to photography the title of art, and to photographers that of artists.

To me the whole thing seems a mere question of words and definitions, for when he admits that "photographs are worth doing if well done, because they give us certain beautiful qualities art cannot give, and that the producers of such may prove themselves as keen seers of the beautiful as the master artists themselves, and they may have art knowledge too," I think it matters very little whether Dr. Emerson calls them artists or photographers. You might just as well dispute over the question whether a man should be called an artist or a painter. Again, the so-called difference between mathematical perspective and physiological perspective seems to be a distinction without a difference. There is really but one perspective, which is ruled by the mathematical laws which govern the correct rendering of different solid objects in different planes on a flat surface. The shapes and sizes of objects thus depicted may appear distorted, altered, or exaggerated from being taken from a point of view from which we do not usually see them, or even could not actually see them, and from which an artist would never take them, because, as Dr. Emerson rightly says, a photograph, or a picture, must be "true in fundamentals to the point of illusion." Speaking practical photographic language, this means, we should use as long-focus lenses as possible, so that no object in a picture should strike us as looking different to what we see it in nature. The painter has the advantage of being able, in case he cannot change his standpoint actually, to be able to do so mentally, and thus render the objects at the same time true to mathematical perspective, and yet so little at variance to the way we see them as to produce the desired illusion. Of course, some painters have purposely altered the true perspective to produce certain effects, but these are exceptions that only prove the rule. The example Dr. Emerson refers to—a man's boot being twice as big as his head—means, I presume, his own pictures, entitled, *The Barley Harvest*, and *The Basket-maker*, and I think any ordinary photographer would tell him that, if he had used a longer-focus lens, and taken his picture from a greater distance, the difference of size would hardly have been noticed. Indeed, Dr. Emerson so well understands this, that he hails with delight Mr. Dallmeyer's new tele-photographic lens, and its length of focus is the only advantage it possesses for artistic work. Used to its full power—as in taking the pictures exhibited last season in London—it could scarcely receive his praise, for a picture

taken under the conditions described in the Exhibition catalogue would seem very different to anything he ever suggested. The following is the description:—"Mont Blanc, at a distance of fifty-six miles; smallest stop; extension of camera, sixty inches; seven minutes' exposure; windy weather." There, everything is pretty well the opposite to what Dr. Emerson recommends in the practical part of his work.

Having now placed before you the position assumed by the author before and after what he calls his renunciation, and having, I think, made it pretty clear that it is in point of fact unchanged, I will now examine what are his methods of teaching, and what is the practical outcome of this teaching.

In his last paper he would seem to reduce his influence on photographic art theory and practice to the discovery by him of the fact "that the closest truth to nature in photography was to be obtained by throwing the background of the picture out of focus to an extent that did not produce destruction of structure, the principal object of the picture being either sharp or just out of the sharp." I think if he had said that this was the *base* from which he started to edify the structure of Naturalistic Photography, he would have more correctly stated his position. It was certainly no new discovery to find out that the background of a photograph should be less sharp than the foreground, nor was it quite new to assert that even the foreground might be part out of focus and yet produce good results. The first was taught by a large number of landscape photographers, the second had been practically demonstrated by Mrs. Cameron and some other portraitists, and the producers of pinhole photographs. The merit, then, of Dr. Emerson's book is not that it gives us these facts for the first time but that, starting from the beginnings of art, it traces up the gradual development of naturalistic feeling in the works of the painters of every age, till it culminates in the modern French school of landscape painting as represented by Rousseau, Corot, Daubigny, Trojon, J. F. Millet and their followers, whom he holds up as models for all times and all men.

Perhaps the hardest thing in all this writing is to find a definition of this *naturalistic* feeling; the nearest thing to it is where the difference is described between realism and naturalism (p. 24). "The realist makes no analysis; he is satisfied with the motes, and leaves out the sunbeam. He will, in so far as he is able, paint all the veins of the leaves as they really are, and not as *they look* as a whole. For example, the realist, if painting a tree one hundred yards off, would not strive to render the tree as it looks to him from where he is sitting, but he would probably gather leaves of the tree and place them before him, and paint them as they looked within twelve inches of his eyes, he might even imitate the local colour of things themselves; whereas the naturalistic painter would care for none of these things, he would endeavour to express the impression of the tree as it appeared to him when standing a hundred yards off, the tree taken as a whole and as it looked, modified as it would be by various phenomena in accidental circumstances."

Having examined the history of art from this one standpoint—and I fear sometimes grievously misjudged it, as men will do when they try to judge things with one preconceived idea—having shown us his ideal in art, he devotes the rest of the work to demonstrating how photography can to a great extent be moulded into the form of this ideal. Now, this seems to me the strong point of Dr. Emerson's teaching, for it at once raises the status of photography from that of a mere mechanical device for copying nature to a graphic art for reproducing nature with a personal modification, as far as its limited means allow. The chapters which follow on the phenomena of sight and art principles derived therefrom are highly instructive. We must not, however, forget that when, in examining and describing the functions of the eye, we compare it to a photographic camera and lens, that we must not for a moment think the view we perceive, admire, and wish to reproduce, if we possess artistic faculty, is simply the miniature representation thrown on the retina as on a ground glass; it is the image as translated by the brain in its full size and proportion, in all its aerial harmony and natural solidity. I think this explains in a great measure the object of throwing a picture out of focus and using rough surfaces for printing, which gives an impression of size and texture as seen in the mind better than the microscopic definition of a lens or a very smooth surface.

The chapters on the practical part of photography are good and useful, but contain little that is new except the part on focussing, which expresses its author's well-known opinion and which many are too apt to associate with his name, to the exclusion of the teachings that have led up to it.

In this part of the work occurs his strong advocacy of grey day effects and a general preference for gloom and haziness over sunshine, brightness, and warmth. This may, I think, be traced to two causes, his admiration for Millet, whose genius was inclined to those effects and to the difficulty that photography has in reproducing correctly strong effects of light and shade. Neither seem to me sufficient reasons for renouncing such beautiful and exhilarating phenomena of nature as sunshine and brightness of atmosphere. What can be more false "quality?" This finishes my notes, and I trust that I have fairly described and judged the system advocated by Dr. Emerson and its results. As I said in the beginning he has done much to advance photography from an art point of view but has done much to spoil the effect of his teaching by the narrowness of his views and by allowing his natural artistic faculty to be interfered with by prejudice. He has sometimes also given pictures of his own to the public which were quite at variance with the theories he has taught and unworthy of his undoubted talent.

G. MANSFIELD.

INFLUENCE OF DEVELOPMENT ON GRADATION.

MR. CHANNON has done us the honour to make five experiments on the lines we have laid down, with the result of satisfying himself that the hundreds of experiments we have made go for nothing, and that our conclusions are erroneous. We cannot submit to be thus summarily disposed of, and as Mr. Channon's opinions may carry some weight, and so retard the progress of what we consider to be the truth, his recent article calls for some reply.

Mr. Channon's conclusions, summed up by himself in one sentence, are, "Development is likely to remain a mere rule-of-thumb matter." Nevertheless, he invites photographers to devote some part of their time to an attempt to add something to the small knowledge we possess of the action of developers. Assuming that we have done nothing whatever to throw even a gleam of light upon the action of developers, we think Mr. Channon might at least have credited us with showing photographers how to go about such an investigation, and with having worked out a system of experimental quantitative photography, of which he has not hesitated to avail himself, and of which he has so far approved as to draw sweeping deductions by its means.

It is not encouraging to us to be informed that things are, after all, only where they were before we devoted our attention to the subject; and we warn those who accept Mr. Channon's invitation to make investigations on development that, whatever may be the results they arrive at, they are sure to interfere with somebody's so-called experience, and to call down upon themselves the fulminations and the ridicule of such who cannot or will not adapt themselves to newer and brighter light. That the old views on the subject of development were not very deeply rooted, because not based upon sound experience, and were consequently easily shaken, is, we think, proved by the flutter and misgivings caused by our original paper.

While Mr. Channon's opinion that "rule-of-thumb" development still holds sway may find acceptance on the part of that extraordinary body of photographers who revel in trying to correct "known errors of exposure," we venture to think that the majority of photographers would prefer to avoid "known errors of exposure," and to regard development as, on the whole, no very complicated matter; indeed, as the comparatively simple matter which our experiments have shown it to be, and, as we shall presently proceed to show, it is demonstrated to be by Mr. Channon's recent and independent experiments.

If, after five experiments, we had, like Mr. Channon, despaired of ever finding in photography that which is characteristic of every other phenomenon in nature, namely, laws of causation, he would, in all probability, have been spared the doubtful honour of having his name associated with the sentence which his despair has called forth. We were not satisfied, however, with five experiments; and, looking *broadly* at the whole of the hundreds of experiments made before and since the publication of our paper by ourselves and others, we say still that *gradation of a negative is essentially a function of the exposure, and cannot be altered at will by modifications in development.*

Mr. Channon has investigated six differently constituted developers in their behaviour to five specified exposures upon one particular make of plate—the Ilford Ordinary. In making his experiments he has closely followed our methods, the exposures given being expressed in our unit of exposure, C.M.S., and the numerical results expressed as "densities" in our sense of the word. Mr. Channon has, with respect to five (he says four, but it really applies to five) of these developers, found that there was not so much variety in the density ratios (gradation) as he had *expected*, and he willingly admits that between the exposures 10 and 100 C.M.S. the density ratios in his experiments vary not more than in similar experiments of our own. He further gives one experiment

(D_5 and D_6) in which our conclusion, that gradation is not affected by time of development, is as accurately confirmed as we ourselves could possibly expect, and within limits very unnecessarily wide, but for this reason all the more satisfactory to Mr. Channon.

The only difference between Mr. Channon's experience and our own is confined to this abnormal behaviour of an abnormally restrained developer. In order to show this clearly we have retabulated all his experiments with the exception of those in which this abnormally constituted developer was used. The following table gives Mr. Channon's results calculated so that the density for the exposure 100 C.M.S. is represented by 100, the other densities being percentages of the density obtained by actual experiment for the exposure 100 C.M.S. :—

Exposure C.M.S.	Mean of all the results.	Pyrogallol.						Eikonogen.	Amidol.	Hydroquinone.
		B 1.	C 1.	D 5.	D 6.	E 1.	E 5.	E 2.	E. 3	E 4.
1	21·0	30·5	29·7	25·5	25·2	18·0	13·2	15·8	17·1	14·0
10	68·1	73·6	77·2	66·2	73·1	69·9	62·4	65·4	63·6	61·7
100	100	100	100	100	100	100	100	100	100	100
1,000	110·8	110	107	112	109	111	117	107	110	114
10,000	118·5	120	117	—	—	—	—	—	—	—
100,000	96·1	—	—	104	101	109	104	84	85	86

Looking at these results broadly, and considering that they were obtained upon four different plates at different times, that there is no guarantee that the four different plates were equally thickly coated, or that the coating was absolutely uniform on any of them, and that there is no guarantee that the illuminations were exactly the same in one experiment as in another, either relatively or absolutely, the wonder is not that the results are so different, but that they are so similar. The similarity is so great that we are sure no expert could have distinguished prints from the nine negatives, supposing them to have been so developed that the densities due to the 100 C.M.S. exposure had been all alike.

We are entitled to maintain that, instead of Mr. Channon's results contradicting our statement, they fully bear it out within the widest ranges of exposure, and it is inconceivable to us how this similarity of results did not lead Mr. Channon to the same conclusions. Were it not that he has candidly admitted that, within the range of exposure we adopted for most of our experiments, his results and ours agree, we could only assume that he is simply desirous of opposing our views at all hazards.

The only fault which Mr. Channon and other critics have found with our work is that, in most of our experiments, we limited the range of exposure to from 10 to 80 C.M.S. If Mr. Channon and our other critics realised, as we have long done, how exaggerated this general impression is as to the range of light intensities which occurs in ordinary photographic work, and that the contrasts to be photographed are usually no greater, and seldom exceed the ratio 1 : 20, either in portraits or landscapes, and if our critics were alive to the fact that a range extending from one to eight is the only really useful range of most brands of plates, they would perhaps have seen that we were wise, in so extensive an investigation, in keeping only practically applicable ranges in view.

It will be perceived from the table that, on an Ilford ordinary plate the whole useful range lies somewhere between 1 and 100 C.M.S. ; for the whole alteration brought about by extending the range from 100 to 10,000 C.M.S. lies only between 100 and 120, and consequently negatives obtained within this extended range of exposure, and developed with any of the developers used by Mr. Channon, would yield flat results, *i.e.*, over-exposures.

Mr. Channon considers that his developer No. 1 is excellently suited for the development of under-exposed negatives, or, as he expresses it, of "instantaneous or very short exposures, in which the light acting on the various parts of the plate ranges from about 100 C.M.S. in the brightest parts down to a fraction of a C.M.S. in the shadows. It has apparently not occurred to him that every other developer he tested on plate E (No. 2 pyrogallol excepted) would have given identically the same, or rather better, results in gradation than this developer No. 1, and that, as far as under-exposure is concerned, his whole research falls to the ground, and ends in the conclusion that no ordinary developer known to him will alter the gradations materially. A glance at our diagram, No. 16 would have informed Mr. Channon that an illumination of 100 C.M.S. already belongs, in the case of the Ilford plates, to what we have termed the period of over-exposure, and the speed of the Ilford Ordinary plate has, since our paper was published, been materially augmented.

Mr. Channon's great discovery, however, consists in the pyrogallol developer No. 2, which is compound of—

Pyrogallol	2 grains,
Sulphite of soda	8 ,,
Bromide of potassium	2 ,,
Ammonia	1 minim,
Water	1 ounce,

or, when expressed centesimally (assuming the ammonia to have been 0·880 specific gravity = 0·300 grammes per litre), 100 c.c. contain

Pyrogallol	0·457
KBr.	0·457
NH_3	0·0625 at most.

If this be compared with the developers used in experiments Nos. 10 and 11 in our original paper, it will be seen that it approaches the condition of a highly restrained developer, the bromide being seven times the weight of the ammonia ; and that it belongs to that class of which we said "development is entirely prevented within four minutes when the amount of bromide is about ten times that of the ammonia present." In experiment No. 16 we go on to show that, if time is only allowed for the development to extend to all the details, *i.e.*, if the usual rule is followed of developing until detail in the shadow is visible, in the negatives then produced, even with developers much richer in bromide than Mr. Channon's was, the density ratios are practically undisturbed. Mr. Channon's developer was so feeble that it took fully fifty minutes before the exposure 1 C.M.S. produced a distinctly measurable result ; but, when this was attained, the resulting negative differed in no material degree from the mean result obtained by the other developers.

The following table gives the results obtained by Mr. Channon with this developer, arranged according to time of development, the result of 100 C.M.S. being put 100, and the mean of all the other experiments being added for comparison :—

Exposure C.M.S.	D 4 mins.	D 10 mins.	B 15 mins.	D 20 mins.	C 30 mins.	E 30 mins.	D 50 mins.	Mean of other Expts.
1	—	—	5·7	3 9	8·5	2·6	16·6	21·0
10	—	17·1	44·3	37·6	53·1	39·2	55·6	68·1
100	100	100	100	100	100	100	100	100
1000	200	202	126	135	129	145	119	110·8
10,000	—	—	138	—	153	—	—	118·5
100,000	316	217	—	107	—	144	91	96·1

Had the development been continued, say for 100 or 120 minutes, we have no hesitation in saying there would have been no essential difference between the negative produced with this developer and those produced with any other.

Thus, Mr. Channon's results with developer No. 2 are in perfect harmony with our experiments on a similarly or even more restrained developer. We admit, however, that the alteration in the rate at which the different densities make their appearance was not investigated by us ; the fact that, when properly developed, the density ratios remained the same as with other developers was, at that time, the only fact of importance to us.

But Mr. Channon thinks that practical use may be made of the intermediate stage in development of over-exposed plates, or of what Mr. Chapman Jones terms the "lagging stage." We say that it cannot ; and we point to Mr. Channon's results as giving the reason for such an answer. He proposes to stop development after ten minutes, and then to intensify. The densities obtained with his developer would, however, be so small, and the range of gradation so contracted, even after intensification, that such a negative would serve no useful purpose. After ten minutes' development he obtained, for 100 C.M.S., a density of only 0·35 ; and for 1,000 C.M.S., a density of only 0·71. Supposing these densities had been fully intensified—they would, at most, have become 0·70 and 1·42 respectively ; thus giving a printing range of only $1·42 - 0·70 = 0·72$, which would be too small to yield even passable prints. After twenty minutes' development, the density for 1000 C.M.S. reached 2·08 ; and for 100 C.M.S. 1·54. Such a negative would not stand intensifying, and, its printing range being only 0·54, would render it wholly useless.

We intend to make an experiment to show the futility of correcting under and over-exposure by Mr. Channon's No. 1 and No. 2 developers

respectively; but, as we have not leisure to do this without delaying the publication of this article, we will reserve our report of the result for another occasion.

We are glad that Mr. Channon has afforded proof that most of our work will bear repetition by others. We are sure that he must see the value of all our units, and of our system generally; and it affords us pleasure to say that we agree entirely as to the facts he has observed, but we differ wholly from him in the sweeping conclusions he has arrived at. We yet hope to accomplish the task of rescuing development from a mere rule-of-thumb operation.

Mr. Channon had the courtesy to send us his plates for inspection, and we are glad to state that his work was done accurately, and that we agree to most of his measurements. His plates bear evidence of serious fogging, and, unless Ilford plates have materially deteriorated, they should yield better results than those obtained by Mr. Channon. The smaller exposures ought to have produced more decided results, and the apparatus used for exposure seems to have been of a very primitive description. It is clear to us also that the ratios of exposures 1 : 10 : 100, &c., were not in all plates of quite equal value.

F. HURTER,
V. C. DRIFFIELD.

CAMERA CLUB CONFERENCE.

THE Seventh Annual Conference of the Camera Club was opened at the Society of Arts, on Wednesday afternoon, April 12, with a comparatively small attendance. The President (Captain Abney), in the course of a brief introductory address, said the Conference must be of benefit to every one interested in photography. Photographers were most strongly conservative, and it was only when radical alterations were proved to be improvements that they were adopted. Those alterations could only be effected at long intervals.

"ESTABLISHING LENS STANDARDS."

Mr. William Taylor (Messrs. Taylor, Taylor, & Hobson) read a paper on this subject, in which he traced the efforts of the Photographic Society of Great Britain, and the International Congresses of Brussels and Paris to standardise units of light, sensitiveness of films, the sizes of plates, &c. After stating that the central purpose of standards should be simplicity, he examined the means necessary to secure their adoption, such as practical convenience, emulating ideals, the force of international law (as in the case of the adoption of the metrical system by France), and the force of accident. Incidentally referring to the standard sizes of plates, Mr. Taylor said he believed that the standardising of large sizes might be useful as affecting the smaller sizes. So long as the standards selected were convenient, he believed they would be ultimately adopted. The Photographic Society of Great Britain, ten years ago, went into the question of screws for the attachment of lenses to the camera, and a new series was suggested. The results were disappointing, as lens-makers, for a long time, did not offer to supply them. The standards, however, were sometimes adopted, and he believed that they were gradually established, as they contained a large measure of practical convenience, which was a strong force tending to secure their adoption.

Mr. J. Traill Taylor, after urging the adoption of standard screws for lens flanges and lenses, put in a plea for a standard screw for attaching the camera to the stand. He had a great many such screws, which when held a couple of feet from the eye looked identical. He entirely sympathised with the subject of the paper.

After some remarks from Mr. Sturmey,

Mr. L. Warnerke thought that the focal lengths of lenses should be engraved on the mounts, and in the case of doublet lenses advocated the interchangeability of screw threads, so that the back and front combinations could be used at will.

Mr. W. Taylor, in reply, pointed out that the focus of a lens engraved on its mount had no reference to any other lens in the world, but the question of standard screws was of universal interest. As regards Mr. Traill Taylor's reference to the adoption of a standard screw by the makers of microscopic object-glasses, it should be observed that only one screw was dealt with. The makers readily undertook a little trouble in the matter, but it was difficult with photographic opticians, who would be put to great expense.

The President, in moving a vote of thanks to Mr. Taylor for his paper, which, he said, was conceived in a philosophic and scientific state of mind, expressed the opinion that standards would not be adopted until photographers had a kind of trades union of their own, who would decide that nobody was to buy only what that union laid down. The matter, therefore, must be relegated to public opinion, which in due time would, no doubt, make up its mind. He pointed out that beginners in photography were ignorant of the requirements of standards, and therefore simply took what was sold them without question.

LENS SYSTEMS.

Mr. T. R. Dallmeyer read a paper on *Lens Systems*, illustrated by diagrams and formulæ, in which he dealt with the question of focometry when applied to lens systems in which the Gauss points are considerably removed from the elements of which they are composed. At the conclusion of the paper Mr. Dallmeyer projected on the screen, with the tele-photo lens, images by positive and negative combinations of equal size, as illustrating a convenient method for determining the "equivalent lens" of a system containing negative lenses of a powerful nature.

In the course of a short discussion which followed Mr. H. M. Elder said that the paper gave them some new ideas about the capacities of the tele-photo lens. He was glad that Mr. Dallmeyer had put the Gauss points so much in evidence; ordinary writers on photographic optics were ignorant of their existence. In the ordinary rectilinear compounds they were not, perhaps, of much importance; but in other combinations they became of very great importance indeed.

Mr. Dallmeyer pointed out that the images shown in both cases were the same, so that the same angle was necessarily included on the same plate, no matter what the focus was; but there was nine degrees more included with the negative in front than with the positive in front.

A vote of thanks was passed to Mr. Dallmeyer for his paper.

ON CERTAINTY IN PHOTOGRAPHY.

Mr. H. Chapman Jones read a paper on this subject, which dealt with the theory of development as propounded by Professor Armstrong, and laid down the conditions of exposure and development under which certainty of uniform results could be obtained.

Mr. H. A. Lawrance reminded the President that he (the President) had read a paper in that room on the photographing of a subject of a uniform colour which bore on the want of truth of photography, and he (Mr. Lawrance) was wondering how the two papers could be reconciled?

Mr. J. Sterry had proved that, if development were stopped in an early stage, the ratios were not the same as if the development were continued.

The President said that a year or two ago he had read a paper in which he stated that he did not think it possible to obtain a true photographic rendering of black and white, and he still held the same view. Mr. Chapman Jones, on the other hand, wound up his paper by saying that it was possible to get a truthful photograph of an object with uniform exposure, development, &c.; that was easy to talk about, but we must take what was theoretically perfect. He had been shown negatives and positives superposed in which the pictures gave even tints, but this was no proof that a theoretically perfect photograph was obtained. In the paper he had shown that there was a possibility of getting a fair approach to truth; but he had proved by calculation that a certain amount of variation was always obtained. In looking through a negative two densities might seem exactly alike, but he would bet a crown to a penny that those two densities were different when measured.

After further observations, the President moved a vote of thanks to Mr. Chapman Jones.

INFLUENCE OF PHOTOGRAPHY ON THE VISION.

Mr. Davison (the Hon. Secretary) read a paper by M. Leon Vidal, which dealt with the influences which the work of Muybridge, Marey, and others, who had photographed rapidly moving objects, had exercised over the art of painting, and also their effect in training the eye to see objects in motion as photography showed them to be.

A discussion followed, chiefly on the point as to the educational influences on the eye which instantaneous photography has had, in which Messrs. Webber, Davison, Keene, Conybeare, and Godbold took part.

SCIENTIFIC APPLICATIONS OF PHOTOGRAPHY.

On Thursday afternoon the Hon. Secretary (Mr. Davison) read a paper on this subject by Professor E. Mach, treating of the employment of photography in photographing sound waves, flying projectiles, waves and vortices of air, by means of the electric spark.

ORGANIZATION OF METEOROLOGICAL PHOTOGRAPHY.

The next paper was on this subject by Mr. A. W. Clayden, who gave for the guidance of photographic societies and individuals, rules for the photographing of cirrus and cumulus clouds, lightning, and other natural phenomena. The paper was in substance a *résumé* of previous remarks on the subject which have appeared in our pages. A discussion followed on a remark by Mr. Webber that he had obtained good cloud effects with a slow plate and a yellow screen, it being pointed out that the use of the latter simply served to prolong the exposure.

The New Art and Photography.

Mr. Hume Nisbet dealt in a critical spirit with recent developments of impressionism in brush work, concluding as follows:—

"But what I wanted chiefly to say, when I dragged in those very modern amateur impressionists with their foolish affectations, was that they can, not help you in any way, but that there are impressionists, such as Whistler, who can help you if you study carefully their suggestiveness, action, and refined naturalism.

"In order to come down to the level of the young school of the so-called impressionists, the plan would be to get the worst plate in the market, put your sitter in the most ungainly position, and unlearn all you have learned of composition, then over-expose your plate while the sitter is encouraged to move about as much as possible, bother as little as you can help about the developing of your negative, and then print as hard as you can in a blazing sunshine; that's the way to become an impressionist photographer, and doubtless you might, if you do this, get some of our new youthful critics, who know as much about painting as they do about the other secrets of humanity in general, to write a glowing article about that mysterious print, whose relations of idea and sound should affect us as beauty, and advise the other lunatics to watch until some mysterious affecting note comes out of the blank; and if all this does not come to them by watching, then this critic will loftily tell the unappreciative that the confusion and affliction from which they suffer are incurable."

Mr. Hector Maclean recommended photographers to leave Whistler and other impressionists severely alone, and to keep to the proper province of photography.

Mr. Rowland Bryant defended impressionism in photography. It gave one more trouble than ordinary photography. Impressionism was the expression of soul with as little external detail as possible. By its means they endeavoured, as it were, to get behind the eye. Years ago Whistler was laughed at, but his work was as good then as it is now, in his popularity.

The President and Rev. F. C. Lambert continued the discussion, when Mr. Nisbet painted an impressionistic picture, which he called a "Purple Thrill in three Gasps." Nobody seemed to know what it meant, and Mr. Nisbet did not enlighten the meeting.

Astigmatism for Pictorial Effect in Photography.

Mr. Bryant's paper treated of the effects produced with spectacle lenses, and the use of various slit diaphragms. He showed a number of pictures in illustration of the subject.

Mr. E. J. Humphrey said the best answer to Mr. Bryant's paper was to read the paper read before it. He believed in softness in certain parts of the picture, but of seeing it as nature enabled one to see it. Mr. Bryant's pictures made nature appear one hopeless, uninteresting, deadly blur.

Mr. W. D. Welford said that before any one could see nature as the pictures showed it he would have to be drunk.

Mr. G. Davison said that no doubt Mr. Welford was able to speak with authority on that matter. (Much laughter.) As regards diffused definition, he thought it was much a matter of individual preference.

The Rev. F. C. Lambert admired the way in which Mr. Bryant had modified his results, and they owed him a debt of gratitude, if he had only pleased himself and was original. He (Mr. Lambert) confessed a preference for out-of-focus effects where occasion—such as a brick wall used as a background—permitted of them.

Mr. Bryant hailed Mr. Lambert as a valuable disciple to the school of softness.

The President, in moving a vote of thanks to Mr. Bryant, said that the effect of some of his pictures upon him was to make him sick. It seemed to him that the same effects might be obtained by shaking the camera in the direction in which the diffusion of the focus was required. He sympathised with Mr. Bryant; but, if he (the President) could not take better photographs than his, he would not take them at all.

The Photo-corrector.

In the evening, before an improved attendance, Mr. H. Van der Weyde read a paper, with lantern illustrations, describing the use of his photo-corrector in the curing of the visual distortion of parts of a portrait by the interposition of a local lens when reproducing the negative. To this we refer elsewhere. The Conference concluded with a paper on *The Speed of Plates* by the President, and *Some Notes on the Effect of Light on Plates* by Mr. H. M. Elder. The discussion on these two highly abstruse papers was adjourned to a future meeting of the Camera Club.

THE SANDELL EXHIBITION.

In aid of the funds of the Photographers' Benevolent Association, an Exhibition of photographs from negatives on multiple-coated plates by Mr. J. T. Sandell and other gentlemen was opened at 24, Regent-street, on Monday last. In all about 140 pictures are on view, the exhibits being arranged on the walls of two rooms.

Regarding the photographs taken by Mr. Sandell himself, we expressed ourselves in general terms in our article, on March 3, on *Multiple-coated Films*, so that we have very little to add to the opinion then given. As examples of Mr. Sandell's interior work, the photographs of the Scalchi Church (Venice), the Jesuit Church (Venice), St. Paul's-without-the-Walls (Rome), St. Peter's at Rome, the Vinery at Frogmore, and other specimens, are, notwithstanding the advantages which the use of the multiple-coated films entails, admirable from a technical point of view, and, in spite of Mr. Sandell's modest protest that he is not a photographer, do him infinite credit. The marble columns in the view of St. Paul's and the Royal Vinery (the latter having an exposure of fifteen minutes in bright sunlight) give an exceptional accuracy of rendering. Some large Alpine views are also of especial merit in the delicacy of their gradation, both as regards near and distant objects.

Prominent among Mr. Sandell's other outdoor views are the Colosseum (a fine photograph), St. Mark's, Venice, St. Peter's at Rome, General View of the Roman Forum (perhaps the best as regards composition), Team of Oxen, Sermione (which, notwithstanding that it was taken in full sunlight, is characterised by great softness and perfect half-tone); and a capital exterior of Wells Cathedral.

Mr. Sandell supplements his own pictures with contributions of great excellence from several other gentlemen. Of these, a series by Mr E J. Hughes of Canterbury Cathedral are perfect of their class. Messrs. Green Bros. of Grasmere show some charming Welsh views in platinum or bromide, thereby relieving the almost universal prevalence of gelatino-chloride, C. F. Oakley (clever snap-shots), A. J. Sargeant (architectural subjects), S. H. Fry (enlargements), and A. Leblanc (a good enlargement from a snap-shot of a cat). A frame of really meritorious small views taken by Mr. Lane, who was using a camera for the first time, is also shown.

All the pictures hung are from negatives on Sandell plates, and the catalogue gives full particulars of light, lens, stop, exposure, and plate in each case. Armed with this catalogue, the young photographer may gain a fund of technical information from an inspection of the pictures on the walls which should be of the greatest service to him. The Exhibition remains open to-day and to-morrow (Friday and Saturday).

CENTRAL PHOTOGRAPHIC CLUB.

On Monday evening last a largely attended meeting of intending members and others interested in the Central Photographic Club was held at the Memorial Hall, Mr. W. D. Welford being voted to the chair.

Mr. Thomas Bedding, (the Hon. Sec. *pro tem.*) having laid a statement of the position of the club before the meeting, the recommendations of the Committee as to the premises in Fleet-lane, Ludgate-circus, for administering the affairs of the Club by means of a limited Company, and the rules as already published were unanimously adopted.

Mr. Howson was appointed Hon. Treasurer, and Messrs. W. Fenton Jones, 12, King Edward-road, Hackney, N.E., and C. H. Oakden, 53, Melbourne-grove, East Dulwich, were appointed Hon. Secretaries.

Our Editorial Table.

Photographer's Guide to Oban.

By M. Isaac & Riddle, Esplanade.

This is, without doubt, the most terse guide we have ever seen, for it contains only four pages, and is of such dimensions as to go into one's card-case. It is issued by a firm of well-known photographers, and its *raison-d'être* is to inform tourist photographers that they reserve a dark room for their exclusive use, where for a small sum they may change plates with safety and procure plates, paper, and chemicals. It also contains a list of places in the neighbourhood that form good pictures. Accompanying the *Guide* are a few "scraps" showing what one may expect to get who is enthusiastic enough not to be afraid of a rough walk; and in a note from the firm we are informed that every information relating to the neighbourhood will be imparted

by Mr. Riddle, who worked the ground for many years in the interests of one of the large photo-publishing houses in Scotland.

The "scraps" referred to are charming, one of them being the finest view of Kilchurn Castle on Loch Awe that we have ever seen. In the interests of the amateur photographic tourist we recommend him to call upon this firm, who will give him good welcome and render his holiday enjoyable. Oban is a pretty place in itself, and forms a nice centre of operation.

Hints on Enlarging.

By the London Stereoscopic and Photographic Company, Limited.

These hints are compiled with special reference to the use of the Company's patent "Black Band" enlarging apparatus. They are well written, and evince the hand of one who has an intimate and intelligent acquaintance with the subject. After bringing the preparation of the print (a bromide enlargement being understood) up to the final stage of being mounted, it is then a question as to further finishing, and we are told that crayons, either black or coloured, may be effectively employed. It is recommended to employ a special kind of black crayon sold under the name of "Bromide Pencils," with which the shadows may be deepened, high lights relieved on lace or drapery, and any obtrusive detail toned down. Beyond this the average amateur is advised not to go, unless he or she has had some experience or training in artistic work. If the effect of a brown tint on the paper is required for working upon in black and white crayons, after the manner of the many art studies published as drawing copies, the print is to be soaked in cold weak coffee until the desired tint is attained. Price sixpence.

Eikonogen Developing Cartridges.

Mr. Arthur Schwarz has sent us a sample of some new developing cartridges prepared by Dr. M. Andresen, and, from a fair trial, we very willingly attest not only the convenience but the real excellence of eikonogen as thus put up. The powder from one cartridge having been dissolved in 100 cubic centimetres of water (distilled water by preference, although rain or any soft water will do) is then ready for use, and in this solution quite a number of plates can be developed.

Over-exposure is simply met by diluting the developer up to twice its volume with water, and, if necessary, a few drops of a solution of bromide of potassium may be added. The resultant image is singularly clean and brilliant, and the tone is a fine black. The simplicity of developing powder put up in this form will commend itself to all, and more especially to a photographer on tour.

Practical Pocket-book of Photography.

By Dr. E. Vogel, Berlin. London: Swan Sonnenschein & Co.

The name of Vogel attached to any book is a sufficient guarantee as to the soundness of the tuition imparted thereby. The present little volume, which is a translation, by E. C. Conrad, F.C.S., from the second German edition, treats with a considerable degree of succinctness on apparatus, the arrangement of the dark room, various negative processes, printing processes on albumenised and plain paper, bromide papers, carbon, platinum, ferro-prussiate, and aniline. Colour sensitising of plates both wet and dry finds a place, and all the methods of preparing the developers in common use also find a place in this comprenensive "Practical Pocket-book." Dr. E. Vogel has compressed much sound information in this manual.

A small sample of sensitised albumenised paper, "The Perfect," has been submitted for trial by Messrs. Williams, Read, & Co. We find that, as stated in a circular by which it was accompanied, it prints quickly and tones readily, and, so far as our trials were permitted to extend, we had no blisters or spots.

Mr. Francesco Duran, of 21, Terrace-road, Handsworth, Birmingham, has submitted to us a number of photographs of scenic and clouded backgrounds painted in flatted oil which he is supplying. The subjects and effects are of a most diversified nature and are generally characterised by artistic taste, while the backgrounds are moderate in price.

RECENT PATENTS.

APPLICATIONS FOR PATENTS.

No. 7307.—"Turn-cards, an Apparatus for Displaying Photographs, Pictures, Advertisements, Samples, &c." F. E. Suddard.—*Dated April* 10, 1893.

No. 7341.—"Improved Means for Preserving Paintings, Prints, and Photographs against Atmospherical Deterioration." W. S. Simpson.—*Dated April* 10, 1893.

No. 7343.—"Improvements in and relating to the Colouring of Photographic Prints, Transparencies, and Negatives." Complete specification. C. Klary.—*Dated April* 10, 1893.

No. 7443.—"An Improved Method of Photographing Persons or Objects in Motion, and Improved Apparatus for Effecting the same, and Improved Apparatus for Exhibiting the same, and for Applying it to the Optical Lantern." J. D. Burton.—*Dated April* 12, 1893.

No. 7480.—"Improved Objective for Use in Photographic Cameras." Communicated by A. Steinheil and R. Steinheil. W. P. Thompson.—*Dated April* 12, 1893.

No. 7481.—"Improvements in Photographic Cameras." W. Rice.—*Dated April* 12, 1893.

No. 7656.—"Coin-freed Apparatus for the Automatic Production of Photographs." Complete specification. Communicated by A. Hahn. A. Strauss-Collin.—*Dated April* 14, 1893.

No. 7680.—"An Automatic Safety Bar and Ejector for Use in Hand Cameras." R. Crowe and H. Nicholls.—*Dated April* 15, 1893.

PATENTS COMPLETED.

Improvements in Photographic Cameras and in Stands for Same.

No. 6303. John Boultbee Brooks, 115, Great Charles-street, Birmingham, Warwickshire.—*March* 18, 1893.

I make the case or dark slide for the plate of cardboard or other suitable material, the slide consisting of two parts, the plate-holder and its cover. The plate-holder is a flat box, open at its front face to expose the surface of the plate, and is a little longer at each end than the plate is. At the back of the plate-holder at one end is a hole, and at the other end a stud, for the purposes hereinafter described. The cover is a flat box open at one end only, and is just sufficiently large to slide over the plate-holder and completely cover it, except a small part at the one end.

The cover has a slot or groove, which extends nearly from end to end of its length, to admit of the stud above mentioned as being on the plate-holder. The cover can thus be slid back and forth, covering or exposing the plate, but the stud engaging in the slot prevents the cover being drawn completely off the inner case.

To prevent the light from entering when the slide is closed, the cover has a tongue projecting from its front edge, which, when the cover is closed, enters a groove across the end of the inner case.

At the rear part of the camera is a slot which admits the dark slide to enter a groove which runs round the inside of the camera; and at the back of the camera, at the side opposite to the slot, I attach a bolt—preferably a spring bolt—which projects through to the inside.

Thus, when the slide is slid into the camera, the bolt engages with the hole before mentioned which is in the back of the plate-holder, and holds the latter fast while the slide cover is drawn out of the exposure. After the exposure, the cover is again thrust in, and on the bolt being pulled back the whole slide (now closed) can be drawn from the camera.

I put an exposure plate or shutter on the camera as follows:—The lens is sunk flush with or below the outside of the camera box, and on the outside of the camera I fix a pair of parallel grooves or slides, one on each side of the lens. For simplicity of manufacture, I may make these grooves by taking a strip of metal and turning the two longer edges over to form a groove down each side. A hole is then pierced out of the centre of the strip to allow the lens to show through. The shutter is a flat strip of metal of the proper width to slide easily in the grooves, and of such length that when it is at either end of the grooves it covers over and shuts out the light from the lens. The shutter has a hole pierced in its centre to give the requisite exposure, and a small projection or a notch at one end to engage with the catch hereinafter mentioned. At one end of the grooves I fix a screw or stud, projecting from the camera, to which I attach a spring of indiarubber; the other end of the spring I attach to the shutter. Or, instead of attaching the spring to one point on the camera, as described, I may attach it to two points at a distance from each other so as to use a longer spring. At the opposite end of the grooves I affix to the camera either a spring trigger catch or a catch bolt, so that when the shutter is drawn down by the finger it is held by the catch, and on the catch being released the shutter is drawn rapidly across the lens, the central hole making the necessary exposure.

For giving a time exposure, the spring may be detached from the shutter, and the shutter worked with the hand.

I construct a stand for supporting or carrying the camera in the following manner:—I construct a metal top plate having on its under side flat metal brackets arranged radially. Towards one end of each bracket I pierce a hole, and at the other end a quadrant-shaped slot. I cut out a slot in the end of each of the wooden supports or legs of the stand, so that it will fit on the metal bracket, to which I pivotally attach it by means of a pin passing through the leg and the hole of the bracket. A screwed pin is now passed through the leg and the quadrant-shaped slot, and by tightening this pin the leg or support is fixed at any desired position or angle.

I make these wooden supports in two or more lengths, and I fix them in any position I desire by means of spring clips hereinafter described. The clip is made from a piece of folded metal, which is made fast to one of the supports by encircling it and fixing with a screw or rivet. The remaining portion of the clip encircles the other part of the support, but slides thereon readily, and is fixed or tightened by means of a lever so arranged that it draws the two ends of the clip together when pressed downwards, and releases on the action being reversed. This lever action is much quicker and readier than a screw.

I may also make the support to the camera so that one leg only is employed, and in so doing I affix the aforesaid clip on the camera, and let the support slide into it; or I fix a peg or projection on the camera and the clip on the support, and let them slide into one another.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
April 24	Camera Club	Charing Cross-road, W.C.
,, 24	Dundee Amateur	Asso. Studio, Nethergate, Dundee.
,, 24	Lantern Society	20, Hanover-square.
,, 24	North Middlesex	Jubilee House, Hornsey-road, N.
,, 24	Putney	Boys' Gymnasium, Charlwood-road.
,, 24	Richmond	Greyhound Hotel.
,, 25	Birmingham Photo. Society	Club Room, Colonnade Hotel.
,, 25	Great Britain (Technical)	50, Great Russell-st., Bloomsbury.
,, 25	Hackney	206, Mare-street, Hackney.
,, 25	Halifax Camera Club	
,, 25	Lancaster	Springfield Barracks, Lancaster.
,, 25	Leith	165, Constitution-street, Leith.
,, 25	Newcastle-on-Tyne & N. Counties	Central Exchange Art Gallery.
,, 25	Paisley	9, Gauze-street, Paisley.
,, 25	Rochester	Mathematical School, Rochester.
,, 25	Warrington	Museum, Bold-street, Warrington.
,, 26	Bath	Roy. Lit. & Sc. Inst., Terrace-walks.
,, 26	Burnley	Bank Chambers, Hargreaves-street.
,, 26	Leytonstone	The Assembly Rooms, High-road.

,, 28	West London	Chiswick School of Art, Chiswick.
,, 29	Hull	71, Prospect-street, Hull.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

APRIL 13,—Mr. T. E. Freshwater in the chair.

There was a long discussion on private matters connected with the Association.

A work on *Elementary Photography* by J. A. Hodges was presented to the Association.

Notice was also given of the Sandell Exhibition, proceeds of which were to be devoted to the Photographers' Benevolent Association.

EXPERIMENTS WITH P.O.P.

Mr. George Lorimer brought forward experiments which he had made. He took a piece of P.O.P., exposed it under a negative, bleached it with mercury, and fixed it; all the image disappeared. He took another piece, exposed, toned it with gold, and fixed it, then treated it with mercuric chloride; found the image vanish a little. Another piece, toned with platinum and then treated with mercuric chloride, was found to be scarcely affected at all. He then followed the treatment advised by Mr. Spiller in THE BRITISH JOURNAL OF PHOTOGRAPHY, but he found the print so treated lost a great deal. He found also that platinum toning degrades P.O.P. very much in the high lights, especially the pink-tinted paper.

Mr. HADDON alluded to Mr. Lorimer's experiments as proving conclusively that platinum was deposited in a print that had been toned with platinum, and said he believed that Mr. Lorimer had sent several prints to Mr. Howson showing such results.

THE SANDELL PLATE.

Mr. J. S. TEAPE stated that he had followed Mr. S. H. Fry's suggestion to repeat his experiment of exposing the Sandell plate to various lengths of magnesium ribbon, and, instead of using a normal developer, to try tentative development; so he reduced the strength of the developer by adding eight ounces of water to one ounce of developer. In twenty minutes a faint image appeared. He then added a drachm at a time of a stronger developer, and ultimately found, after one hour's development, that the results were no more satisfactory as regards halation than when using a normal developer. He did not wish to find any fault with the Sandell plates, and he would suggest that by using them backed they would be proof against any halation whatever. The plates he used were double-coated.

Mr. BECKETT asked whether a triple-coated plate should not have been used if such a test as Mr. Teape's was applied?

Mr. ARCHER CLARKE referred to Mr. Sandell's exposures abroad, and would like to know what was used to develope them, as they were told all the various exposures were developed in the same solution. He also referred to a make of plate that was not in the market now that for interiors was perfectly free from halation. He believed the emulsion contained a large quantity of iodide.

North Middlesex Photographic Society.—April 10.—Mr. J. Humphries, F.S.A., the former President, attended, and showed samples of a new lantern plate which had been patented. The great advantages claimed were that it was unbreakable and non-burnable, thus being able to stand the fiercest heat produced in any lantern. The support was a prepared mica. Great trouble had been taken to find a way of treating the mica to give it such a surface as would take and retain colour, but this, he claimed, had at last been accomplished. The specimens he produced were all by a mechanical process, but he expected that they would shortly be on the market coated with emulsion for ordinary photographic use. The mica was beautifully clear and translucent, of a fine white colour, and absolutely free from spots and blemishes. Mr. Cox opened a discussion on development. He restricted his remarks to the pyro developer, as he found he could get results with that agent that were not surpassed by any of its more modern rivals. He recommended sulphite of soda as the preservative, with citric acid to render it neutral, using four ounces of sulphite and eighty grains of citric acid to the ounce of pyro. He produced some of his stock solution which had been kept eighteen months, and it had only changed to a straw colour. He dealt fully with the development of over and under-exposed plates, and for the latter recommended a preliminary bath of either hypo (1 or 2 parts to 1000 of water) or a weak solution of ammonia followed by a developer weak in pyro, strong in ammonia, and strong enough in bromide to prevent fog being caused by the ammonia, and followed, should the negative be wanting in density, by a fresh solution strong in pyro and weak in ammonia and bromide. To get the fullest gradations of nature a thickly coated plate was necessary, as, although printing density could be obtained on a "starved" plate, the range of tone would be limited. He always used cathedral green glass and one thickness of canary fabric as being better to work by than a ruby light, and by exercising care in keeping the plate from the direct light rays no fog caused by light would be found to take place. A most interesting discussion ensued, in which Messrs. Beadle, Mattocks, Gregory, McIntosh, Wall, Smith, Marchant, and others took part. Mr. MCINTOSH mentioned that metabisulphite, if used as a preservative, became more acid by keeping, and required the addition of more ammonia, often leading beginners to think their plates under-exposed. The award for the best print from plates exposed at the outing at Penshurst was gained by Mr. H. Smith. Next meeting on the 24th, when the subject of *Retouching* will be treated by Mr. J. Matthews, who will illustrate his paper with lantern slides.

THE fourth of the series of elementary technical classes being given by the above Society was held on Wednesday, 12th inst., when Mr. J. C. S. Mummery dispensed practical instruction in toning gelatino-chloride paper, with both the combined and separate baths. The next evening has been fixed for May 10, when the subject will be the improvement of negatives (intensification and reduction), by Mr. J. McIntosh. Any gentleman wishing to attend is requested to make application to the Hon. Secretary, M. G. Gosling, 13, Lausanne-road, Hornsey.

Hackney Photographic Society.—Mr. E. Puttock in the chair.—The Hon. Secretary (Mr. W. Fenton-Jones) was welcomed back by the members after his tour through Italy and Switzerland, and he informed them he would give an account of his trip later on in the year, with slides from negatives taken by him. From the question box: "What is the cause of a negative turning pink?" A suggestion was that the hypo had not been eliminated sufficiently. Mr. Beckett showed a table showing loss of reflection from polished glass plate (lent him by Mr. Wall). Messrs. Sodeau and Smith showed comparative tests in unbacked, backed, and Sandell plates. In the backed and Sandell plates there was hardly any halation, but the unbacked one had much halation. Other work was shown by Messrs. Salmon, Roofe, Richardson, Hudson, after which lantern slides, the work of Messrs. Roofe, Roder, Carpenter, Wire, Barker, Barton, Dean, Salmon, Cross, Olney, Harvey, Hudson, and Beckett were shown.

Kensington and Bayswater Photographic Society.—April 17, Mr. C. W. Brummell in the chair. The Hon. L. M. St. Clair gave a lantern lecture on Norway and Sweden, and also showed slides from negatives taken in Nepaul, Thibet, and India. The lecturer also exhibited native weapons, &c., describing the manners and customs of the people in each of the countries.

West London Photographic Society.—On the 11th inst., Mr. W. S. Rogers, the Hon. Secretary of this Society, gave a practical demonstration in *Frame-making*. He explained the method of cutting the mitre joints, and showed how the four sections of moulding could be readily glued up to form a picture frame. Mr. Rogers employed for the purpose of his demonstration a bench by Messrs. Syer & Co., and he exhibited and explained a very ingenious mitre-cutting machine, by Messrs. Booth Bros., both of which had been lent for the occasion. Afterwards a series of slides by Mr. H. Selby, illustrating a tour in the counties of Durham and Yorkshire, were put through the lantern, and Mr. Selby gave an interesting discursive lecture on the places represented.

Croydon Microscopical and Natural History Club (Photographic Section).—April 14, Lantern Evening, Lecture on *Winchelsea and Rye*, by Mr. A. Brooker.—In tracing the history of these picturesque and old-fashioned towns, the lecturer showed, by means of ancient maps, the vast changes that, owing to the vagaries of the sea, had taken place round the mouth of the Rother, whereby these ports had been left stranded, high and dry, surrounded by marshes. The lecture was copiously illustrated by views of the numerous archæological remains, and of marshland and shipping scenes, some of these latter being particularly fine.

Liverpool Amateur Photographic Association.—A Reception and After noon Tea was given by a few of the ladies of the Association on Thursday, April 13. A large number of the members and their friends attended. The arrangements were in the able hands of Mrs. Marriott, Miss Adams, Mrs. Morrison, and Mrs. Southell. The Club room had quite a holiday appearance with the decorations, flowers, and other comforts known to the fair sex. In the evening a practical demonstration on *Alpha and Bromide Paper* was given by Mr. Wilkinson, of Manchester. He also exhibited and gave the formula for a home-sensitised print-out paper.

FORTHCOMING EXHIBITIONS.

April 21-29 ..... *Crystal Palace. The Executive, Crystal Palace, S.E.

,, 21-29 ..... *Photographic Society of Philadelphia. Hon. Secretary, R. S. Redfield, 1601, Callowhill-street, Philadelphia, U.S.A.

May 4-6 ..... *Forfarshire Photographic Association. Hon. Secretary, W. J. Anckorn, West Port, Arbroath, N.B.

* Signifies that there are open classes.

Correspondence.

☞ *Correspondents should never write on both sides of the paper. No notice is taken of communications unless the names and addresses of the writers are given.*

LENS STANDARDS.

To the EDITOR.

SIR,—I was pleased to read your article on "Lens Standards" in your issue of April 14, not alone because of your kindly reference to my work, but because your JOURNAL may thus be one of the most effective instrumenta in the real establishing of such standards as those to which you refer. It has fallen to my lot to observe, perhaps more closely than any one, the progress made in the establishing of standard interchangeable fittings for the attachment of lenses to cameras, and I have been particularly struck with the fact that, while every one recognises the great conveniences which will be secured to photographers by the effective establishing of such uniformity of practice, each individual concerned seems to expect that it is the business of every one but himself to act in the matter.

There is a tendency among users of lenses to look to the opticians for the necessary action. Few photographers can, however, realise the enormous cost in cash and inconvenience which the departure from his old standards will entail on each individual optician, and it cannot be expected that opticians will adopt new standards except under pressure of public demand.

I believe that the time has now arrived when sufficient interest has been awakened in this matter to secure among photographers the solid belief that these standards must ultimately be everywhere adopted, and what I should like to point out is the need of individual effort. Any photographer who wishes to have standard fittings to his lenses can have them, probably by merely specifying these standards when ordering lenses, although the optician may not offer the standards under ordinary circumstances.

I believe that the work of improving these fittings which is associated with the name of my firm, will do much to make the standards popular, through securing to them several great advantages of practical usefulness which belong to no other system.—I am, yours, &c.,

Leicester, April 17, 1893. WILLIAM TAYLOR.

DETERMINATION OF THE SPEED OF PLATES.

To the EDITOR.

SIR,—I gather from the report in your issue of April 14th of the remarks made by Mr. G. F. Williams before the London and Provincial Photographic Association, that he bases his conclusions on the fact (as he asserts) that certain speed numbers placed on boxes of plates by makers who have adopted Messrs. Hurter & Driffield's system have not proved in practice to represent truly their *relative* speeds.

During last season I had a considerable number of plates from different makers tested by means of Messrs. Hurter & Driffield's system by Mr. R. C. Phillips, of Oxford-street, Manchester, the result of which testing showed that frequently the printed descriptions of the plates on the boxes were very misleading. Certain boxes were marked with speeds purporting to represent *accurately* their speed on the Hurter & Driffield scale. It turned out, however, that in some cases the numbers were entirely wrong, the fact being that the makers had either misunderstood or misapplied Messrs. Hurter & Driffield's method of testing. This was admitted to be the case with some of the batches first tested.

The correctness of speeds, as determined by Mr. Phillips, were subsequently verified when the plates were used in the camera, the exposure being, of course, calculated with the actinograph. I believe I am correct in saying that I have not had a single incorrect exposure on the numerous plates so used.

I, like Mr. Williams, felt that I had a right to demand that the goods sold to me should be what they were represented to be. It is easy to understand, however, that, in first adopting the system, errors might be made; and it is unfortunate that any makers should have placed the speed numbers on the boxes before they had made quite certain that they were using the system aright. I have little doubt that, by this time, experience has taught them to use the method correctly.

If Mr. Williams did not have any of the plates he experimented with tested by Hurter & Driffield's system *independently*, it is evident that he may have obtained some, as I did, wrongly marked, which would be sufficient to account for his having formed an adverse opinion of the system, though his method of testing can scarcely be considered an accurate one, and he would certainly have arrived at very different, and probably correct, conclusions had he tested the system itself.

As regards orthochromatic plates, Mr. Phillips tested only one of such for me, with the result that the speed given by the same procedure as in testing the other plates was very largely in excess, as one might reasonably expect, of its true daylight speed.

Mr. Phillips tells me, however, that he finds no difficulty in establishing a special constant for any particular make of orthochromatic plates, though, of course, it is not very likely that the same constant would be applicable to plates orthochromatised by different methods and treated with different staining substances.

I trust that these few remarks may be the means of deterring those who have read some of the recent adverse criticisms of Messrs. Hurter & Driffield's system from forming an opinion that it is faulty or unreliable.

No one who is competent to form an opinion on these researches can do otherwise than appreciate their scientific value and thoroughness. Beyond this, however, experience of the practical application of the system proves it to be perfectly reliable and of enormous convenience and economy, and I am confident that, if the numerous users of the system will make known their experience, this fact will be fully substantiated.—I am, yours, &c., WALTER BOURKE.

Worsley, April 18, 1893.

MR. TEAPE AND THE SANDELL PLATES.

To the EDITOR.

SIR,—Will you kindly allow me a brief reply to the remarks of Mr. S. H. Fry in your last issue? I consider that I was quite justified in using the Thomas's hydroquinone developer undiluted under the circumstances.

I purchased a box of Sandell plates. There were no instructions of any kind in or on the box. This was mentioned at the meeting. I asked Mr. Fry if the method of tentative development was given in the instructions with the Sandell plates. Mr. Fry answered, "No, he believed not. New instructions were being made out."

I think you will see by this that I had no information to guide me to any particular mode of development for the Sandell plates, and that there was nothing remarkable in my selection of the said developer and using it undiluted.

My experiments were comparative, and made for the purpose of showing the presence or absence of halation in the two kinds of plates given absolutely the same exposure and treatment in development. If this is rough treatment for the Sandell, it should prove the same for the other plate in the production of halation. This is proved to be the case, for, in my later experiments developed tentatively as explained by Mr. Fry, the same relative amount of halation is shown—that is, most halation on the unbacked Paget XXX, less on the Sandell, and none on the Paget XXX backed.

I have also used the Paget XXXXX under the same conditions, with the same result. The development of these plates extended over sixty-five minutes, and I could have withdrawn the Paget plates in forty-five minutes, for they had attained quite enough density, but I kept them in for the same time as the Sandell. This must have been a great strain in the direction of producing halation on the Paget XXXXX. These plates are in the library of the London and Provincial Photographic Association, and may be seen by any one interested in the matter.—I am, yours, &c., J. S. TEAPE.

London, April 15, 1893.

THE CONCENTRIC LENS.

To the EDITOR.

SIR,—I note that, in a communication to one of the photographic journals, Professor Burton says that the concentric lens, when used with a stop of *f*-22, "gives excellent definition." I send you some spoiled negatives—not caring to put good ones in a letter, though on Eastman films—to show that the definition of the concentric with *f*-16 is as good as with a smaller stop. The two pairs were made simply with a view to test this power of the lens, and are the centres of 8×10 negatives, taken with an eight-inch lens, one with *f*-16 and the other with *f*-64. Will you be good enough to examine them, and say frankly if you find that the larger stop shows any inferiority in definition? The negatives were spoiled by a crack in the camera front, which let light in on the foreground, and the development was not completed; but I may say that up to the workable dimensions of the negative, say 7×9, there was no falling off in the margins as far as definition was concerned, though certainly there was a better illumination up to the very corners in those taken with the *f*-64 than in the others. But it must be remembered that this is a case of straining the lens, for, the focus being eight inches, we have no right to expect it at *f*-16 to cover a field of 8×10 with equal illumination. Should there be no near foreground, the lens will cover a whole plate with the *f*-16 so well, that for all ordinary observation no one could tell whether the stop was *f*-16 or *f*-64 when it comes to the printing.

As the Roman season for photography is just opening, and colleagues of the camera may be drifting this way, I take the opportunity to supply an omission in the ALMANAC of this year by giving the address of our Amateur Club, which we regard as the primate of Italy. It is in the Piazza di Pietro, at the back of the Bourse, and visitors will find there all facilities for developing their own negatives, or having them done by our technist, Cav. Montagna. We have an excellent portrait studio, enlarging room, and half a dozen dark rooms, some for cold and some for hot weather. In the Via di Pietro, which leads to the Piazza, there is a very quiet little hotel, the Hotel Cesari, kept by a member of the club, one of our most enthusiastic amateurs, where the visitors will

find, at the top of the house, a studio and a dark room always at his service if he does not care to go to the club. The Cesari is excellently suited to wanderers, as it does not furnish meals except breakfast, leaving the client free to dine and lunch where he pleases. He takes his room, and, if he likes, his coffee in the morning, and comes home at night, with no further limitations. The quarter is the healthiest in Rome.—I am, yours, &c.,

W. J. STILLMAN.

Rome, April 16, 1893.

THE SPEED OF PLATES.

To the EDITOR.

SIR,—In Mr. Williams's remarks respecting determination of speed of plates by the Hurter & Driffield method, made before the London and Provincial Photographic Association, there occurs a little inaccuracy, conveying a wrong impression.

Mr. Williams says:

"To this correspondence I replied briefly, to the effect that I should abide by my experiments, and such was the courage of my own opinions, that I offered to submit everything to a disinterested jury, and I further offered to repeat any individual experiment such jury might select. *To this challenge none of my dissentients have responded.*"

In Marion & Co.'s letter to Mr. Williams, published February 10, they say:

"Knowing the value of the system from more than twelve months' daily working, we are most desirous of offering the utmost facilities for its trial. We should be pleased *if Mr. Williams or any committee of experts would take the matter up with us.* We invite Mr. Williams to favour us with a visit at Southgate, and, in conjunction with our Mr. Cowan, practically test the speed numbers."

Mr. Williams could scarcely expect us to respond to his challenge when he himself has not cared to accept ours, which was *issued a week previous* to his own. We still leave our challenge open for Mr. Williams' acceptance, with any committee of experts nominated by the Society before whom Mr. Williams' paper was read.—We are, yours, &c.,

April 19, 1893. MARION & Co.

IMPORTANT NOTICE—AMIDOL OR DIAMIDOPHENOL; METOL OR MONOMETHYL-PARA-AMIDOPHENOL; GLYCIN OR OXYPHENYL-GLYCIN—PATENTS IN ALL COUNTRIES.

To the EDITOR.

SIR,—We beg to inform you, and we shall feel obliged if you will give publicity to the fact, that the patent disputes between the manufacturers of the above developers have been settled amicably by mutual consent, and in future the sale of same in Great Britain and colonies will be effected through the undersigned firms, at even prices and terms.

All photographic dealers will supply these products at the retail prices advertised, and professionals as well as amateurs will, no doubt, continue to derive satisfaction from the use of these now well-known developers.—We are, yours, &c.,

FUERST BROTHERS,
17, *Philpot-lane, London, E.C.,*
Sole Agents for
J. HAUFF,
Chemische Fabrik,
Feuerbach, near Stuttgart.

HENRY HAUSSMANN,
Dashwood House, New Broad-street, London, E.C.,
Sole Agent for
DR. M. ANDRESEN,
Actiengesellschaft fuer Anilinfabrikation, Berlin.

Answers to Correspondents.

*** *All matters intended for the text portion of this* JOURNAL, *including queries and Exchanges, must be addressed to* "THE EDITOR, THE BRITISH JOURNAL OF PHOTOGRAPHY," 2, *York-street, Covent Garden, London. Inattention to this ensures delay.*

*** *Correspondents are informed that we cannot undertake to answer communications through the post.*

*** *Communications relating to Advertisements and general business affairs should be addressed to Messrs.* HENRY GREENWOOD & Co., 2 *York-street, Covent Garden, London.*

PHOTOGRAPHS REGISTERED:—

Alexandor Gendall Gibson, Penzance.—*Two photographs of the ship "Horsa" ashore at St. Martin's, Scilly Isles.*

Alexander Gendall Gibson, Penzance.—*Two photographs of the ship "Horsa" ashore at St. Martin's, Scilly Isles.*

James Soames, jun., Oxford.—*Photograph of a bulldog dressed in football cap and jersey. Two photographs of bulldogs in barristers' costumes.*

H. W. H.—In the formula referred to, cyanide of potassium and tincture of iodine are meant.

RAJAH inquires if we can tell him of some good provincial town where the club system has not yet been introduced?—We cannot.

X. Y. Z.—From your description, we cannot quite understand the alteration made on the lens. Please send a rough drawing.

LIGHTS.—The address of the Incandescent Lights Company is Palmer-street, Westminster, S.W.

W. J. N.—It is certainly possible to use sympathetic ink in printing, but water is usually the solvent for such inks, whereas you will require an oleaginous ink.

C. R.—The question is one entirely for the County Court. As the man was acting as an agent, and not as a servant, we do not see how he can be charged with embezzlement.

AUGUST BAER (Winterthur).—We do not know the name of the manufacturer of the air brush, but Ross & Co. are the sole agents for this country. See advertisement in ALMANAC.

EDGAR SCAMELL.—Of the two designs for a studio we should prefer No. 1, if the ridge be carried more towards the centre and the glass also taken up proportionately higher.

AVONDALE.—We have heard the London-made production well spoken of, but cannot speak of its capabilities from personal knowledge. We think, however, it should serve your purpose.

E. WALKEN desires to know if grit would make his Beard's regulators unworkable, and asks Mr. Birrell's opinion as to this, and further, as to whether the anti-friction arrangement could be adapted to them.

ERRATUM.—We are reminded by Mr. W. Wray that, in giving their sources of supply of optical glass in our article last week, we have omitted the Jena glass, of which they use a considerable quantity.

H. DUNNING.—We have returned the correspondence to you. Possibly the matter had better end with the expression of our opinion that the matter was entirely one for settlement between you and the other party.

W. W. T.—1. We do not know any work which treats specially of photographing anatomical subjects. 2. A paper on *Architectural Photography*, by Mr. S. F. Clarkson, published in our volume for 1886, may help you.

SALOP.—If you have publicly charged the man with infringing your copyright photograph, while you have no copyright in it, you will most likely find yourself in an unpleasant position. An apology ought to be tendered.

B. W. C.—Ether should be used for thinning down collodion, especially so if the thickness arises from evaporation. We do not know the composition of any retouching varnish such as you describe, in which collodion plays a part.

S. SINGLETON.—No difficulty will be experienced in photographing in Germany, provided the camera is not used in the neighbourhood of fortifications. It will, however, be advisable to be provided with a passport in case of accidents.

INQUIRER.—We do not know any American paper that takes just such a position. Your course is first to determine in what city you would wish to reside and then advertise in those papers published in that city. Having thus decided, you may write to us again.

G. I. J.—The opening out of the aperture in the lens to *f*-9 should, theoretically, cause it to work with an equal degree of rapidity to the rapid rectilinear of similar aperture, although of different focus, provided its correction is such as to give sharpness when thus opened.

F. E. G.—We suspect that your cyanide has lost its virtue by long keeping. Stick cyanide at best is but weak. As an alternative, try a strong mixture of solution of ferridcyanide of potassium and hyposulphite of soda, or you may use them singly, the ferridcyanide first, of course.

S. RUNNICLES (Braila).—The cement referred to may be obtained through any English stationer. Nothing is better for mounting photographs than freshly made starch paste. Most, if not all, the cements sold that do not require heating are not to be recommended for photographic purposes.

T. JENNINGS.—If the transparencies are not dense enough, they can be intensified. Carbon transparencies are intensified by treating them with a solution of permanganate of potash. The strength is unimportant. Ten to fifteen grains to the ounce of water is, however, a good proportion.

DUBIOUS.—As you say that the toning and sensitising baths are in good order, and that only three or four prints out of a batch are defective, it is clear the paper is not at fault. Therefore the trouble is due to the manipulation, but in what way it is impossible to say without seeing the operations carried out.

LOUIS MELDON.—On examining the negative microscopically, we find a well-marked nucleus in the centre of each spot, but how caused, or what it consists of, we are unable to say. Place a little of the water employed in a clean test-tube, and examine for any floating specks through a magnifying-glass.

H. B. W.—If the negatives are very much under-exposed, there is no remedy in the development to anything like the extent there is with over-exposure. Amidol will sometimes bring out detail where pyro fails. Try that, and use a fair share of patience. Then some of the plates may be made to yield fair negatives.

A. RAWSON.—There is certainly no novelty in the idea of coating albumen prints with collodion with the object of making them more permanent. This was tried in a series of comparative experiments many years ago, and the result was that some prints treated with the collodion were found in some instances to fade quicker than corresponding ones that were not coated. From this it will be seen that the proposed patent, if obtained, would not be valid.

W. O. J.—Read the articles on the various photo-mechanical processes in the ALMANAC and then experiment for yourself. We fear you will not get much that is reliable with regard to the practical details of working without paying for it—and rather a good price, too. Practical details are treated much in the light of trade secrets.

A. X. Y.—Very likely, if you exhibited, you might get a medal. We have seen worse pictures that have obtained medals at societies of the Little Peddlington type. These are the societies that the avowed "pot hunter" usually seeks. In the best societies he is usually conspicuous by his absence. The prints would be best in platinotype.

A. MACKINNON.—Your trouble is, no doubt, increased by over-sensitising the tissue. Five minutes' immersion in a five per cent. bichromate bath at this season is too much. Reduce the strength of the solution to three per cent. and the time of immersion to three minutes. Are you aware that carbon tissue can be purchased in small quantities ready sensitised?

SULPHC.—1. By procuring a copy of the Poisons Act from Eyre & Spottis woode, New Street-square, you would be able to see if the chemicals are scheduled. 2. We scarcely understand the question. Sulphite, as a preservative for pyro in solution, is best in a neutral state, although, as a rule, it is faintly alkaline. If it is placed with the soda solution, it is also doubtless present with the pyro.

W. C. DRUMMOND.—It will be very difficult to etch on glass by the method you adopt, because no portion of the surface is quite denuded of gelatine, which acts as a resist to the etching fluid, which we suppose to be fluoric acid. The interposition of a grating might aid you. Instead of glass, you might try a copper or brass plate, and etch in the manner adopted by Fox Talbot.

DUBLIN.—There are many causes that may conduce to an emulsion yielding foggy plates. If it were prepared strictly according to the formula quoted, we should say the most probable cause was over-cooking. Try again, and boil for half the time, and see the result. The gelatine appears to be the right brand. But we may add that many of the finer kinds of thin gelatine are so similar in appearance that it is quite impossible to recognise them by the examination of a single flake.

A. J. BONSON writes as follows: "I have a quantity of chloride of silver from the washings of prints. Is there any means by which I can convert it into nitrate without sending it to the refiner? I may say that I have no furnace by which I could bring the chloride to the metallic state. I have heard or read somewhere that there is a method by which it can be done."—Proceed as under: Wash the chloride, and drain it closely. Then strongly acidify it with sulphuric acid and drop in a few pieces of pure zinc, and allow it to rest for a day or so. This treatment will reduce the chloride to metallic silver. Any zinc remaining must be carefully removed, and the silver well washed. After the zinc is taken out, it is a good plan to add some more sulphuric acid to dissolve any small fragments of zinc that may have become detached. After the silver is thoroughly washed, it is dissolved in nitric acid and crystallised.

RECEIVED:—Morley & Cooper's price list of cameras.

PHOTOGRAPHIC CLUB.—April 26, *Novelties in Hand Cameras*. May 3, *Lenses for Copying*.

THE fishing picture, *Steady*, at the Crystal Palace, which we referred to as being by Mr. H. Young, should have been attributed to Mr. H. Smith.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—April 25, Technical Meeting, *The Manufacture of Gelatine Plates*. A demonstration by Mr. J. Desiré England at 8 p.m.

ERRATA.—Mr. W. Birrell writes: "Permit me point out to you that you have put 'cork' instead of 'cock,' which renders the meaning of my last week's letter hard to discover."

WE have received from Mr. W. F. Slater, of 169, Southampton-street, S.E., his price-list of frames and mounts. Mr. Slater's frames are always distinguished by excellence of taste and other good qualities.

MESSRS. ARTHUR SCHWARZ & CO. inform us that the specimens of coloured photographs sent in for the Brunn's Gossy Colours Competition are on view at the National Photographic Exhibition now being held at the Crystal Palace.

MESSRS. MARION & CO. inform us that they are bringing out a new trade catalogue in sections. They have sent us a copy of the section relating to camera stands and shutters, which is replete with illustrated descriptions thereof. Other sections will appear in due course.

REDUCTION OF AMIDOL PRINTS IN THE FIXING BATH.—With reference to this, Mr. A. K. Dresser has handed us our bromide prints, developed each respectively in sulpho-quinone, metol, eikonogen, and amidol. The development was in each case carried to the same stage, and the prints were soaked in a strong solution of hyposulphite of soda for a night. There is no apparent reduction in any of them. It is Mr. Dresser's opinion that the reduction of amidol-developed images would not be heard of if photographers would give a shorter exposure and a longer development.

CRYSTAL PALACE NATIONAL PHOTOGRAPHIC EXHIBITION.—List of awards. National challenge cup, the West London Photographic Society: Gold medal, W. M. Warneuke; silver medal, E. T. F. Goodwin; bronze medal, Messrs. Morgan & Kidd, A. R. Dresser. Art division: Silver medals, William Howell, C. H. Oakden, W. J. Wright, J. E. Goold, C. Job, E. Hawkins, G. Hankins, Miss A. Heath; bronze medals, F. W. Edwards, G. H. Catt, R. H. Lord; certificates, Douglas Pym, E. M. Stone, C. Court Cole. Scientific photographs: Silver medal, Sir Henry E. Roscoe and Joseph Lunt (joint exhibit); bronze medal, John Carpenter. Lantern-slide division (professional photographers): Silver medal, George E. Thomson; bronze medal, P. H. Fincham. Amateur photographers: Silver medal, F. Golby; bronze medal, J. Shaw, G. Bingley; certificate, Harry Holt; silver medal, W. E. Cowan; bronze medal, J. O. Grant; certificate, W. Taverner; bronze medal, W. C. Beetham; silver medal, F. Anyon; bronze medal, E. Dockree.

DESTRUCTIVE FIRE AT A BARNSLEY PHOTOGRAPHER'S.—A fire which caused considerable damage occurred on Wednesday night, April 12, on premises in Sheffield-road, owned by Mr. Walter Guest, tobacconist, and occupied by Eastman's, Limited, butchers; Mr. Eddison, photographer; the Danish Butter Company; the London and Counties' Tea Company; and others. The fire was discovered by Inspector Mellor and P.S. Williams about nine o'clock on the night named. They at once gave information to the Corporation Fire Brigade, who were soon on the spot. They were able to obtain a good supply of water from the street mains, and the fire was totally extinguished by eleven o'clock. The greatest amount of damage was done to the property of Mr. Eddison. The room which he occupied was used as artists' room, and contained a number of pictures that were ready for sending out, and also frame mouldings. Mr. Eddison estimates the damage at about 1000*l*. His property was fully insured with the Royal Exchange Assurance Company. The damage to the building is computed at 350*l*., and is also covered by insurance. Messrs. Eastman's damage amounts to about 50*l*.; and the Tea Company's to from 50*l*. to 100*l*. It appears from subsequent examination that the fire began in a small place partitioned off from the butcher's shop, to which it belongs.

BOLTON PHOTOGRAPHIC SOCIETY'S EXHIBITION.—On Wednesday, April 12, the Bolton Photographic Society opened an exhibition of its work. Mr. J. R. Bridson J.P., the President of the Society, had for exhibition over a dozen fine pictures, including portraits of Princess May, Miss Bridson, Miss Fortescue, and various landscapes, some of which were worked up in colour and crayon. In portraiture there was a very fair representation of professional artists in the town, some highly finished work being exhibited by Mr. Nathan S. Kay, Mr. F. Proctor, and Messrs. Weatherley, Bros. whilst Mr. H. Birtwistle was also an exhibitor in this class. Mr. J. S. Roscoe, a skilled amateur, had several landscapes on view, and also worthy of special mention in the miscellaneous exhibits were Messrs. Walter Staton, W. Collier, W. L. Entwistle, H. Haywood, J. Kellett, W. Green, and A. Harper. Other exhibitors who figured very creditably were Dr. Johnston, and Messrs. E. J. Roscow, F. Roscow, J. Thornley, Jabez Boothroyd, R. Fielding, jun., R. Paiton, S. L. Coulthurst, A. Graham, J. Leach, Jas. Morris, J. H. Galloway, R. Leigh, R. Gregson (Blackburn), J. H. Cowan, J. Lomax, I. Brooks, and J. Young. Several manufacturers of photographic materials had on view specimens of their latest processes, and local dealers in photographic outfits, including Mr. W. Banks, Corporation-street, and Mr. T. H. Heyes, Deansgate, had very interesting exhibits of their specialities on view. The Eastman Company had on exhibition eight views as specimens of their bromide and solio processes; but the exhibit which was the commanding attraction in the room was Messrs. Elliott & Son's green carbon enlargement, *Break, break, break, at the foot of thy crags, O sea!* which is seven feet by five feet in size, and attracted great attention at the Pall Mall Exhibition last year. In opening the Exhibition Mr. Bridson expressed his pleasure at seeing so large an assembly and such an encouraging manifestation of interest by the public in the science of photography. He thought the display on view that night was a great improvement on its predecessors. The Bolton Society had been in existence fourteen or fifteen years, and had a membership of one hundred, which he trusted might be increased as the result of the Exhibition. The results of the judging were then announced as follows:—Members of the Society only: Class 1: Best set of six photographs from negatives taken since March, 1889.—1, Silver medal, Walter Staton; 2, bronze medal, H. Heywood; 3, bronze medal, A. Harper; and highly commended, Dr. Johnston. Class 2: Best set of at least six photographs taken at Society's outdoor meetings during 1892.—1, Silver medal, W. Collier; 2, bronze medal, W. L. Entwistle. Class 3: Best set of transparencies from negatives taken during 1892.—1, Silver medal, W. L. Entwistle; 2, James Kellett; 3. Ernest J. Roscow. Class 4 (open to all professional photographers): Best set of six portraits.—1, Silver medal, N. S. Kay; 2, bronze medal, F. Proctor. Classes 5 and 6, no competition. Class 7: Best picture in the Exhibition, belonging to any member of the Society.—1, Silver medal, J. S. Roscow; 2, bronze medal, W. Green. As supplementary attractions to the Exhibition the Committee arranged a series of musical entertainments and an excellent programme of American and other scenery. The Judges were Messrs. J. H. Welch, E. L. Marriott, and H. Hall, of the Liverpool Amateur Photographic Association. The Exhibition closed on Saturday. The room was crowded, the chief attraction being a lantern display, the *Peaks and Dales of Derbyshire*, which was highly appreciated. During the four days the Exhibition has been open upwards of 1200 people have visited it, and it has been a thorough success in every way.

*** We have received from Mr. Joseph George Hudson the sum of 15*s*., the proceeds of sale of groups taken by him at Anderton's Hotel on February 11, 1892, and which, as requested, we have handed over to the Treasurer of the Photographers' Benevolent Association.

No. 1721. Vol. XL.—APRIL 28, 1893.

PERSPECTIVE IN PORTRAITURE.

Somewhat allied to, and suggested by, the subject of our article last week on the so-called photo-corrector, is the cognate subject of incorrectness of portraiture, produced by placing the lens and camera too near to the sitter.

Every one knows that, if the hand or foot projects, it will be rendered on a scale larger than it ought to be in comparison with the rest of the figure; but every one does not, seemingly, realise that this applies also to the projecting parts of the face in relation to those further away from the lens. This perspective distortion is, in both cases, the more pronounced the closer the lens—the point of sight—is to the figure. By receding, or withdrawing the camera to a greater distance, this disproportion becomes less and less, until it ceases to be noticeable.

While no one with any artistic perception would pose a figure so as to allow the hands or feet to unduly project, still t may be well to indicate in what manner such may be equalised without the necessity for having recourse to adventitious modes, such as are afforded by retouching or "photo-correctors."

The simplest and most obvious means for adoption is to avoid placing the camera too near the sitter. If, as we have seen some do, the lens is brought to within six or eight feet of the sitter, or even still closer, as when a large head is desired, what can one expect other than this distortion of perspective? While it is true that the perspective is not really false, still it is violent, and the portrait obtained in this way may not convey an accurate idea of the sitter. A useful object-lesson is to make a direct large portrait of a sitter from a distance of four to five feet, and then remove the camera till twenty-five or thirty feet intervene between them, afterwards enlarging the portrait last taken until of the same size as the first, and then comparing the two. It will be seen how much superior the one is to the other. Some studios may not be sufficiently long to permit of this being done; and this is a great misfortune, for, while no studio should be under twenty feet in length, it is still better when it exceeds this by twelve feet, or is thirty-two feet long. If it is found that at a distance of about fifteen feet the portrait is too small for the dimensions required, it is much preferable to attain this end by employing a lens of longer focus than moving the camera much closer to the sitter. What is said here about diminishing the too violent perspective of the component parts, so to speak, of a single sitter, applies also with even greater force to the taking of two or more figures in one picture.

In the case of a sitting figure, in which the feet almost necessarily project, any apparent enlarging of them can be reduced by the judicious use of the rising front and swing-back of the camera, observing this, that, in order to reduce the size of the feet, that part of the focussing screen—the top—on which these members are depicted must be brought nearer to the lens, although, when the face has been brought to a sharp focus, the feet, especially if the lens is at full aperture, will be less sharply defined than if the tilting were in the opposite direction. This defective definition must be ameliorated by stopping the down lens. The adoption of the system here outlined will prove useful, if not quite necessary, to the photographer whose studio is limited in length.

Who that is interested in the perspective distortion of the human face does not remember almost with a shudder the "chamber of horrors" opened in our midst in 1872, on the occasion of the late Mr. Robert Crawshay, of Cyfarthfa Castle, Wales, having offered liberal prizes for the production, direct in the camera, of *life-size* heads? Every large lens capable of doing the work, with others specially constructed for the purpose, was pressed into the service of photographers anxious to produce faces from five inches and a half to nine inches. This was in the times of collodion, and as the lenses, which had to be close to the sitters, could not be stopped down too much on account of the prolonged exposure then necessary, it is easy to conceive of the horrid caricatures of the "face divine" that often resulted from working with a moderately open portrait lens at such a short distance. The days when these things could be tolerated are now happily past, and a better taste prevails.

COMBINING ENLARGEMENTS FROM DIFFERENT NEGATIVES.

In an article a few weeks ago, it was explained how enlargements from different negatives could easily be combined into one picture. Then it was assumed that the negatives were in duplicate, and the object was to replace one or more faulty portraits in the one by more satisfactory ones from the other. It sometimes happens, however, that it is required to introduce the portraits of persons who do not figure in or were not even present when the original group was taken, while the only negatives of them available are on a different scale from that of the one to be enlarged. Suppose, for example, a cabinet-size negative, a group, say, of half a dozen persons has to be enlarged, and it is desired to introduce a couple more people, and the only negatives to be had of them are single figures on a larger scale, for instance, a head and bust in the one case, and a three-quarter figure in the other. Here, it is manifest, these negatives will require considerably less enlargement than will the principal or group negative.

If the method described in the previous article were followed,

it would prove, except with a deal of practice, somewhat troublesome, and then not altogether satisfactory. Anyhow, it will be clear to all that it would be convenient to be able to remove the sensitive paper from the easel. We are again assuming the picture is to be on bromide paper, between the different exposures, so that the various negatives can be adjusted to size, got into position, and focussed on a separate screen. This, as will presently be seen, is really easy of accomplishment.

Supposing that the finished enlargement is to be twenty-four by eighteen inches, we take two sheets of stout, white mounting board of these dimensions. On one we fix the bromide paper with strips of gum paper at the edges, or with a few touches of indiarubber solution at the back. This can then be put on one side till required. The other card is to be used as a focussing screen. A print is taken from the principal negative, and the positions the new figures are to occupy decided upon and then roughly sketched in with pencil. It will be better, in the majority of instances, for them to appear behind, rather than in front of, the others. Indeed, when bust portraits have to be dealt with, it becomes imperative that they do so. It must also be decided how much of the subject in the original negative is to be included in the enlargement, and this must be marked upon it at its margins with bold ink or pencil lines. Next, those portions of the two or more supplementary negatives that are not required are neatly stopped out with black varnish, leaving only such portions of the figures as are wanted. The negatives are now all ready for use.

The principal negative is placed in the enlarging camera or lantern, and the image projected on to the easel, upon which has been fixed the plain mounting board. But this must be so fixed that it can be removed from time to time, and replaced in exactly the same position and registration by that bearing the sensitive paper. This is easily ensured by utilising the principle adopted by lithographic printers in arranging "the lay." When the cardboard is placed in position on the easel, drive in a couple of small nails, or drugget pins, for it to rest upon; then, say, on the left-hand side, near the top, drive in another nail for the board to butt against. A few drawing pins will retain it in position. Now, it will be obvious that this board, the focussing screen, and also that carrying the bromide paper can be removed and replaced as often as desired, and identically the same position secured, if the simple precaution be taken that they always rest on the bottom pins and that the sides butt against the side one.

The image of the principal negative is now adjusted to size and focussed. The outlines of the figures are then roughly traced in with a black-lead pencil and the marginal marks, that denote the amount of subject, are also traced exactly—that is important. The card is then removed, and the tracing supplemented with sketches of the other figures that are to be included, and in their proper proportions. It is then replaced on the easel. The negative is then taken out, and one of the others put into its place. Its image is now adjusted so that it occupies the same position on the sketch, and is of the same size that it is to be in the finished picture. The focussing card is now replaced by that carrying the bromide paper, and the first exposure made. The lens is now covered with a yellow glass screen, and the image painted over as described in the former article (see page 209, *ante*). The paper is then taken away, the focussing screen substituted, and the image of the second negative arranged in position, and to size, upon it, and focussed. The paper is again put upon the easel, and the second exposure made. This image is also painted over, as was the other, the same procedure being followed if any more figures have to be introduced. The supplementary figures all being exposed and painted over, the focussing card is again put up and the principal negative introduced in the camera, and adjusted so that the marks on its margin, indicating the amount of subject, exactly coincide with those made on the sketch. This will ensure the image being accurate to the scale, and in the precise position first decided upon. It only remains now to put the sensitive paper once more in position, and make the final exposure. The pigment is removed with spirits, and the paper developed in the usual way.

Photography for Discovering Minor Planets.—The use of photography in this connexion seems likely to become embarrassing, as astronomers can scarcely keep time with the march of discovery. Thus, last month, no fewer than fourteen were discovered by the camera, the total number now known amounting to 375.

Death of M. Letellier.—We are sorry to learn of the death of Monsieur E. A. Letellier, who was a frequent contributor to several of the French photographic journals. M. Letellier, who was fifty-nine years of age at his death, was an officer of the Academy of Science, and was associated with several photographic and other learned societies.

International Photographic Exhibition at Geneva.—During the ensuing month of August an international Photographic Exhibition, under the auspices of the Association des Photographes Suisses and the Société Genévoise de Photographie will be held at Geneva. The Hon. Secretary is M. Th. Penard, 3, Boulevard de Plainpalais, Geneva, of whom particulars and entry forms may be obtained. The session of the Union Internationale de Photographie (the third International Congress of Photography) will be held concurrently with the Exhibition in Geneva, during the week from August 21 to 26.

An Exhibition of Daguerreotypes.—On May 23 Mr. W. England will demonstrate the Daguerreotype process before the Photographic Society of Great Britain. In connexion with the demonstration an exhibition of specimens of the Daguerreotype process is being organized, to which the Assistant Secretary, Mr. R. Child Bayley, 50, Great Russell-street, will be glad to receive contributions from those possessing them. We hope those of our readers having such will communicate with Mr. Child Bayley. A collection of Daguerreotypes would, we are sure, be of great historical and educational interest to many modern photographers, who have only a hearsay acquaintance with this charming process.

Gold Residues.—From inquiries we have made, we are inclined to think that the saving of gold is not much practised by photographers, although a considerable amount must be annually put aside in rejected baths and naturally accumulated in the stone bottles for toning solutions. The method of most simple employment would be that by solutions of iron, which throws down the gold almost immediately. It is, however, well to point out that so much silver chloride accompanies most gold deposits from photographic solutions that the best way is to redissolve the washed precipitate, precipitate again, dry, and weigh. The powder so obtained is nearly pure gold, quite good enough for chloride-making; the chloride may be roughly estimated as being equal to about double the weight of this brown gold powder. A solution made with a minimum of acid may be used without crystallisation, care being taken to neutralise the acid before use.

"The Linked Ring."—We gather from a Haddingtonshire paper, an extract from which has been sent us by a friend, that Mr. W. Crooke, the well-known photographer, of Edinburgh, has been

"asked to join a select body of amateur and professional photographers known as "The Linked Ring," the object of which is to promote artistic photography. It is understood that "The Linked Ring" has taken the Dudley Gallery for an exhibition, which is to be held in the autumn of this year." We wish the new Association, if formed, all the success it may deserve, and hope that it will falsify the fears to which a body having the usual attributes of a "select ring" inevitably gives rise in the minds of the public. A great deal of secresy seems to have been observed about the matter, a feature that rarely tells in favour of any movement.

Volatilisation of Precious Metals.—We have been assured by a veracious correspondent that when reducing silver from residues in a strong heat—a blacksmith's forge being the means employed—he dissipated a large proportion of the metal by volatilisation, on account of an assistant, through a misapprehension, continuing the heating of the crucible for a couple of hours. How far he was right we are not able to say, but in a recent paper by T. K. Rose, read before the Chemical Society, he conclusively shows that gold is volatilisable at a high temperature. We may give the brief summary of his results, merely premising that to photographers they would possess more interest if they had referred to silver, gold residues being mostly treated by wet methods. Mr. Rose says an increase in the loss of gold takes place when the temperature is high. A large amount is volatilised in an atmosphere mainly consisting of carbonic oxide. A comparatively small amount of gold is carried away by the more volatile metals, copper appearing to exert an exceptional action.

Photography and the Star Maps.—The advent of photography for this purpose was hailed as unerring, convenient, and useful beyond compare; but, as investigations are pushed, it is found that this handmaid to science needs considerable "looking after." It was found that different telescopes gave different results, as also which any practical photographer would have expected, did different makes of plates. Recently it is shown, by Schaeberle, that the height in the heavens is a most important factor. Thus a star at the zenith that had a photographic brightness represented by 1 would at a zenith distance of 79° be only ·87 bright, and on the horizon ·01. Lately M. Loewy has shown that the negatives obtained thus still remain important corrections to be made in the measurements. He shows that an error of $\pm 0{\cdot}1''$ is a probable error in the equatorial co-ordinates; in his own words: "Comme il faut encore admettre les erreurs réelles plus fortes que les valeurs théoriques calculées, il devient évident que le dégré d'exactitude obtenu, bien que suffisant, *est loin d'être exagéré!*"

Light and Electricity.—Some very singular light effects, as linked with electrical manifestations, have recently been described. In a paper to the Royal Prussian Academy, Dr. Philipp Lenard gives a description of some interesting experiments he has made regarding the phosphorescent light from the negative pole of a Geissler tube. Thin metal plates are quite transparent to these rays; and, taking advantage of this fact, he closed a small aperture in the glass tube by a very thin plate of aluminium, and so could study their properties outside the tube. These rays, passing through metal, produce a slight luminosity in air, and when falling on phosphorescent bodies near the metallic window caused them to glow. A quartz plate entirely arrested them, but gold, copper, or aluminium leaf allowed them to pass almost unchecked. The most remarkable fact about these rays—one which is the very opposite of all previously recorded behaviours of light rays—is that they do not pass in straight lines, but are diffused to such an extent that it is not possible to obtain a sharp shadow of a body placed between the window and a phosphorescent substance. These rays, composed of the smallest known waves, are thus acted on by gas as though it were a non-homogeneous medium, each molecule acting as an obstacle in diffusing the rays. Then, in another direction, M. Edouard Branly, in last week's *Comptes Rendus*, notes some very interesting light results. A disc of aluminium polished, and after a few days charged with electricity, parts with it in the usual gradual manner whatever light is allowed to act upon it; but, if charged immediately after polishing, the loss of electricity is rapid even in diffused light, and is only slightly diminished by surrounding it by orange glass, thus showing that the loss has not been, as has previously been thought, due, to any great extent, to what are commonly termed the photographic active rays, *i.e.*, those of the more refrangible end of the spectrum.

ALBUMEN BROMIDE PAPER FOR CONTACT PRINTING.

Some few years back a formula or method was published by which ordinary ready-sensitised paper—or, for that matter, any sensitised albumen paper—might at a pinch be converted to the purpose of enlargement, the chloride and excess of nitrate being converted into bromide of silver by floating on a solution of bromide of potassium, when, after a pretty thorough washing to remove the superfluous soluble salts, the paper might be exposed either wet or dry, and subjected to development in the same manner as gelatino-bromide or other papers. That such paper possessed any advantage over or even equalled the ordinary commercial productions I do not think was ever claimed, but that it formed an easily prepared makeshift in an emergency was proved.

I am not now going to recommend such a process as possessing any claim to practical utility when there are so many different kinds of paper both for printing out and for development on the market, and so easily obtainable that almost every country town that boasts a chemist's shop affords a supply; but, following out the lines indicated in connexion with dry plates in an article in last week's issue, I wish to show how a somewhat similar process may not unfrequently prove of use in working off what would otherwise be waste material, fit only to go amongst the residues.

Those who are in the habit of using ready-sensitised paper are, I dare say, like myself, not unfamiliar with the fact that a batch of paper will sometimes "go wrong," or discolour in an abnormally short time. It may be that it has been "old stock" before it reached the consumer's hands, or possibly the fault may be due to some defect in preparation, but the fact remains that a batch of spoilt paper is a by no means uncommon occurrence. Such a batch at present in my possession I can scarcely with fairness blame on to the paper itself, or on the sensitiser, since I have had it in stock for nearly twelve months, and during an illness, lasting through the best part of last summer, it remained simply wrapped in paper, without any further protection against the heat and variation of atmospheric conditions. When I add that it has passed the winter in a particularly damp cupboard, its condition, when I opened it a short time ago, may be easily imagined.

It occurred to me, more for the sake of experiment than with any hope that it could be converted to any practical use, to submit it to a somewhat similar course of treatment to that described in my article last week. Of course, there was no prospect of restoring it to usable conditions as a printing-out paper—at least, if such were possible, the game would scarcely be worth the candle—but there did seem to be a possible chance of converting it into a practically developable condition. The appearances were certainly not promising to commence with, for, in addition to its being "as yellow as a guinea," much of it was covered with irregular patches of metallic surface-bronzing. However, I decided to try the experiment.

In the first water the paper was washed to remove the free silver before submitting it to further treatment; but this seemed to be an unnecessary waste of the precious metal, of which there was none too much present, so in subsequent experiments the paper was floated at once on the restoring solution, floating seeming to offer the better chance of a uniform conversion of the free silver.

The restoring solution consisted of a five-grain solution of bichromate of potash, to each ounce of which a few drops of hydrochloric acid were added. The action of this solution was rather slow, but I found it necessary to use it weak in order to avoid the yellow stain otherwise produced. Subsequently I used a soluble chloride in place of the hydrochloric acid, but even then a slight trace of the acid seemed desirable. The action of this solution was to slowly restore the paper to its pristine whiteness—that is to say, after it had been washed to remove the bichromate—and this took place even in the

parts affected by the metallic markings. In fact, so far as appearances went, the change was far more complete than I had expected, and, indeed, as perfect as need be wished.

As already stated, the restored paper could not be expected to work as a "print-out," owing to the entire absence of free nitrate or any organic salt of silver; on direct exposure to light it darkened pretty rapidly to a dull, cold, slaty grey colour, and there stopped. On development, however, after a brief exposure in the printing frame, a better result was obtained, though I have not yet succeeded with chloride of silver in getting just the tone I should like, nor in securing perfect cleanness in development, possibly because I have not yet hit the right way. Plain chloride of silver is notoriously more difficult to develop satisfactorily than bromide, but with old and very weak ferrous oxalate, and with amidol also used weak, I managed to get very tolerable results, though not perfect.

The sensitiveness of the paper so restored was, I found, by no means of a high character, fifteen or twenty seconds with a negative of ordinary density being required in good daylight by contact, so that, for enlarging, the paper would have been practically useless. I therefore resolved to try the conversion into bromide paper instead of chloride, in the hope of securing greater sensitiveness, as well as a better tone and character of image. In this expectation the trial proved that I was quite justified, for the results obtained on the first attempt proved really surprising, and, so far as the technical qualities of the paper are concerned, as nearly perfect as possible. With ferrous oxalate, the delicate grey image of the best gelatino-bromide prints was obtained without difficulty, while, by a modification of the same developer, or, better still, by using amidol, a pure neutral black tone and image of greater robustness was the result.

The mode of procedure was precisely the same as that already described, with the exception that the restoring solution can be used stronger, for the reason I shall point out. In fact, the same solution as that applied to plates may be used, namely:—

Bichromate of potassium	2 drachms.
Bromide of potassium	1 drachm.
Water	10 ounces.

Upon this solution the paper should be floated with as much care as in sensitising paper in the ordinary way, and, of course, the same precautions must be taken for the avoidance of air bells, &c. If anything, I think, perhaps, a little more care is needful, for any check in the even flow of the solution over the surface of the paper has a tendency to leave a permanent mark, as occurs under similar circumstances in "dipping" a collodion plate. This arises, without doubt, from the action of the bromide in the restoring solution upon the free and organic silver salts in the paper. The floating must be continued for at least five minutes, in order to convert the whole of the chloride, for the solution is not strong in bromide; but it is not safe to greatly increase the quantity above that given, owing to the solvent action of a stronger solution upon bromide of silver. If hydrobromic acid be substituted for the bromide, or partially so, then a more rapidly acting solution may be employed.

In order to facilitate the floating it will be found a good plan to take the "curl" out of the paper in the usual way—that is to say, by laying it face downwards upon a sheet of clean paper, and, with a paper knife or straight edge pressed firmly on it, to draw it sharply across the edge until it curls in the reverse direction. It is then in condition to be easily and quickly floated without danger of air bells or other trouble.

Perfect conversion of the silver salts into bromide is the end to be attained, and beyond that the time of floating is immaterial—that is, floating for a longer time than is absolutely necessary is not injurious as in sensitising—*ergo*, float long enough. There is just the chance, if the floating is protracted excessively, that the bichromate may cause a permanent yellow stain, but this can be removed afterwards. After floating, the paper is first rinsed rapidly in one or two changes of water, and then left to soak for an hour or two, or until, on testing the drops that come from the paper itself in draining, there is not the least trace of chromic salts. This last may be performed by allowing the greater portion of the water to drain from a piece of the paper, and then causing two or three of the last drops to fall on a sheet of white blotting-paper. If the spot so formed be touched with a glass rod dipped in a solution of nitrate of silver, a red stain will be formed if any chromate be present. The test will be rendered more delicate if the solution of silver nitrate be preceded by a weak solution of carbonate of soda.

Should there be any tendency to permanent yellowness from the action of the bichromate upon the albumen surface of the paper, it may be discharged, if not very pronounced, by adding a very small quantity of hydrochloric acid to the washing water. In worse cases, the liquid sulphurous acid of the chemists' shops will be preferable, or, if it be at hand, metabisulphite of potash, which, by virtue of its free acid, reduces the yellow chromate, and removes the stain. Ordinary sulphite of soda, to which a small quantity of hydrochloric acid has been added, will produce the same effect, but in employing this solution it is necessary to bear in mind that bromide, and especially chloride, of silver are dissolved by it. Hence the strength of the solution must be kept down; indeed, in restoring the paper to the form of chloride it is scarcely safe to use sulphite at all, on account of the easy solubility of silver chloride.

After thoroughly washing the paper, there remains nothing to be done but dry it, an operation that requires no special care, except to protect the paper from light; when once dry, the albumen paper may be expected to keep at least as well, and probably much better, than most gelatine papers, owing to its thoroughly insoluble film, and the entire absence of any soluble matter or organic silver compounds. It has the great advantage over gelatine paper of insolubility of surface, and capability of being treated with warm solutions, if needful.

As regards sensitiveness, I have not used paper prepared in this manner for enlarging, but I should judge it is fully sensitive enough for the purpose. A momentary exposure to diffused daylight in the printing frame, or from ten to twenty seconds to lamplight, are sufficient for contact printing, and the development may be with ferrous oxalate or amidol, according to the tone preferred. So far I have only attempted black tones by development alone; I do not know whether it is possible by lengthy exposure and weak development to produce warm tones, but very probably such is the case.

W. B. Bolton.

AMERICAN NOTES AND NEWS.

A New Telephoto Objective.—Another new photographic lens, and Europe is not "in it!" *Credat Judæus!* We have seen no account of the nature or construction of this wonderful lens which is, from what we hear, going to lick all creation. True, we are put in possession of some of what we may term its externals, but are afforded no clue as to its optical nature. This, however, may not be a very difficult matter on which to hazard a guess. The invention, so far as we glean from a paper by the inventor, Mr. Albert B. Parvin, read at a meeting of the Philadelphia Photographic Society, consists of an objective, all the parts of which are mounted in a solid tube—that is to say, a mount in which there are no draw tubes by which to provide for any adjustment in magnitudes of the image. The mount is of short length, and can be screwed in the camera to alternate with the lenses in ordinary use. What Mr. Parvin claims specially as his invention is—a photographic objective of simple construction and effective action for enlarging the image of an object or objects at equal or unequal distances from each other with respect to the position of the camera; an objective having a non-extensible tube provided with a compound or combination lens; and a single negative lens of different length with respect to each other for securing enlarged images of distant objects with a marked degree of sharpness of detail. Now, by what means, different from those already recognised on this side of the Atlantic, are these features to be attained? The reply is tantalising. They are "due to the character of the lenses employed," and this is all. We certainly do learn a *little* more, but that little conveys no optical information. For example, in a 7 × 5 objective, "the combination positive lenses are 6½ inches focus, the negative single lens is 6 inches focus, and these are mounted in a tube of 2⅝ inches long. The diameter of both lenses is 1⅜ inches." Now, while there is but little real information here imparted, we very cheerfully admit that, judging from a lovely specimen of its work given in the *American Journal of Photography*, and from the high encomiums given at the meeting by Mr. John

Carbutt, the new lens will prove good and useful. We think, however, that Mr. Carbutt can scarcely have been lucidly reported, for, while he says that this lens "excelled" anything that had yet been brought before the public—and this with special reference to European productions of the sort—yet he felt certain that, in the near future, America would turn out lenses "equal" to any that came from Europe. Perhaps Mr. Carbutt will kindly enlighten us as to this.

Who first applied Bromine in Daguerreotyping?—A matter of much interest in reference to historical photography has been brought before the Franklin Institute (an American Society, something like our Society of Arts, only more technical) by Mr. Julius F. Sachse, who brings a second Richmond into the field. Here have we, and all the world, for these vast numbers of years, been quietly reposing in the belief that the first man who applied bromine in the sensitising of Daguerreotype plates, and by which that process was rendered sufficiently sensitive to enable portraiture to be easily possible, was J. F. Goddard, a lecturer in the Royal Polytechnic Institution of London, and who, between thirty and forty years ago, received fairly handsome recognition of his discovery after a long delay. Now, says in effect this Franklin Institute Iconoclast, you have been altogether wrong, for it is an American discovery. We have read Mr. Sachse's paper carefully, and in all fairness must state that the claim he has put in on behalf of Philadelphia having been early indeed in developing photography, seems just. He has arrayed a large number of facts, notes, and dates. From these we learn that another Goddard—not ours, but Dr. Paul Beck Goddard, of Philadelphia—in December, 1839, produced perfect specimens of the Daguerreotype, through the agency of bromine as an accelerator, and proof of this is adduced by reference to vol. iii. page 180, of the *Proceedings of the American Philosophical Society*, to which we have no present means of obtaining access. Now, it was in the autumn of the year following that our Goddard (curious coincidence of names) made his discovery, and published it in the *Literary Gazette* of December 12, 1840, and two months later (February, 1841) deposited a paper in the Archives of the Royal Society, detailing his sensitive process of bromine with iodine, for taking portraits from life by the Daguerreotype process. Be it understood that we are not here discussing the question as to who was the first to use bromine in photography in general, so far as it existed in those days—for that honour belongs, unquestionably, to Fox Talbot, who published his discovery nine months previous to the date claimed for the earliest of the other rivals—but who first applied it to the Daguerreotype? It is curious that both these should, although unrelated, bear a similar name, and that both should have been experimenting in a similar direction. It is highly suggestive of the simultaneous discovery of the planet Neptune by Leverrier, of Paris, and Adams, of Cambridge. Mr. Sachse further gives a facsimile of what is believed to be the first portrait ever made by the Daguerreotype process, which was taken by Robert Cornelius, in Philadelphia, November, 1839. But, as we recorded only a few weeks ago (April 7, page 211), the "first" portrait Daguerreotype, which is now on its way for exhibition at the World's Fair at Chicago, and which was taken in New York by Professor Draper in 1840, interposes an element of disturbance, for, if the Philadelphia history be correct, the New York one cannot be so, and *vice versâ*. The subject is not likely to cause a war between the "Empire City" and the "City of Brotherly Love," but the photo-archæologists of these rival cities must somehow have the matter settled. To do this once and for ever ought not to prove a very difficult matter.

Strong Hypo.—We learn that a chemical company in Massachusetts is manufacturing a hyposulphite of soda of a strength one-fifth greater than has ever before been accomplished. Although primarily intended for chrome tannage in the manufacture of morocco leather, it will, doubtless, soon find its uses in photography also.

A Kind Act.—An act such as we are now about to mention deserves being placed on record. Mr. H. H. Snelling was, two score years ago, conductor of the *Photographic Art Journal*, a high-class periodical, but now non-existent. He fell upon hard times, and in his old age became almost entirely blind, helpless, and destitute. But for Mr. W. H. Clark and Mrs. Fitzgibbon Clark, of the *St. Louis and Canadian Photographer*, poor Snelling's lot would have been a hard one, indeed; but these friends rescued him, brought him to St. Louis, and have kept him an inmate of their house for seven months. They have made appeals to the fraternity, with such effect that Mr. Snelling has been admitted into the Memorial Home of St. Louis, where he will be well cared for during the remainder of his life. Mr. Snelling, many years since, was an occasional contributor to THE BRITISH JOURNAL OF PHOTOGRAPHY.

A New Order.—The photographers of San Francisco and Oakland have started an organization bearing the title of United Order of Photographers, Studio No. 1. The meetings are to be held weekly. Their intention is to endeavour to remove the many evils which they say beset a number of their galleries, and to elevate the scale of prices to a paying basis. The *Pacific Coast Photographer* considers that, in order to effect the desired ends, it will be requisite that every gallery enters into the arrangements and compact. It anticipates much good to result from the organization.

An American in England.—A short time since we were much gratified at receiving a visit from one of America's oldest and most experienced technical photographers, Mr. T. C. Roche, who has for so many years been connected with the firm of E. & H. T. Anthony, New York. Mr. Roche is a man of vast information, both historically and technically, and has probably seen more of the American continent in company of his camera than any other man alive. We embrace this opportunity to say that any American visiting London during the forthcoming summer will always be well welcomed by us, and will have the privileges of our dark room for changing or developing his or her plates.

PHOTOGRAPHIC METASTASIS.

SOONER or later all investigation aims at elucidating "the whole truth." In this endeavour it is of paramount importance that, as a basis of operation, as far as it has gone, it is in possession of "the truth, and nothing but the truth!"

But this standpoint can only be attained by a few of those who have before them all the evidence that has hitherto been produced. For, although memory, penetration, reason, and impartiality are common gifts, they are seldom bestowed all at once, in equal measure, and in more than average quantity, on all and sundry. Therefore the dictum of him who has read much, of him who sees clearly, of him who reasons deeply, and of him who simply reads, sees, and reasons without bias are alike untrustworthy. Consequently, as the study of photography presents an exceptional array of facts difficult to reconcile with each other, and as photographers are as unfamiliar with *the scientific method* as the scientist is ignorant of photographic phenomena, it naturally follows that, although we have a plethora of nebulous hypotheses, we have not a single theory, worthy of the name, or capable of holding water, sufficient to quench the mildest milk-and-waterest thirst for knowledge.

The following remarks are intended as an elucidatory introduction to a description and analysis of the form, localisation, and nature of the various and variable parts of *minute* simple images, obtained by widely varying exposures, but submitted for the same length of time to the action of a constant developer. These images were of many different shapes, and were produced by two general methods. The first way was that of concentrating upon the film the images of several kinds of flames by means of a lens. The second was that of allowing light from divers sources to penetrate apertures of many geometrical forms cut in an opaque screen interposed between the light and the film.

The chief outcome of these experiments was a speculative investigation as to the nature of a *clear* "halo" "nimbus," or "ring," as I have indifferently termed it, and I would earnestly request the reader of these lines constantly to bear in mind that, where not otherwise specified, it is not the developed or fixed image which is the subject of conjecture, but the "latent" "developable" or *potential* image at the moment it is brought into contact with a given developer of constant constitution, and at that moment only.

Now, although I have no desire to press the analogy too far, I cannot but perceive, and be keenly impressed with, the very close resemblance between the growth of a plant and of a photographic image, for both forms of growth are subject to a twofold action of light—one chemical, the other mechanical. In both the chemical action at least gives rise to electrical displacement; both are retarded by cold and accelerated by heat. The presence of an alkali or basylous element, and the formation of a solution of the plastic material, is essential to both; and in both an excess of some essential—light, or one or other of its coefficients—greatly modifies or reverses the original form of growth.

When the light acts too strongly the plant becomes "struck," or "stuck" as it is technically termed, and when thus gorged it assumes, so to speak, a petrified or constipated aspect, and blanches through the destruction of the plastic material, the green colouring matter. A plant is only in normal robust health when the forces acting on its system are properly balanced. In botanical economy the two chief factors in the nutrition of the plant are the processes of *assimilation* and *metastasis*. Assimilation, which I regard as the counterpart of that normal reduction which gives rise to the normal negative or positive "plucky" image, or "perfect" picture, is only performed in cells containing chlorophyll, and then only under the influence of light, and ceases in the dark. The elaboration of the inorganic elements of two oxides (CO_2 and H_2O) into a carbohydrate I look upon as the type of the multiplication or development of the elemental molecules of the changed sensitive silver salt.

This process is quite distinct from that by which *the assimilated carbohydrate undergoes further alteration and changes its position* from one cell to another, this transference being accompanied by a change in chemical composition which constitutes metastasis, by which one compound, the carbohydrate, the protoplasmic prototype of our normally developable nucleus, is changed into another. But the resemblance between the conditions under which assimilation and metastasis occur, and between the circumstances accompanying a change from "normal" to "reversal" by no means ends here; for we have not only—

(*a*) Assimilation of inorganic elements into (organic) compounds, compared and contrasted with the metastatic resolution of these compounds into others which I accept with certain definite reservations as embodying the conditions under which the normal and reversing developable nucleus exists at the moment of contact with the developer, but we have—

(*b*) Assimilation taking place only in the presence of chlorophyll, whereas metastasis occurs indifferently either in the presence or absence of the green colouring matter. The former of these reactions is here to be viewed as equivalent to that state of matters in which the presence of a silver salt is essential to that aggregation of particles which admits of the formation of a normal image. The latter corresponds to that disintegration and displacement of the plastic material which takes place independently of the presence of a silver salt, as such.

(*c*) Assimilation, as a process which can only be accomplished under the influence of light, is different from that *continuing* metastatic process which, initiated indirectly by reflex action under that influence, goes on or is developed quite independently of its presence afterwards.

Note.—We must here carefully guard against confounding the parallel just drawn, and which runs closely throughout, with that which might suggest itself in the case of carbon printing. My leading idea is the comparison of the phases of silver salt normal, neutral, reversal, neutral, and normal, potential images, with a plant which, though it ultimately dies, sprouts, blossoms, remains comparatively stationary, fades, remains comparatively stationary, and blossoms again periodically.

(*d*) Assimilation as a process in which a chlorous element (oxygen) is liberated, is opposed to that metastatic process by which the chlorous element (oxygen) is recombined and its equivalent (in CO_2) liberated. These reactions are analogous to those conditions respectively admitting of the separation and recombination of the elements of the silver salt, developable alternately into a normal or reversal.

(*e*) In assimilation the dry weight of the plant is increased by the *fixation* of the essential element (carbon), and by the formation of carbohydrates. In metastasis there is loss of weight through production of removable chlorous (oxygenous) compounds from the organism. In normally exposed, developed, and fixed images the greatest density occupies that part of the film which has received most light; whereas, in the reversal, the part which has received most light develops no density and fixes more clearly. Thus we again see that the phases themselves form the scale upon which the difference between the assimilated or metastased material is read off, s upon a vernier, thus:—

(1) Half density = *assimilation mean.*
(2) Normal = *assimilation at a maximum.*
(3) Neutral or double half density = *assimilation mean and metastasis mean.*
(4) Reversal = *metastasis at a maximum.* HUGH BRENNER.

DETERMINATION OF PLATE SPEEDS.

A REPLY TO MR. WILLIAMS.

[London and Provincial Photographic Association.]

HAVING had the opportunity of seeing Mr. Williams's paper in print I venture the following remarks.

The first point that strikes me is where he says, "Such was the courage of my own opinions that I offered to submit everything to a disinterested jury;" and he then says, "To this challenge none of my dissentients have responded." In reply to this, I must remind him that a week previous to this the firm I have the honour to represent invited Mr. Williams and any committee of experts to practically test the matter at their works at Southgate, where every means is at hand to fully investigate the matter, but that, up to the present time, he had not availed himself of the offer.

Next Mr. Williams says, "For reasons best known to themselves, certain manufacturers have thought fit to adopt the system introduced by Messrs. Hurter & Driffield." All I can say in reply to this is that, for ourselves, the reason we adopted it was that, after exhaustive trials, we were compelled to admit that it was practically far and away the best method we were able to find for estimating the speed of plates, and after some thousands of trials we are more than ever convinced that we were right in taking the matter up and giving to the public the rapidity exactly as we found it of each batch of plates.

That we may have made some mistakes is quite possible, but I think if they had been very grievous ones we should certainly have heard about them soon enough; but I am sure that, if such has been the case, they have been quite accidental, and only incidental to the difficulty of at once perfectly mastering a rather delicate operation.

Mr. Williams, in the beginning of another paragraph, says: "Judging from the tone of the correspondence, one might imagine I had sat down with the deliberate intention of demolishing the Hurter & Driffield theory." Now, I think, if Mr. Williams will refer to the opening paragraph in his original paper, he must really see that he did give some occasion for this idea, for his words were, "So one event in photographic history has been the complete discrediting of the results shown by the Warnerke sensitometer, and we shall probably not have long to wait before we see a similar fiasco." But I am glad to see that he concludes the paragraph in the present paper with, "As a matter of fact, I had no such idea."

In connexion with the paragraphs marked *a* and *b*, all I can say is this, such is my confidence in the Hurter & Driffield principle, that, if plates we mark do not answer to the relative speed number marked, it is we that have, as Mr. Williams puts it, "blundered," but that the "system is right." And members of this Society know how often, from time to time, I have shown results that fully bear out this contention, that the system is right.

With regard to the isochromatic portion of the paper, I submit that it would have been better not to have imported it into this discussion at all, as it is certainly a subject that requires separate attention.

Mr. Williams, in his concluding paragraph, quotes Mr. Andrew Pringle's article, alluding to Messrs. Hurter & Driffield as saying, "If they mean that, after all, we can materially control our practical results by controlling the developer and the following operations, then no more need be said; but, with their writings before us, we must say that it is by no means clear what they do mean in the matter." Now, I really think that, if their original paper is carefully read, it will be found that they have been very careful to express what they really did mean.

They first began by asking the question, "What is a perfect negative?" and defining is as being, "mathematically, the true inverse of the original when the opacities of its gradations are proportional to the light reflected by those parts of the original which they represent."

Again, they say "their experiments conclusively show that the only control the photographer has over the development lies in securing a greater or less density of image, and that he has no control whatever over the gradations of the negative."

"That, with a well-balanced developer, there is a limit to density,

which depends upon the action of light, and that, so far, the only control the photographer has lies in deciding whether he will reach that limit or not."

"That the length of time of development does not affect the ratio of densities among themselves, but increases every density by proportional amounts."

"That during the period of under-exposure the amount of silver reduced is directly proportional to the exposure."

"That during the period of correct representation the densities are proportional to the logarithms of the exposures."

So that a negative can only be theoretically perfect by "carefully adjusting the time to the intensity of the light, that the exposures may fall within that period of correct representation."

"That thickly coated plates give a very much greater latitude of exposure." This I take to mean, in the matter of over-exposure.

"That thinly coated plates, on the other hand, need very accurately timed exposures."

And lastly, "that, when the inertia of the plate is known, it is possible to time the exposures in the camera so that the densities of the gradations are almost exactly proportional to the light intensities which produced them."

After these quotations, it can scarcely be fairly said that "it is by no means clear what they do mean in the matter."

I was very pleased to find, on referring to this leader in *Photography*, quoted above by Mr. Williams, that in the sentence immediately preceding it Mr. Andrew Pringle says: "We have, from the first, applauded and valued the investigations of Messrs. Hurter & Driffield, and it is possible that we are at one with them; in fact, of late we have begun to think we are at one."

There is only one other point that occurred in the discussion that I should like to make a remark upon, and that was Mr. Williams's remark that you could not be sure of getting the same speed number of a batch at different times. In answer to that, I can only say that I have reproduced the same number at various times from pieces of the same plate (seven times), extending over a period of eight months, with the greatest error of four per cent.

In conclusion, I should like to read you part of a letter I received on Saturday from a member of this Society, at whose request I had tested five different plates and films which were unknown to me.

He wrote: "No. 5 is one of the sample plates you sent me some time ago. In this case the Hurter & Driffield number on the box tallies *exactly* with the one now given me, viz., 75. This goes far to prove that your method of testing is accurate, as, of course, you could not know that No. 5 was your own plate. When I get back into the civilised world, I must come to you to see how you do this testing, as it certainly seems the truest that I know of."

ALEXANDER COWAN.

THE MULTIPOTENT CAMERA.

[Cardiff Photographic Society. Abridged.]

THE camera which I am to show you this evening was invented by me in February last year. It represents an attempt to make a complete camera for small plates, and has, I think, important advantages.

This machine is the first model, and those which I am now making will be better, as, until I had made and tried the first model, it was impossible to settle the best size for every part.

I had hoped that one of the three now being made would have been ready to show you, but both the mechanic who is making them and myself have had so many other things to do that we have been able to devote very little time to them. No professional camera-maker has worked at this camera, so you must excuse imperfections. The only important alteration in the new camera is that I have greatly simplified and, I think, improved the mechanism for actuating the shutter; but the store-box grooves and all the parts are more accurately made to the sizes I have found best by the experience gained with this model.

The construction will be found fully explained in my complete specification, patent No. 3680 (1892), and I shall be pleased to lend any one a copy who may wish to understand the details; but I will not weary you by reading it now, but will briefly explain the camera and method of working it, and will afterwards point out its advantages.

In the upper half of the camera is the exposing chamber. There is a rising front, which carries the lens and contains the shutter at one end, and there is a door for focussing at the other. Below the exposing chamber is a fixed store box, extending from the back of the lens to nearly the plane of equivalent focus. This store box is grooved to hold twenty-five plates; it has a door at the bottom, through which the plates are inserted, and light is excluded from the top of it by leather bands, which are attached to a slotted plate, which is covered by a sliding door.

There is an exposing frame, which traverses the exposing chamber over the store box. This is actuated by a tail piece, which passes out through the back of the camera and is hinged so as to lie down in a recess. It has twenty-five holes drilled in it (in series of five), corresponding with the twenty-five grooves in the store-box.

If I want No. 13 plate, I put a peg in No. 13 hole and push the tail piece in till the peg stops it, then invert the camera, and No. 13 plate slides into the exposing frame and, still keeping the camera inverted, I pull the tail piece fully out, and press it down into the recess against a focussing screw which will be found there. This brings the plate into true focus for whatever distance the focussing screw is set.

To return the plate when exposed I again invert the camera, and push the tail piece into the peg (which has been left in No. 13 hole), then turn the camera the right way up, and the plate falls back into No. 13 groove in the store box. If, as generally happens, I want the next plate, I put the peg in No. 14 hole and proceed as before; but, if I want a lower number, say, No. 5, I first pull the tail piece fully back and then pull the pointers, which are attached to the leather bands, and which move in a slot at the bottom of the camera, forwords, put the peg in No. 5 hole and proceed as before.

The rule for changing plates is:—*When the exposing frame is empty, the camera must be held the right way up whilst the tail piece is moved. When the exposing frame has a plate in it, the camera must be inverted whilst the tail piece is being moved.*

I fill the holes in the tail piece with coloured wax to correspond with the kind of plates in the store box. For example, ordinary plates, white; extra rapid, red; isochromatic, green; and so on. When a plate is changed the peg pushes out the wax, so that I can tell at a glance what plates have been used and what are left.

The shutter is a disc perforated with two openings, one of which is shaped so as to give equal exposure over the plate, the other so as to give more exposure to the foreground than to the sky. The disc is attached to a drum, round which two cords are wound in opposite directions, and each cord is fixed to a spring. There is a catch on the drum, which is held by triggers. There are four triggers. If the right-hand spring is pulled down and held tight by a screw, it will pull the right-hand cord and cause the catch to press against the lower right-hand trigger. When this trigger is pulled, the catch is released, the disc flies round half a revolution till the catch is stopped by the left upper trigger, and the opening, which gives more exposure to the foreground than to the sky, will have passed across the lens. For the next exposure the right-hand spring is released, and the left-hand spring pulled down and secured by its screw, and to make the exposure the lower left-hand trigger is pulled. In landscape work this opening is used for about eight pictures out of ten, but when the other opening, giving equal exposure over the plate is required, the upper triggers are pulled instead of the lower.

For time exposures the triggers are put out of gear and the disc moved by pulling down the screw. This is a simpler way of actuating the disc than in my first model. I have not tried it yet, but I believe it will work as well, if not better. In the model a rocking lever is used to pull the drum round. This I have now done away with.

I prefer not to use a finder, but to work with a spirit level in combination with the rising front. My experience, when I used a finder, was that I was very apt to get buildings all wrong, but by working with the level there is no difficulty—all one has to do is to keep the camera level and point in the right direction and the horizontal line is settled by the rising front. Usually, of course, it will come about one-third up the plate.

The following appear to me to be the chief advantages of my camera:—

1. *It is very small and portable.* The quarter-plate size, with 4½-inch rapid rectilinear lens is only 7¾ inches high, 5 inches wide, and 6⅞ inches long; equals 265 cubic inches, and yet it carries 25 plates. This is considerably smaller than most automatic magazine cameras which carry only 12 plates.

I believe the new one will weigh about four pounds. It is well balanced, the centre of gravity being under the middle instead of at one end as usual.

2. *It has a full-size ground-glass screen,* which can be carried and used when the camera is on the stand as an ordinary focussing screen. I usually carry this in No. 25 groove.

3. There is a gripping contrivance so arranged that the camera can be easily attached and detached without shaking the tripod.

4. This enables stereoscopic pictures to be taken sufficiently quickly to do most views and some groups by first taking a picture with the left side up, and afterwards another with the right side of the camera up.

5. The front rises both for vertical or horizontal pictures.

6. The focussing can be adjusted from four feet to any distance, and, unless altered for any special reason, the focussing of every plate is automatic.

7. *The plates can be changed at the rate of three a minute.*

8. *Ordinary quarter-plates, extra rapid isochromatic, films in sheaths can be carried together, as well as ground-glass focussing plate, and used in any required order. Any number can be carried up to twenty-five.*

9. The coloured wax shows clearly what plates and what kind of plates have been used, and what are left, so there is no fear of double exposure.

10. *The shutter automatically covers the lens when not exposing, and is ever set.* It will give exposures of any length.

11. *The shutter will give equal exposure over the plate, or more exposure to the foreground than to the sky, as required for each picture.*

12. *The camera is easy to use and works well.* I find it much easier to use than an ordinary camera, whether for hand or stand work.

Even with this first model there are no hitches, except when the plates are too thick. I did not make the grooves sufficiently wide for some of the thicker plates which occasionally come in a box. In the new camera that is rectified, and also the grooves are accurate, which is not the case in the first model.

13. There appears to be a singular freedom from halation. I think this is due to the construction of the camera, by which the light has to pass through the plate some little distance before it reaches any backing.

What I have done with it in the limited time I have been able to give to it I will now show you with the lantern. I think you will agree that the interior of the Cardiff Market, or the Arcade outside our rooms here, is the most difficult, as they had both to be done in about one-tenth of a second. I used *f*-5·65 and very rapid plates for them.

T. E. HEATH.

Our Editorial Table.

CADETT'S "SNAP-SHOT" AND "LIGHTNING" PLATES.

MESSRS. CADETT & NEALL, Ashtead, have sent us samples of their "Snap-shot" (125° Hurter & Driffield) and "Lightning" (140°) plates. Both kinds of plates work to a remarkable degree of rapidity—the "Lightning" especially so—and yield with normal development images of great fineness and brilliancy. It should be mentioned that Messrs. Cadett now pack some of the sizes of their plates face to face with the films uncut.

OPTIMUS OPAL PRINTING FRAME.

By PERKEN, SON, & RAYMENT.

THIS well-known firm are placing on the market an opal printing frame which is calculated to prove eminently useful to all who practise opal printing. The frame is hinged (book fashion) in the middle. In one half provision is made for holding the negative so rigidly that it cannot possibly get displaced, similar provision being made in the other wing for holding the sensitive opal plate, which can be brought into the most intimate contact with the surface of the negative and remain undisturbed throughout, no matter how often the frame is opened up for inspecting the progress of the printing. This perfection of registration will commend itself to the user. The frames are being made in various sizes.

AMATEUR PHOTOGRAPHY.

By W. L. ADAMS. New York: The Baker & Taylor Co.

THIS little volume has not been written for the scientific or practical photographer, but for the class which desires to have a popular knowledge of an art of which every person is now supposed to know something. It forms in a large measure a reprint of popular articles written for the *Christian Union* and *Outing*. We think the author does not do his countrymen full justice in saying that instantaneous photography is but a few years old, and that it was only made possible by the introduction of gelatine plates, for not only have instantaneous street views of New York taken by collodion been reviewed in this JOURNAL nearly a quarter of a century since, but the taking of such pictures has been specially referred to in Snelling's New York publications in 1853. The *brochure*, however, forms pleasant popular reading.

THE NEW CATALOGUE OF MORGAN & KIDD, RICHMOND, LONDON, S.W.

THIS is a most useful and comprehensive price list of all the specialities of this firm, which are now of a very extended nature. Comprehending their argentic gelatino-bromide papers for enlargements and contact prints; enlarging apparatus and materials; dry plates and oil paintings on canvas, with or without photographic base; enlarging on every practicable medium, whether canvas, opal, or paper; miniatures on ivory; platinotype, collotype, mounts, and even frames, all find place in tabulated form in this well-arranged price list.

THE Brighton Enlarging Company, of 57 and 58, Clarence-square, Brighton, are issuing a revised trade price list of enlargements in carbon, bromide, platinum, &c.; copying and negative making; printing in silver, bromide, &c.; and painting in oils and water-colours. The prices appear to be very reasonable. We note with pleasure, as evidence of the progress of trade printing at the Queen of Watering-places, that the Company has an installation of electricity for lighting and drying purposes.

THE Imperial Dry Plate Company, Cricklewood, have issued a booklet containing the formulæ which the Company consider the best to use with their plates, as well as hints regarding the dark room, exposures, taking the negative, toning, &c. The information and hints are in such a form as to be very useful, not only to users of the Company's excellent plates, but also to photographers generally.

PATENTS COMPLETED.

IMPROVEMENTS IN AND RELATING TO FILM PACKAGES FOR PHOTOGRAPHIC CAMERAS.

No. 8650. B. J. EDWARDS, The Grove, Hackney, Middlesex. *March* 4, 1893.

MY invention relates to film packages for photographic cameras and roller slides, and to means for adapting my improved packages to be used in ordinary roll-holders or cameras.

One object of my invention is to provide a light-tight film package for roller slides, which may be used in existing cameras or roll-holders, and changed in daylight, and which packages will take the full width of film for which such cameras or roll-holders are constructed.

Another object of my invention is to make the film packages interchangeable, so that in existing cameras the empty roller, with its sheath, can be changed and used as a receiving roller.

According to one part of my invention, I provide a film package so constructed that the extreme length of the said package exceeds but a very trifling amount the width of the film to be contained therein, and so mount the roller in a sheath that no light shall be admitted to the interior of the package. To this end I construct my improved packages with special end pieces or caps of very thin material, which also serve as efficient bearings or support for the roller, and also allow of the roller being rotated from the outside of the case.

My improved package comprises a roller on which the film is wound, and a sheath or covering for enclosing the film and protecting the said film from light. The sheath or covering is made of cardboard or other suitable material shaped or folded so as to form a hollow tube having a slit or opening throughout its entire length, through which slit the film is drawn. This slit is made light-tight by binding its edges with strips of velvet or the like. I provide the folded sheath or covering with end pieces constructed of very thin material, preferably of thin sheet metal, which can be very cheaply produced of the required shape by stamping. The bearings I form as follows:—I provide an annular recess in each end of the roller, and I stamp or otherwise form a central circular opening in each cap or end piece, and turn inward the edges of the said openings so as to form flanges which fit into the said annular recesses in the roller and serve as bearings therefor. The outer edges or rims of the said caps are turned or flanged inward to fit tightly over the ends of the sheath

or covering. By this construction I not only utilise the full length of the roller for the film, but I avoid, in a simple manner, all risk of the light finding its way into the covering and so spoiling the film. I construct one or both ends of the roller to form a clutch to engage with the fittings of the camera or roll-holder, thereby enabling the roller to be turned from the outside of the case by the winding key.

In order to enable my improved light-tight film packages to be used in roll-holders or cameras as usually constructed, which are not adapted for being charged or refilled in daylight, and in which the fittings of the discharging and receiving rollers are not of a uniform pattern, I provide a device which I term an "adapter." This device is adapted to fit without turning in the end of my improved spool or roller, and is shaped at its outer end to fit on the usual key or clutch of the receiving roller of the ordinary roll-holder or camera. This "adapter" can be arranged to fit or connect with any kind of clutch, and is removable or interchangeable. By means of this device my film packages can be used in existing cameras and the empty spool or roller with its light-tight case may be used as a receiving roller, the ordinary receiving roller being dispensed with. When the receiving roller is full, it can be removed and an empty spool with its light-tight case put in its place, the "adapter" being changed from the full roller to the empty one.

The claims are:—1. A film package or case having a roller provided with an annular groove in one or both ends, to form a bearing surface or bearing surfaces on which the roller can turn for the purpose specified. 2. A film package or case provided with caps or end pieces having annular interval projections to form bearings for the roller, substantially as described, for the purpose specified. 3. In a film package or case, a roller having an annular groove formed in one or both ends, forming bearing surfaces for the roller, in combination with end pieces having central openings, the edges of which are turned inward and are adapted to fit in the said annular grooves for the purpose specified. 4. The combination with the light-tight sheaf or covering and the roller, of thin sheet metal or other suitable end pieces, having rims adapted to fit tightly on the sheath and central circular openings, the edges of which turn inward and are adapted to enter annular grooves in the ends of the roller, and form bearings for the roller, with or without other fastenings to hold the ends in place, substantially as described for the purpose specified. 5. A light-tight film package or case provided with internal annular bearings for the roller, which enable the roller to be rotated from outside the case, substantially as described. 6. A light-tight film package or case constructed substantially as described with reference to the drawings. 7. In a roller slide a movable "adapter," which enables the rollers to be interchanged, substantially as described. 8. The combination of the light-tight sheath, its end pieces, the roller, and a sensitive film wrapped on the roller, substantially as described.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

April 25,—Technical Meeting,—Mr. T. Sebastian Davis in the chair.

The Hon. Secretary exhibited and explained a model of a new hand camera by Messrs. Campion & Delacre. It has a reflecting mirror inside, so that the image can be seen of the size of the original. The principal movements are effected by working a lever at the side of the camera, which first of all uncovers the lens, then covers it up, actuates the shutter, and changes the plate. It was said to be possible to expose a dozen plates in twenty-five seconds in this camera.

"The Manufacture of Gelatine Dry Plates."

Mr. J. Desiré England gave a practical demonstration of gelatine emulsion-making, saying that if no great rapidity was desired, the first process he should describe was a very simple one for the purpose. Sensitiveness depended upon the formula and method of working, as well as many small details. The preparation of an emulsion might be divided into three stages—the mixing, the emulsification, and the washing. The gelatine for the first stage should be of a soft kind, such as Nelson's No. 1, and for adding to the emulsion a hard kind, such as Heinrich's or Drescher's. Having reviewed the stewing, boiling, and ammonia methods of emulsification, he gave the following formula, recommending a temperature of 110° to 120° Fahr., for mixing Nos. 1 and 2.

1.

Potassium bromide	90 grains.
Potassium iodide	3 ,,
Soft gelatine	20 ,,
Hydrochloric acid	2 minims.
Water	1½ ounces.

2.

Silver nitrate	120 grains.
Distilled water	2½ ounces.

3.

Gelatine (hard)	150 grains.

The silver solution was passed slowly into the bromide solution through a plug of cotton wool placed in the neck of a funnel, the wool also acting as a filter, the bulk of the gelatine being added afterwards. The acid obviated fog, which would be caused by the gelatine and bromide of potassium being alkaline. When first mixed, the emulsion should be of a ruby colour by transmitted light, showing that the particles of bromide were in a finely divided state; the colour passed by boiling for an hour or so to violet, blue, green, grey, but the latter should be avoided or the plates would fog. Mr. England then gave the following formula for an ammonia process which, he said, gave great rapidity, and was due to Mr. Henderson, a great authority on the ammonia method:—

1.

Soft gelatine	20 grains.
Potassium bromide	180 ,,
Potassium iodide	3 ,,
Water	4 ounces.

2.

Silver nitrate	240 grains.
Distilled water	4 ounces.

3.

Gelatine	360 grains.

No. 2 is converted into silver ammonio-nitrate with the strongest liquor ammonia, and 1 and 2 mixed at 105–110° Fahr. The emulsion should be placed in a vessel, and in three quarts of water at 130°, and when the water has cooled the emulsion might be considered sufficiently rapid.

Mr. England then recapitulated the various methods of washing, demonstrating the process by squeezing some set emulsion into fine shreds through some mosquito netting into the wash water. After washing for four or five hours in different changes of water, it is melted at 110°, five per cent. of methylated spirit and from one-eighth to one-quarter grain of chrome alum per ounce added. It is then filtered through swansdown, which, tied over one end of a lamp-glass, Mr. England finds a useful filter. He recommended coating with the emulsion at a temperature of 100–105°, and for drying said nothing answered better than the drying box suggested by his father, Mr. W. England, several years ago.

Most of the points mentioned in his address were demonstrated by Mr. England, who was thanked by the meeting. A discussion took place, but no new point of interest was elicited.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

April 20,—Mr. E. J. Wall in the chair.

Messrs. F. B. Shaw and T. J. Honeybourne were elected members.

Determination of Plate Speeds.

The adjourned discussion on Mr. G. F. Williams's paper was resumed by Mr. A. Cowan, who read a reply thereto [see p. 262].

Mr. James Cadett said he had had an opportunity of reading Mr. Williams's paper in print, which began with an attack on the Hurter & Driffield system and finished with a personal attack on a platemaker, of which he (Mr. Cadett) did not know the true motive. Therefore perhaps Mr. Williams would say, as there was a general idea that he was connected with the Ilford Company, and had written in *Photographic Scraps* as "Technique," whether he was in the pay or the employ of any platemaker whatever. He asked the question because there seemed to some animus on Mr. Williams's part. Mr. Williams, in his first paper, condemned the system, but in the second he altered his conclusion, saying, "If these plates" (the plates he had tried) "had ever been submitted to an examination in an instrument of precision, such as we are led to believe the Hurter & Driffield modification of Bunsen's photometer is, then I say, if the system is right, the plates are wrong, and the examiners either do not understand the system or have blundered." It showed a very poor decision on Mr. Williams's part if he was unable to decide where the fault was. If Mr. Williams was unbiassed, he might have suggested that the apparatus was wrong, or that some matter had upset the results which would not destroy the theory. He had said elsewhere that he did not care to accept his (Mr. Cadett's) challenge, knowing that the theories of both of them were so wide apart, but Mr. Williams had never given his view of the theory. Mr.

Williams said he did not believe the statement with regard to the densities, or rather of the opacities, being proportional to the exposure, therefore the theory was wrong. The whole theory of the system was that the opacities were directly proportional to the intensities of the light that produced them. That was either right or wrong, and if Mr. Williams said it was wrong, perhaps he would tell them why. Mr. Williams had pointed out the admission of an error on their part. It was true that in December he and Mr. Cowan had admitted errors of twenty-five per cent. with the standard candle, but that was stated in *Dry Plates* before Mr. Williams's paper appeared. As regards what Mr. Driffield had said as to orthochromatic plates, he wished to qualify what he had told them. He had made no systematic or exhaustive investigations on the subject. In the few instances of orthochromatic plates tested, he had found the speed ascertained by candle to be confirmed in the camera. Having complained of Mr. Williams's tone with reference to orthochromatic plates, Mr. Cadett said he had not conveyed that orthochromatic plates were not orthochromatic. They clearly were so. Last week at the Camera Club Conference, he had attended Captain Abney's and Mr. H. M. Elder's lectures on the speed of plates, and he was exceedingly pleased to find that they both confirmed the general accuracy of the Hurter & Driffield system. Captain Abney was a strong opponent of the system, but it was a pleasure to argue with him. He (Mr. Cadett) could confirm what Mr. Cowan had said as to the system being right. Mr. Williams said the system would probably be thrown up. Mr. Williams was wrong. They wanted figures before them before they gave it up. At the previous discussion Mr. A. C. Edwards remarked of the two plates passed round by Mr. Williams, one of which was developed more than the other, that any one could see that one had had a little more exposure than the other, and asked why Mr. Williams should have forced it. Even among two opponents of the Hurter & Driffield system, they found very considerable divergence. With regard to the Warnerke system, there were two reasons why it was not successful; one was the practical difficulties of making the screen, and the next was that all those who used it found that if they judged the exposure by the last few faint tints, it did not agree with the camera tests. In Mr. Williams's tests he went for the last faint tints and those only. In using the screen we got into that very period of under-exposure which Hurter & Driffield pointed out. We used to get into the habit of including the last five figures, and try and judge by the row immediately preceding them. Messrs. Hurter & Driffield said that, theoretically, the point chosen by them to indicate the speed of the plate was not the correct one; it was a sort of geometrical mean in the densities, but practically it would not be easily found, so that they carried the line to the base, and made a constant. Those who found fault with the figures in the Warnerke system were trying to get at what Hurter & Driffield had got at. In testing plates to-day, they only found a very small period of correct exposure, all the rest was either over or under-exposure. The result was, that unless we took a range throughout the speed, it was quite impossible to tell what the correct speed was. During the last two days he had tried some foreign orthochromatic plates with regard to the Hurter & Driffield system. He found that the period of under-exposure was so enormous, that he practically got two straight lines in the two cases.

Mr. W. E. DEBENHAM said that, with regard to the question of orthochromatic plates, the use of a candle was really equivalent to that of a screen; the light contained some blue, but it was very rich in yellow. If a plate was found which bore the same proportion to candle-light and daylight, it should not be called orthochromatic. Those who have affirmed that they find no difference, should make some conclusive tests, and show them to be similar. His impression was they would come out as from 4 to 10 : 1.

Mr. CADETT did not find that the orthochromatic plates he had tried were very slow in the camera.

Mr. COWAN had cut two standardised plates in half, and taken two medium and two instantaneous isochromatic plates. One of each three was exposed to candle-light without any screen. Upon measuring, the ordinary plate came out 1·15, the medium isochromatic 1·1, the instantaneous ·55, practically double the speed of the medium. Then he had exposed the other three, using the yellow cap and the readings were respectively, ·80, ·775, ·475, so that the three plates practically kept their same relative rapidity with the glass that they did with the candle.

Mr. CADETT had witnessed measurements of orthochromatic plates by the spectrum, when it was found that their sensitiveness to yellow had increased 500 times.

Mr. DEBENHAM understood Mr. Cadett to say that he found the camera not accurate. If by comparison with Hurter & Driffield's tests it was not accurate, then that system must be wrong. Mr. Cadett had spoken of the Warnerke sensitometer giving incorrect results if we took the last few figures. On that point Mr. W. K. Burton and he made some experiments several years ago, proving that if the last few numbers on the Warnerke screen came very much alike they ought to be disregarded, and that they ought to take the point where there appeared to be a decided increase. Messrs. Hurter & Driffield had done a very good thing in carrying that idea out, and showing where the point of departure should come. As regards Mr. Cadett's question to Mr. Williams as to whether he wrote for *Photographic Scraps* as "Technique," he would ask Mr. Williams in consideration of journalistic etiquette not to give any reply to the question.

After some remarks from Mr. J. B. SPURGE, who said he got the same shape of curve with any system, and who promised to develop the subject of his remarks on a future occasion,

Mr. ASHLEY COWAN read the following remarks on the subject:—In Mr. Williams's original paper he mentions that, "when the unreliability of Warnerke's sensitometer became apparent, our plate-makers quickly relinquished the issue of plates bearing any actinometer or sensitometer number, and a pretty general return set in to using the old nomenclature, such as ordinary, medium, instantaneous, drop-shutters," &c. And Mr. Williams further remarks that the description given to their plates by makers of good brands is such as probably fulfils all present requirements; the name fairly indicates the speed, and in the absence of any reliable method is actually preferable to misleading numbers. Now, I think that Mr. Williams, if he always made his exposures according to these names only, would find himself more at sea than if he went by these numbers; for to suppose that plates issued as ordinary or special, or whatever title it may be, by different makers, should of necessity be of the same speed, is out of the question, and, as has been the case this last year, where plates of even the same brands have been probably nearly doubled in speed. It is rather surprising that Mr. Williams (who in the commencement of his original paper) regrets that in photography we have no apparatus for the nicety of measurements such as we have in kindred sciences, should be content to judge his results in an unscientific manner when he can have at his command a system based on scientific principles, and which has taken years of patient thought and experimenting to build up and give as it was freely to the world for the advancement of the science of photography. The fact that the conclusions arrived at by Messrs. Hurter & Driffield are at variance with the ideas of Mr. Williams and other photographers does not of necessity in any way invalidate their system, any more than the old idea that the earth was flat did not in the least alter the fact that it was round all the time. And I hope in the same way we shall have Mr. Williams, when he has gone more carefully into Messrs. Hurter & Driffield's system, and worked it out for himself with the proper instruments, that he will find there is more in the principle than he at present thinks. Mr. Williams, I suppose, will admit that for every plate exposed, on whatever subject, there must be within the limits of the plate and the subject some correct exposure, and I should think he would admit that the more data that can be given to enable the operator to correctly judge that exposure the more nearly will his result approach perfection. Mr. Williams took objection to Messrs. Hurter & Driffield's photometer, and said that he found that he could not read the same with precision within two or three degrees. Claiming perhaps to have made as many readings with this instrument as any one, I must emphatically say that, if readings cannot be made within five per cent. of error, it is the fault of the operator, and not the instrument; only, of course, it cannot be expected that the first time any one reads with an instrument of this sort that they can at once master all the technical difficulties that have to be contended with, any more than if we set a novice to weighing in a chemical balance, and expect him to do it off correctly at once. Mr. Williams will, I should think, admit that when a new system is brought out, and a system which requires a certain amount of experience to work, it is not to be expected that, at the first go off everything is to be perfect. It must of necessity be a work of time to find out and rectify any little difficulties that may be met with, and, if any errors have occurred at the outset, they are surely not sufficient evidence to bring forward against the system itself. Mr. Wilson mentioned that he thought Messrs. H. & D.'s system was correct, within certain limits, but that development and temperature might affect the result. It was for this very reason we recognised the necessity that all who used this system should work with a developer of fixed proportions for a fixed time and at a fixed temperature, and we hope to be able in time to give a numerical value corresponding to alterations in development and temperature. But it must be understood that those who use this system and wish to work to the same standard of speed should carry out all their tests under precisely the same conditions. Dr. Hurter at the Camera Club very ably expressed in the form of an equation the different factors which governed the negative or as he expressed it, R the result.

$$R = I, L, T (S) D, t', \phi.$$

He shows that R, the result, is governed by the following factors:—

First, the I or intensity of the light;
T, time of action of that light;
L, lens which reduced it on to the plate.

These for simplicity we may call (E) or exposure. Then we have the speed of the plate (S):—

(D), development;
(t'), time of development;
ϕ, temperature of development.

∴ We have an equation,

$$R = E, (S), D, t, \phi;$$

So that here we see Messrs. Hurter & Driffield do admit there is control of the negative.

From this equation we know that, keeping all conditions the same, our result, R, must be the same.

And therefore, to get always the same value for S, the speed of the plate, we must keep the remaining factors constant. Then, when we know the speed of the plate, we can find what alterations we can get in R, our result, when we vary either E, D, t, or ϕ. So that here we have a very valuable stepping-stone to enable us to estimate the value by different alterations in development, temperature, etc., what we certainly did not have, before Messrs. Hurter & Driffield gave their valuable discovery to the world.

Mr. P. EVERITT said that the difference of results which Mr. Williams had noticed when compared with Messrs. Cadett and Cowan's might be largely due to the manner of procedure. Mr. Williams, perhaps, had not been accustomed to using Messrs. Hurter & Driffield's instruments, of which Messrs. Cadett and Cowan had had extensive experience. Mr. Williams was in the position of a man with a delicate chemical balance, who was used to weighing with a chandler's-shop scales. A person who judged densities as Mr. Williams had done was in that position. [Laughter.] They must also bear in mind that, if the Hurter & Driffield system was based on the standard candle, it had a variable balance to work on. It did not militate against the system if the results varied. The difference lay in the instruments used rather than in the system.

Mr. DEBENHAM remarked that if Mr. Everitt had been aware that Mr. Williams was one of the earliest experimenters with rapid plates, he would have withdrawn that observation.

Mr. EVERITT did not mean to make the observation with any personal intent.

Mr. WILLIAMS, in reply, said he felt he must not touch upon all the subjects raised, or they would not get away that night. As to Mr. Cowan's remarks

on the jury, what he (Mr. Williams) had said had been misunderstood. His (Mr. Williams's) proposal was that the jury might be selected by those gentlemen who were in opposition to him, and for them to nominate it. He was prepared to repeat his experiments before that jury. He had not the slightest doubt that there was a considerable number of blunders made in the estimation of the speed of plates. The only course open to him was to judge by the plates that came into his hands. As regards the orthochromatic part of his paper, that was at his (Mr. Williams's) option. Mr. Cadett's remarks were extremely weak. He (Mr. Williams) had spoken of crass ignorance or wilful perversion, and he had not backed out of it, and did not mean to alter his phraseology. Messrs. Hurter & Driffield's definition of a negative was wrong and incorrect, and it had been pointed out to them. They had said that we had no control over the ratios of densities, but they were climbing down. With reference to their ten years' experiments, had we not known other people who had given more time to subjects which have proved myths, such as perpetual motion? Mr. Cadett in his remarks said that density and density alone is how we must judge of the rapidity of plates. He (Mr. Williams) said they could not judge of the rapidity of plates by their densities. As to the standard candle, Mr. Cadett admitted its inaccuracy, and said he is investigating a light himself. If the Hurter & Driffield system was perfect, what was the necessity for a further standard light? If the system was correct, any uniform light should do. Then as to the photometer; probably not half a dozen gentlemen present had used it, and could not know the difficulties there were in using it. It was extremely difficult to read densities by it, and you might arrive at any conclusion you liked. One was likely to arrive at different conclusions every time plates were measured, and be too ready to adopt suggestions of any one standing by. The instrument was about five inches in dimension in each direction, and two paraffin lamps were used. It was extremely difficult to read the densities with anything like an approach to accuracy, and after reading them you had to plot them out on a chart [shown] and had to make a straight line come somehow. Personally, he would rather rely on his own estimation. His first articles in THE BRITISH JOURNAL OF PHOTOGRAPHY had been published because he was opposed to the principles of Hurter & Driffield's system, and desired to investigate their investigations. He would answer Mr. Cadett's question. He was not in the pay of any platemaker, nor had he been, and he had no animus in the matter. His motives had been misunderstood. He had a decided belief that the Hurter & Driffield theory was wrong, and the only way open to him at the moment was, when he saw plates speeded by their method, to test them. If they had been correct, he would have adopted the system. He had found discrepancies of about sixty-five per cent., and nothing was said about that; a great deal had been said about the ten per cent. on the two plates he had shown, which proved that manufacturers themselves did not agree on speed. Probably nobody but Dr. Emerson was flabbergasted by the Hurter & Driffield theory until plates speeded according to it were issued. After touching upon other points raised, Mr. Williams said that, if Mr. Ashley Cowan would give the speed numbers correctly, he (Mr. Williams) would adopt the system. He had heard a gentleman say that the Hurter & Driffield method was good for the platemakers, because the users did not know whether the speeds were right or wrong. In conclusion he said :—"I don't believe that light is the sole controlling factor in producing a negative, or that density is to be taken as an indication of rapidity; or that the ratios are unaltered by development, or that a candle is a suitable light when wishing to ascertain daylight densities. When we buy plates, it is for exposing in the camera; but we must not judge of them ourselves, but submit them to this machine and take Hurter & Driffield's speed!"

Mr. FRANK BISHOP said it appeared to him that Mr. Williams's experiments had been singularly unfortunate, as they had been made with plates that had been admitted to have been wrong in speed, and therefore Mr. Williams's arguments were wrong. His firm would give Mr. Williams six of their plates differing in speed considerably, and the same batches should be given to that Association for testing, and this would prove that the speed numbers were right.

After other remarks, a vote of thanks was passed to Mr. Williams, and the discussion terminated.

North London Photographic Society.—April 18, Mr. W. Walker in the chair.—The HON. SECRETARY said that with the fixing bath of ordinary strength he did not find amidol-developed prints lose density, and he showed a print which had been treated as follows :—After exposure the print had been cut into halves, one of which was developed with amidol and the other with eikonogen as equally as possible. The print being then cut into quarters, two of them, one by each developer, were left in the fixing bath for half an hour, and the others for one hour. After washing, the print was then mounted, and no sign of reduction was apparent in any part. Mr. F. HART then gave a demonstration on *The Chemical Treatment of Prints after Fixing*. He said the treatment referred to had for its purpose the elimination of hyposulphite of soda from the prints by chemical means instead of by the prolonged mechanical washing, which latter method was uncertain in bringing about the desired result, and generally brought about an undesired result by deteriorating the brilliancy of the prints. He had demonstrated his process to his fellow-members of the Society some years ago, but, in compliance with a request, he had pleasure in bringing it again before them; the more so, as only recently had he ascertained its usefulness in the manipulation of the gelatino-chloride and bromide papers, which had come into use in recent times. He had brought prints on albumenised, developed bromide, and printing-out gelatino-chloride papers. After fixing they had been washed in three changes of water, for two or three minutes in each water. He had a bottle of the third washing water with him, which he would presently show was well charged with hypo. The tray into which he was now about to put the prints contained a solution composed of thirty minims of his hypo eliminator (a special preparation of hypochlorite) to ten ounces of water. An iodide test paper, prepared with iodide of potassium and starch, dipped into this bath, was coloured a deep blue, caused by the production of iodide of starch. This paper, being then put into some of the third washing water just mentioned, was deprived of the colour, showing the presence of hyposulphite of soda in the water. The prints were then placed in the bath for five minutes. A test paper was not then so deeply coloured by it as at first, showing that the hypo in the prints had attacked the iodide in the solution, and rendered it less powerful to produce iodide of starch. The bath was then poured off and another of the same strength poured over the prints, in which they were left for another five minutes. A test paper then dipped into this bath turned the same deep-blue tint as the one dipped into the fresh solution, showing that there was then no hypo left in the second bath. The prints were then removed to a bath composed of twenty minims of strong ammonia to five ounces of water. The ammonia bath combines with the remaining eliminator, and there are left small quantities of chloride of sodium, ammonium, and sulphate of soda only in the solution, which are all removed by the final rinsings, and traces of which are of no more harm than the natural salts of ordinary tap water. After remaining in the ammonia bath for five minutes, the albumen prints were rinsed in two or three changes of water, and were then ready for mounting. The gelatine prints can be put into an alum bath for a short time before the final rinsings. The whole process takes about thirty minutes. Mr. BISHOP: The action of the hypo dissolves the unaltered chloride of silver and produces a double hyposulphite of silver, which is redissolved by the hypo, and is then perfectly soluble and can be washed out. If instead of washing out you eliminate the hypo which holds the silver in solution, it would seem that the silver must be dropped in the process, and this left in the print would be deleterious. Mr. HART: Not exactly so. The first action of the hypo is to produce hyposulphite of silver; this, in presence of an excess of sodium hyposulphite, forms the double hyposulphite of sodium and silver—a salt soluble in water. Now, in adding the eliminator, the hyposulphite is first converted into sulphate, and the trace of silver into chloride in presence of sodium chloride, and then the ammonia bath takes up the traces of silver chloride which is cleared away in solution. Mr. PARFITT: Under the ordinary process of washing, is there no way of ascertaining if there is any hypo left in the print? Mr. HART: You cannot very well arrive at it without destroying the print; you can test the washing water by letting the prints drip into water, and then generate hydrogen from that by pure zinc and hydrochloric acid, allowing the resulting hydrogen to impinge on lead paper. If the paper is discoloured, you know you have sulphur coming off, and by inference the solution contained sodium hyposulphite. Mr. BISHOP usually tested the washing water with the permanganate of potash test. Mr. HART: That is not a delicate test, as any oxidisable organic matter found in water will act on the permanganate. In answer to questions, Mr. Hart said that his process was a safeguard against blisters, and that it could be used for negatives as well as for prints. He had used it now for just upon thirty years with uniform success. As a word of warning, in conclusion, he would say, When you know that your print is free from hypo, see that the card you are going to mount it on, and also the mountant, are above suspicion.

North Middlesex Photographic Society.—April 24.—Mr. J. Matthews read a paper on *Retouching*, dealing with the subject not so much from the technical side as from the art point of view. He exhibited on the screen a number of slides from untouched negatives, and went fully into their defects, showing how a high light should be strengthened here, a shadow toned down there, and an unpleasant expression modified in another place, and then showing another slide from the same negative, after retouching, from which the practical value of the hints given could be seen. He stated, incidentally, that he preferred Faber's pencils to work with, and found he could do all he required with Nos. 2 and 3. He also went fully into the subject of matt varnishing and colouring on the back. The award for the best picture taken at Strand-on-the-Green was gained by Mr. H. Smith, and that for Waltham Abbey by Mr. S. E. Wall. The next meeting will be on May 8, when a demonstration of the carbon process will be given by the Autotype Company. Visitors are welcome.

Hackney Photographic Society.—April 18, Mr. J. O. Grant in the chair.—The Hon. Secretary invited members of the Society to join the new Central Club. Mr. T. J. Jones was nominated for membership. From the question box: "How to intensify an under-developed hydroquinone negative?" Mr. S. BECKETT said: "Use acidified mercury chloride, followed by cyanide of silver and potassium." The CHAIRMAN said he would use mercury chloride, followed by ammonia; had not found negatives fade. "How to strip a film without enlarging?" The HON. SECRETARY thought alum would prevent expansion after stripping. Mr. R. BECKETT suggested methylated spirit. Work was then shown by Messrs. J. S. Beckett, R. Beckett, Sodeau, T. H. Smith, Moore, Perry, Nunn, Dean, and Cross. Owing to some discussion having ensued at the previous meeting respecting the power of getting density with amidol, Mr. Sodeau was called upon to demonstrate that density was easily obtainable. The Hon. Secretary had requested some negatives to be brought up, having received varying exposures unknown to Mr. Sodeau, and the latter, with amidol, used dry, and twenty per cent. sulphite soda solution speedily and successfully obtained plenty of density. He said, in over-exposure he would use more amidol, and advocated, too, the use of citrate of soda (twenty per cent. solution), half-drachm to the ounce.

Putney Photographic Society.—Mr. H. Faulkner in the chair.—Mr. S. HERBERT FRY delivered a lecture on the *Sandell Plate*. Mr. Fry said it would not be necessary to take up the time of the meeting by demonstrating the development, as the process presented no special features as compared with any ordinary plate. The "Sandell" plates were made of two kinds, the "General" and the "Especial," the former having two films, the latter three. Each film was of a different speed, the slowest being nearest the glass in each case. For most purposes the "General" would meet all requirements; the "Especial" was necessary only for very difficult subjects, such as dark interiors, with windows opening on a bright light, where the shadows would require exposures hundreds of times longer than the best lighted parts. In manufacture the glass plates are first coated with an extremely thin film of the slower emulsion, which is allowed to become quite dry before the rapid films are added, each in turn being allowed to dry before the next is applied. The films were thus not in chemical or even mechanical contact with each other. Mr. Fry explained that the action of the films would be as follows :—The rapid

film would receive the first impression of the image through the lens; in case of prolonged exposure this film might be correctly exposed for the deepest shadows, and more or less over-exposed for the other parts; the developed film would therefore show full detail and correct density for the shadows, the other parts would show the usual symptoms of over-exposure, being practically clear glass in the highest lights. Now, as regards the second film. Each being very thin, the light will penetrate the first and act on the second, and the latter, being slower, will probably be about correctly exposed for the half tones; on development the shadows would be found to be nearly clear, and the sky probably somewhat lacking in density. To the third film somewhat less light will have penetrated, and, being slower than the others, all parts of the surface except the high lights will be under-exposed, and therefore develop up more or less as clear glass, whereas the high lights will have full density. When the three films are now considered as a whole, it will be found that the resulting negative will have full detail in the shadows due to the first film, being backed in these places by the clear glass of the second and third. The second film will give detail and density in the half tones, the first helping it as regards detail, and the third as to density in case of it having been perhaps a little over-exposed. The third film will give the required density to the high lights, the first and second having lost most of it owing to over-exposure, but will, on the other hand, retain detail. Obviously, the two extremes to be guarded against are exposures so short that the first film is not sufficiently acted upon, or so excessively long that even the last film is over-exposed. The first contingency is the most likely to happen, although it is claimed for the plates that they are as rapid as any in the market. Over-exposure is almost impossible, as the latitude with the triple and even with double film is simply enormous. As an example, it was mentioned in the course of the discussion which followed the lecture, that three plates had been exposed by a member of the Society on the same subject, one receiving one-twentieth, the other one, and the third twenty seconds' exposure, the range being 400. The three plates were developed in the same developer, and gave very presentable negatives. Mr. Fry stated that, in modifying the developer, even this remarkable range might be exceeded without materially affecting the resulting negatives. It might at first sight appear that there would be little or no advantage in using these plates for very short exposures, as probably only the rapid outer film might be brought into action. This was, however, not the case, as the entire absence of halation gave a roundness and vigour to the image which could not be obtained by any other plate to the same degree, even when backed in the most effective manner. In order to take full advantage of the qualities of the plate, it was in contemplation to use so rapid an outer film as could not possibly be worked on any ordinary plate, as such a film could not by itself be made to give the necessary density by any known developer, the difficulty of obtaining density being at present the obstacle which limits the speed of plates coated with only one emulsion. Mr. Fry gave the formulæ sent out with the plates, and remarked that they also appeared to work very well with others in general use. The particular formula had certain advantages, among others that it did not soil the hands; it was well worth a trial, and he urged its adoption. The development did not present any special features. It might with advantage be carried on tentatively, starting with a somewhat weak developer and increasing the strength as required. By this method the top film was kept free from fog, and progress could be more readily judged. If the developer happened to be too active, the image on the first film might flash up and fog over as usual with over-exposure; but this by no means meant that the negative would be a thin or poor one. Development should be proceeded with until the necessary density was obtained, and this could be judged by transmitted light in the usual way, and the worst that would be found to have happened would be that the outer film might be slightly veiled over; but this would not affect the printing qualities of the negative in any other way than slightly retarding the operation. It was necessary to use a strong fixing bath —eight ounces of hypo to the pint of water was recommended. Mr. Fry exhibited specimen prints and some of the negatives from which they were taken, both "General" and "Especial," and they fully bore out the claims made. The interiors, many of which were taken under extremely trying conditions, were entirely free from every trace of halation; full detail was given in the deepest shadows and highest lights, and the half-tones and gradation were excellent. There was also a roundness and relief which are too often absent from prints from ordinary negatives. Snap-shots, showing people and animals in rapid motion, yachting, wave studies and scenes from the seaside full of life and animation, clearly showed the capacity of the plates as regards speed; their sharpness proved beyond argument that the shutter had been used at a high velocity, and their technical excellence was a tribute to the high character of the other qualities of these plates.

South London Photographic Society.—April 17, Mr. H. G. Banks (Vice-President) in the chair.—Mr. Moss reported that, in using Mr. Warnerke's developer for gelatino-chloride paper, he found that xylonite dishes were dissolved by the acid, and at the same time discoloured the pictures. Mr. H. G. Banks exhibited a number of slides illustrating the scenery on the Pennsylvania Railway. Mr. John A. Hodges, President of the West London Photographic Society, apologised for not being able, owing to an accident to his slides, to deliver his lecture on *North Wales* in its entirety, but brought others illustrating other photographic fields. He opened his lecture with views of north Somerset and north Devon. Dunster he considered to be one of the finest places for photographic work. After several views in the village and district, he described the villages of Porlock, Lyumouth, and Lynton, and introduced his hearers to the beauties of East Lyn about Watersmelt and Rockford. Ilfracombe and Clovelly were also illustrated. Mr. Hodges reminded his hearers that it was not necessary to go far to get pictures. He illustrated this by showing views of Hampton Court, Kew Gardens, Strand-on-the-Green, Kew, Burnham Beeches, and Stoke Pogis, and some figure studies. Haddon Hall was next shown. The photographer was allowed for a small fee of 2*s.* to hire the keys of all the doors there, and photograph to his heart's content. The Vale of Llangollen and Dolgelly contained some very fine views, in which foliage predominated. He believed the secret of taking such views successfully was to give a long exposure, and showed a view that had had two minutes' exposure at *f*-22, the sun shining at the time. Barmouth he recommended to them with not much time to spare, and was a capital centre. Bettws-y-coed and neighbourhood received some attention. In conclusion, Mr. Hodges suggested that Societies should join with each other in their excursions.

Tooting Camera Club.—April 14, Mr. Anderson (President) in the chair.—The report of the Sub-Committee, *re* headquarters, was read to the General Committee, and after some discussion it was decided to submit the matter to the ordinary meeting, which was done, and, after being thoroughly debated, unanimously adopted; so that, within a week or two, as soon as the necessary alterations can be completed, the Club will be in exclusive possession of a large meeting room capable of holding one hundred persons, a good-sized dark room, and a corridor fitted with shelving and containing plenty of room for lockers. An adjoining flat roof will also be found useful for printing and camera work, as likewise the meeting room itself, being exceptionally well lighted. The rooms will be at the service of the members at all times. The same Sub-Committee, viz.:—Messrs. Beckett, Child, and Dollery, were asked and undertook to carry out all the necessary arrangements. Messrs. Alexander, Buchanan, C. Sorrell, and Nock were elected active members, and Messrs. Fraser, Mellhuish, Morden, and Newman honorary members, making a total of eight new members for that night.

Croydon Camera Club.—April 19, debate, *What is the best System of Judging?*—This was opened by the President, and after a discussion, it appeared that the opinions expressed were decidedly in favour of the mark system. The medals awarded at the late Exhibition were presented to Messrs. White and Hallum.

Greenwich Photographic Society.—April 5, Mr. W. Ellis, F.R.A.S., in the chair.—Messrs. C. Churchill and G. S. Criswick were appointed delegates to the affiliated photographic societies. Messrs. Graham, A. Haddon, T. Lewis, and C. Churchill were appointed to form an excursion committee. Mr. G. S. Criswick, F.R.A.S., then delivered a most interesting lecture on *Star Charting by Photography*, illustrated with lantern slides prepared by himself. This apparently abstruse subject was treated so skilfully by Mr. Criswick that it was of unique interest to those present. It may be of interest to amateurs and professionals alike to know that, for the stellar survey which is at present being carried out, an aggregate of no less than 22,400 negatives will have to be supplied by the various observatories at work. At the close of Mr. Criswick's lecture, a very hearty vote of thanks was accorded him. Mr. S. Herbert Fry gave an exhibition of pictures taken on Sandell plates, which evoked considerable discussion, Mr. A. Haddon producing results obtained on ordinary plates, by backing, which he justly claimed were quite equal to anything turned out on Sandell plates.

Woolwich Photographic Society.—April 13, Rev. S. Chettoe, M.A. (President), in the chair.—Mr. W. John Belton gave a successful demonstration on the *Paget Printing-Out Opals and Lantern Plates*. He toned several plates during the evening which were generally admired.

Ashton-under-Lyne Photographic Society.—April 13, Exhibition of Lantern Slides.—A vote of thanks was given to Mr. Charles Lord for his present to the Society of a framed 20 × 14 enlargement of one of his Swiss views.

April 22.—The members of the Society, numbering seventy ladies and gentlemen, had their first ramble of the season, to Marple. They were met at the station by Mr. Joel Wainwright, a resident of that delightful neighbourhood, who conducted the party, through private grounds, to some of the oldest buildings, and most beautiful scenery, for which Marple is noted. He made the ramble very interesting by his description of the places of historic interest, interspersed with much humour and poetic language. The party took a great number of views, and finally finished up the afternoon, by Mr. Wainwright's kind invitation, at his residence, "Finchwood," where he had provided tea and other refreshments on the lawn. After partaking of these good things, the party were photographed in front of the house. There were thirty-six cameras in the company, and over 150 plates were exposed during the afternoon.

Birmingham Photographic Society.—April 18, Mr. G. F. Lyndon in th chair.—Five new members were elected. A set of slides lent by the Chelten ham Society were shown. Especially fine were a series of interiors of Glou cester Cathedral, beautifully chosen, and splendidly executed. A number o hand-camera seaside studies were also very good.

Derby Photographic Society.—April 18, Mr. A. B. Hamilton occupyin the chair.—The Chairman announced that two delegates were required for the Photographic Society of Great Britain in connexion with the affiliation scheme. Messrs. R. Keene and T. A. Scotton (Hon. Secretary) were elected. Mr. R. Keene was then called upon to give a paper entitled *A Six Days' Photographic Tour through Derbyshire*. This tour took place between twenty and thirty years ago, when photography was very much different from what it is at the present day, the party having to take with them a huge cart, with rope attachment, and which they had great difficulty in pulling about from place to place. Commencing at Rowsley, where the Midland Railway then terminated, the route taken was by Baslow, Eyam, Hathersage, Castleton, Miller's Dale, and back to the starting-place. Mr. Keene had to illustrate his paper by 170 lantern slides, most of which had been taken on this excursion. These were very beautiful examples of his work. Mr. C. B. Keene officiated at the lantern.

Gosport Photographic Society.—April 11, Mr. T. E. Williams, Vice-President, occupied the chair. Mr. R. E. Froude read a paper on *Experiences of a Kodak with Continuous Films*.

Newark Camera Club (Newark, N.J.).—April 10.—The following Officers were elected for the ensuing year:—*President:* Mr. Thomas A. Hine.—*Vice-President:* Mr. J. M. Foote.—*Executive Committee:* Messrs. William Archibald, Harry W. Smith, William A. Halsey, Charles Leroy, Frank S. Olds, A. C. Munn H. C. McDougall, J. M. Foote, Fred A. Schuetz.—*Treasurer:* Mr. C. G. Hine —*Secretary:* Mr. D. S. Plumb.

Newcastle-on-Tyne Photographic Association.—A monthly meeting of the Newcastle-on-Tyne and Northern Counties Photographic Association was held on April 11 in the Meeting-room of the Art Gallery, Newcastle. Mr. H. G. Ridgeway (Vice-President) was in the chair, and there was a large attendance of members.—The outdoor meetings for the present year were fixed as follows:—May, Steward-le-Peel; June, Fountains Abbey; July, Richmond; August, Alnwick; September, Seaton Sluice and Seaton Delaval. Mr. WILLIAM PARRY read a paper on *Retouching*, and a discussion followed.

Rotherham Photographic Society.—April 11, Dr. Baldwin (President) in the chair.—Three new members were elected. Mr. Leadbeater (Treasurer), in a paper on hand cameras, considered such apparatus as the premier plate spoiler, and said he should like information as to the proportion of really good negatives out of total plates exposed. When understood, the hand camera was a most interesting and enjoyable companion, and had been one of the best advertisers of modern photography. Hints on construction and use of hand cameras, and also on plate and film development, were given.

Society of Amateur Photographers of New York.—April 11.—The following Officers and Directors were elected for the ensuing year. *President:* Mr. R. A. B. Dayton.—*Vice-President:* Mr. L. B. Schram.—*Directors:* Messrs. C. Van Brunt, R. L. Bracklow, R. H. Lawrence, F. C. Elger, E. Warrin, H. S. Mack, H. A. Smith, A. F. Schoen.—*Treasurer:* Mr. C. C. Rommage.—*Recording Secretary:* Mr. T. J. Burton.—*Corresponding Secretary:* Mr. W. F. Hapgood.—*Secretary:* Mr. T. J. Burton.

FORTHCOMING EXHIBITIONS.

April 28–29	*Crystal Palace. The Executive, Crystal Palace, S.E.
,, 28–29	*Photographic Society of Philadelphia. Hon. Secretary, R. S. Redfield, 1601, Callowhill-street, Philadelphia, U.S.A.
May 4–6	*Forfarshire Photographic Association. Hon. Secretary, W. J. Anckorn, West Port, Arbroath, N.B.

* Signifies that there are open classes.

Exchange Column.

*** *No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance. The full name of the advertiser must in all cases be given for publication, otherwise the Exchanges will not be inserted.*

Exchange Morgan's multiplex background for studio accessories, children's principally.—Address, PARKINSON, photographer, Warrington.

Exchange cabinet rolling machine, plate glass bed, for good cabinet lens, background, or studio camera.—Address, C. H. HATCH, Alderley Edge.

Wanted, half-plate camera, McKellen or similar pattern, in exchange for Marion's embossing press complete.—Address, W. H. HUNT, 73, Trafalgar-road, Peckham, S.E.

Wanted, 12×10 camera lens, modern make globe enameller, stereoscopic outfit or hand camera. Exchange tricycle by Singer & Co., Coventry, almost new.—Address, J. ASTON BRIGGS, Whitby.

Exchange tricyle, Beeston Humber, worth 5*l.* or 6*l.*, for 10×8, 12×10, or hand camera; machine in good condition, and easy driver.—Address, R. H. BLYTH, photographer, Ilfracombe.

Wanted, good whole-plate field camera, reversible back, with three or six slides, ease and stand, in exchange for 10×8 camera (Fallowfields) and two slides. Difference cash.—Address, WHITE, High-street, Lewisham.

Will exchange quarter-plate camera, Kinnear pattern, latest improvement, three double slides, three folding tripod, for half-plate camera, Kinnear pattern, and three double slides, and tripod in good condition, approval.—Address, J. K. SMITH, Little London, Rawdon, near Leeds, Yorks.

Correspondence.

☞ *Correspondents should never write on both sides of the paper. No notice is taken of communications unless the names and addresses of the writers are given.*

MR. TEAPE AND THE SANDELL PLATES.

To the EDITOR.

SIR,—Referring to Mr. Teape's letter in your last issue, I am glad to note that he continues to find the "Sandell" plates less subject to halation than the other plate against which he tested it. We are at one upon that head, and when my critic consents to abandon the pseudo-scientific or magnesium-wire method of testing, and instead makes negatives upon the plates, for which purpose they are intended, I think we shall be in accord again in the finding that for all practical purposes a multiple film gets rid of the defect of halation. There is no test so convincing, and I may add so useful, as the test of making a negative upon the plate under trial. There is none so liable to mislead as the semi-scientific test. But, whatever test be adopted, development should be effected so as to make the best of each competing plate.

Regarding the "tentative" development, I am quite doubtful whether Mr. Teape and I mean the same thing. Sixty-five minutes, as mentioned in his letter, is slow development, not tentative. By tentative development I mean that I begin with a sufficiently weak and restrained solution, which I gradually increase in energy by adding a concentrated developer, and I take care to only make the solution sufficiently energetic to produce an image of proper density. This will never take more than one-third the time quoted by Mr. Teape, and seldom so long.

I do not think I need trespass further upon your space. Mr. Teape concedes all I ask, viz., that the multiple film gives less halation than a single film. It is therefore a step in the direction of progress.—I am, yours, &c., S. HERBERT FRY.

April 24, 1893.

To the EDITOR.

SIR,—In reference to Mr. Teape's letter in your last issue, you will perhaps allow me to make an observation or two. I have not the pleasure of Mr. Teape's acquaintance, therefore do not know what measure of accuracy to expect from him; but I must beg of him, in again quoting or experimenting with "Sandell" or any other make of plates, to be somewhat more specific in his description. He should have known, I think, that "Sandell" does not sufficiently describe the plate when spoken of in connexion with halation experiments. Would he think me honest if, in writing or speaking of Messrs. Wratten's plates at a Society meeting, I asserted they were not rapid on the strength of exposures made on their "ordinary" plate? There is far too much of this culpable carelessness current, sir. The offenders forget their words appear in print and are liable to befool a greater circle than their immediate listeners.—I am, yours, &c., J. T. SANDELL.

Thornton Heath, April 24, 1893.

[We can so readily testify to Mr. Teape's care and fairness as an experimentalist that we are sure he would be the last to willingly convey a conscious inaccuracy. The correspondence here terminates.—ED.]

ART IN PHOTOGRAPHY.

To the EDITOR.

SIR,—Last week's edition of this JOURNAL contains, under the heading "On Things in General," the following two questions:—"If there is no fine art in photography, how is it that it is possible to produce by photography a scene, a view, or a representation that no artist can tell by simple inspection whether it is an engraving in one class, or a sepia or monochrome painting in another? Secondly, if a painter of repute took pains to learn photography, would or would not some of his results be more artistic than those of the photographer with no art education?"

In answer of the first question I say that, in about thirty years, the time I am connected with photography, I never have seen a *photograph* which could not be recognised as such, or mistaken by an artist for an engraving, or a sepia, or monochrome painting.

To the second query I reply that, by arrangement, by posing, &c., an artist would be able to improve a representation, but would never be able to make *photography* more artistic than a photographer without art education.—I am, yours, &c., F. B.

SUGGESTIONS FOR AN EXPERIMENT.

To the EDITOR.

SIR,—If it has not yet been tried and reported upon, I beg to suggest an experiment which may prove interesting, and perhaps instructive, to users of dry plates.

Take two plates, coated one with slow, the other with rapid emulsion. Place them in contact, film to film; expose, as follows, in the camera, under conditions similar to what would be used for a Sandell plate:—

(*a*) Present glass side of rapid plate for exposure.

(*b*) With a second couple expose glass side of slow plate.

(*c*) After exposure, separate the plates and develop.

A further variation might be made by using three plates on thin glass—or, better still, three celluloid films—coated each with a different emulsion, slow, medium, and rapid, the medium being sandwiched between the other two. Experiments could also be made with orthochromatic plates.

I have not myself the time at present to make experiments, but I throw out the above suggestion for others to use if they see fit, and trust they will give the photographic fraternity the benefit of any knowledge acquired.—I am, yours, &c., DUNCAN C. DALLAS.

5, *Furnival-street, London, E.C., April* 15, 1893.

DETERMINATION OF THE SPEED OF PLATES.

To the EDITOR.

SIR,—The above gives such a lot of jottings that I look in vain for a critique to the point from "Cosmos." I prepared my own dry plates at

home for five years (5 lb. a batch), therefore know from experience that fresh plates are more sensitive than older ones. The difference in the first two or three weeks is sometimes remarkable; there is also a difference in the plates first coated and those done last, also each corner of the drying room imparts a different character to the plate. Well, I can't see the way out of the dilemma—that a once tested plate is condemned to bear the once given test numbers. Kindly excuse one who only expects possibilities, and is content to remain—Yours, &c.,

April 21, 1893. AUDACIOUS OPERATOR.

To the EDITOR.

SIR,—In their article in this week's BRITISH JOURNAL OF PHOTOGRAPHY, Messrs. Hurter & Driffield write that, after making five experiments, I have satisfied myself that all their hundreds of experiments go for nothing, and that their conclusions are erroneous. That, however, is far from being a correct description of the opinions I have formed. Messrs. Hurter & Driffield's investigations covered a wide field, and they have done a service to photography which I should be the last to underrate. They have investigated matters which badly need elucidation, and have made an excellent beginning towards placing on true scientific bases such matters as the connexion between exposure and density, &c. I may add also that I fully appreciate the value of Messrs. Hurter & Driffield's system of experimenting, and have not hesitated to employ it in my recent experiments. Their original paper described almost the first attempt to make matters clear in the branch of photographic science dealt with, and it has been a most valuable contribution towards that end; but it is very improbable that every conclusion which the two experimenters arrived at, in a new and difficult line of investigation, will prove to be beyond criticism, and it would be but a poor compliment to them if photographers simply swallowed the paper as a whole, and abstained from pointing out what appeared to be doubtful features in the reasoning, or felt any hesitation in otherwise testing their results. After carefully studying their paper, my greatest doubts have been, firstly, in regard to certain theoretical questions on which there was some discussion last year in THE BRITISH JOURNAL OF PHOTOGRAPHY; and, secondly, as to the correctness of some of their conclusions on what they consider a matter of secondary importance, viz., the influence of development. Their conclusions on that subject are laid down very broadly in the original paper, and quite without qualification. They claim to have shown conclusively that in development the photographer has "no control whatever over the gradations of the negative," and the following expressions occur in the paper:—"The ratio of densities is given by light alone, and is not affected by time of development." "This ratio we find is altogether unalterable." "These experiments all confirm the statement that the gradations of a negative as expressed by the ratios of the densities, are independent of time of development, cannot be effected by alterations in the composition of developers, and are almost identically the same whatever developer is employed." Now, these are opinions which I believe my experiments have shown will require serious modification. In fact, Messrs. Hurter & Driffield scarcely seem to insist that the ratios are independent of the time of development, but admit the existence of a "lagging stage," and only express the opinion that, after sufficiently prolonged development, their principles will be found in all cases to apply. That may be, but how can it now be maintained that the ratios are "independent of the time of development?"

The principal subject which engaged my attention in my recent experiments (four out of the five being wholly directed to it, except that the effect of time of development on gradation was in one instance examined) was a comparison of the action of two pyro developers of widely different composition, and I found in every case that there were very great differences between the gradations produced by one developer as compared with those produced by the other. In the fifth experiment the actions of several species of developers, mixed in normal proportions, were compared, and, as I implied in the article, did not show results which differed very greatly from what might have been expected on Messrs. Hurter & Driffield's principles; but, as my object was *not* that of "simply opposing their views at all hazards," I thought I ought to publish an account of the experiment, as any results which help us towards forming correct opinions on these matters are not without value. I certainly expressed an opinion that, on other plates than the "Ilford Ordinary," greater variation in results might possibly be shown, and that opinion is now greatly strengthened, owing to an advertisement in yesterday's BRITISH JOURNAL OF PHOTOGRAPHY, in which Messrs. Marion & Co. announce that, in the case of two of the developers experimented with, viz., eikonogen and amidol, it is found that *their plates* require less than normal exposure, and that the actinograph number may be taken from one-third to one-half higher when these (among other) developers are employed. There is a trifling misprint in my article which it may be well to mention. In summing up the conclusions I had formed, I wrote—or intended to write—"On the whole, the experiments show," &c., but the last two words are printed, "experiment shows," making it appear that I was referring only to plate E.

My previous remarks will, perhaps, explain why I do not find the first table given by Messrs. Hurter & Driffield, in their last article, very instructive. I have described experiments made almost solely for the purpose of comparing the action of two developers, and they give a table in which is compared the densities of all the strips developed with *one only* of the mixtures, simply showing that strips which have had similar treatment have similar gradation; there are also added the densities of the strips produced in an experiment on which I had laid very little stress, and Messrs. Hurter & Driffield consider that the ratios of the gradations of all the strips agree fairly well. Considering, however, that the figures on the first line vary between thirteen per cent. and thirty per cent., and also that there is great irregularity in the amount of reversal, I do not see much evidence of uniformity in the gradation. The sources of error mentioned by Messrs. Hurter & Driffield might, of course, account for great differences in gradation between strips cut from different plates, especially as it was never intended, when making the experiments, that the strips used in one should be compared with those of another, but such differences might tell either way.

To return to my article, I think any reader of it who compares the results given by developer No. 1 with those of No. 2, or examines the various ratios of plate D, will admit that gradation—at any rate, over a wide range—may be much influenced by the method of development, and if so, the statements given in Messrs. Hurter & Driffield's original paper require modification. In fact, these principles already appear to be undergoing modification. We now have the idea accepted that a "lagging stage" exists, and that being admitted, it is clear it can be no longer maintained that the alterations in density which occur during the progress of development may, as stated in the paper, be accurately represented by simply giving successively increased values to the factor γ of Messrs. Hurter & Driffield's two formulæ. It really appears to be scarcely contested that gradation over a wide scale of exposures *may* be modified, but it is doubted whether any alteration can be made by means of development in the small range constituting the "period of correct representation." To settle that point, as I stated in my article, far more elaborate experiments than mine would be necessary, and I do not think the published experiments of Messrs. Hurter & Driffield dispose of the question; but it seems improbable that that part of the scale, and that only, should be invariable in the ratio of its gradations. In any case, other parts of the scale are also interesting, for those "extraordinary" photographers who sometimes make errors in exposure are, I believe, far more numerous than Messrs. Hurter & Driffield appear to suppose, and it is important to most of us to find how we can obtain the best possible results on a wrongly exposed plate. I am sure, at any rate, it is to hand-camera workers. The experiments which Messrs. Hurter & Driffield intend to make as to correcting under or over-exposure will certainly, like all others of theirs, be very interesting.

My supposed oversight in describing the No. 1 mixture as excellently suited for developing under-exposed negatives, and not noticing that others which I had used were equally good (a questionable point), may be easily explained. My statement was *not* that it was excellent for the purpose, but that it was far superior to No. 2, a point on which there can hardly be a difference of opinion. The proposed method of saving a much over-exposed plate by stopping the development at an early stage and afterwards intensifying, is regarded by Messrs. Hurter & Driffield as an impossible one, because the intensification would, at most, only double the densities, and that in the instance given would be an insufficient increase; but they overlook the fact that, as Mr. Chapman Jones has recently pointed out, the process may be repeated more than once. There is also another possible alternative, viz., reproduction of the negative.

In conclusion, I may say that my state of despair is not quite so deep as Messrs. Hurter & Driffield suppose, and in writing that development seemed likely to remain a mere rule-of-thumb matter, I did not mean that I was without hope of that unsatisfactory state of things being at last remedied. That hope is much strengthened by learning that Messrs. Hurter & Driffield will endeavour to come to the rescue, and are not therefore deterred, as I feared they would be, from further investigations by the belief that nothing more remained to be discovered. They are not, I presume then, still of opinion that nothing can be changed by varying the composition of the developer, or time of development, except the value of the simple factor γ.—I am, yours, &c., H. J. CHANNON.

Woodlands, Lewisham, S.E., April 22, 1893.

THE TOOTING CAMERA CLUB.

To the EDITOR.

SIR,—I think that it is my duty to call the special attention of photographers who may reside in the neighbourhood of Balham, Streatham, Wandsworth, &c., to the announcement made in this week's report of the Tooting Camera Club, viz., that we shall hereafter have our own meeting and dark rooms, situated in High-street, Tooting (near the tram terminus), being both central and convenient of access.

Few of the London clubs have the same facilities as we shall soon be in possession of, and photographers who would like to share the same, but are unacquainted with any of our members, should write to me at the undermentioned address.—I am, yours, &c., J. F. CHILD, *Hon. Sec.*

Harzville, Leigham Valley-road, Streatham.

"OPEN HOUSE."

To the EDITOR.

SIR,—The Society of Amateur Photographers of New York desire to extend the hospitality and use of their rooms to all amateur photographers who intend visiting the World's Fair at Chicago, and who will pass through New York during the coming summer.—I am, yours, &c.,

T. J. BURTON, *Secretary.*

Society of Amateur Photographers of New York, 113, *West Thirty-eighth-street, New York, April* 15, 1893.

"MUTATO NOMINE," &c.

To the EDITOR.

SIR,—The following fragment of a fable which has come into my possession may, at the present moment, interest a portion of your readers.

THE KING AND HIS PETS.

"There once lived a good-natured king who delighted to entertain all the animals which roamed around his palace; so from time to time he in turn invited them to his mighty dwelling-place, and feasted them right royally with rare viands, garnished with silver and with gold. And all were exceeding glad, except some of a very wonderful sort that mostly went on three legs and had each but one eye. These, having for a while enjoyed full share of the good fare, yearned for still better, and, moreover, they became wroth and forward that they were not, while in his glittering palace, even as was the king himself. And so, said they, 'although it be garnished with gold and silver, we will not eat of his food unless he bow the knee to us.' Therefore they stayed without in the wilderness, and, a blight falling upon the land, the fruits of the earth were scanty, and it came about that——"

Most provokingly the MS. breaks off at the most interesting part. Your readers may, however, possibly find profitable entertainment in trying to supply the missing words.—I am, yours, &c.,

HECTOR MACLEAN.

34 *Newmount-road, Croydon, April* 18, 1893.

GELATINO-CHLORIDE *VERSUS* ALBUMEN.

To the EDITOR.

SIR,—My experiences with the gelatino-chloride papers are as follows—I find no difficulty in the manipulation up to the finishing of the prints; I then find the surface has such an affinity for specks and dirt adhering to it, that it takes much longer time to touch and finish up than albumenised paper; but any speck is easier removed with spirits of wine than water, which destroy the surface. With a bar burnisher it is impossible to avoid spoiling some cards, as they get scraped like enclosed copy—not the ordinary "scratch." This alone makes me throw the paper aside meantime.

With the gelatino-chloride papers I obtain a more brilliant print from a negative if wanting in contrast or density than with albumenised paper. That is the only advantage I find unless there is any on the score of permanence, which time will tell.

I have also used the ready-sensitised paper to some extent. The great drawback to it is the rapidity with which the prints spoil that is made on it. The same mottled marking soon appears on the print that shows on the paper when it is kept any time and printed. The mottling more readily develops when prints are put in a show-case, or where they have a chance of damp and are soon spoiled.

I think there is nothing yet to beat the "home-prepared" albumenised paper for good results.

I have carefully read all that has been written on printing papers in the JOURNAL, and would be glad to see more on the subject from workers. I only write in the interests of the profession.—I am, yours, &c.,

April 20, 1893. B. B.

[Experienced workers do not find any difficulties with gelatino-chloride papers such as those met with by our correspondent; but, for the benefit of professional photographers, we should be glad to open our columns to an exchange of views on the subject.—ED.]

THE CAMERA CLUB PAPERS.

To the EDITOR.

SIR,—As from comments in your valuable JOURNAL there appears to be some misunderstanding in regard to the publication of papers read at the Camera Club, will you kindly allow me to state that, although all rights are reserved as regards copying, the public are not debarred from access to the papers, inasmuch as the full Conference *Journal* will be published by Messrs. Harrison & Sons as usual, and all important papers from the ordinary monthly issues of the Club *Journal* will be issued separately in pamphlet form (by the same publishers) available for subscribers.—I am, yours, &c., G. DAVISON, *Hon. Sec.*

Camera Club, Charing Cross-road, W.C., April 24, 1893.

BEARD'S REGULATOR.

To the EDITOR.

SIR,—I regret that I cannot answer Mr. Walker's questions regarding Beard's regulator, as I have no recollection of its structure, unless it was the one that got a medal at Falmouth a number of years ago. It had a spindle through a flexible diaphragm. There was a weight on the top of spindle, and a valve at its lower end. It was almost a facsimile of one that a Mr. Broughton, of Fountainbridge, near Edinburgh, had patented many years previously. They were used for some time on the street lamps in Glasgow. Before taking out a patent for my regulator, I satisfied myself that the keyed cock was superior to a valve, as the former will last a lifetime.

Regarding the anti-friction cock, although I have them on the apparatus I use myself, it is not patented yet, although I have got permission that they may be used wherever the Glasgow is used. I will send Mr. Walker a drawing when I get it patented.—I am, yours, &c.,

Airdrie, April 24, 1893. WILLIAM BIRRELL.

AMIDOL.

To the EDITOR.

SIR,—Will you kindly allow me space in your next issue to reply very briefly to a remark by "Cosmos" in last week's "Jottings" respecting amidol.

He refers to a statement by Mr. Peal, of Ealing, that exposure can be reduced two-thirds the usual duration if amidol is used to develop, and asks for experimental evidence in support of that statement.

Mr. Peal will, doubtless, answer for himself, and I must offer him my apologies for attempting to reply to a question addressed directly to him; but, as I have publicly for several months been making an identical claim on behalf of amidol, I may, perhaps, be excused for interfering in the matter.

Having had a fairly extensive experience of the properties of amidol, I can fully confirm Mr. Peal's opinion, and have also had confirmation of the statement from several professional photographers in various parts of the country who have taken up amidol in preference to pyro. To put the matter simply, the claim for amidol is that, if under ordinary conditions the necessary exposure (using pyro) is, say, three seconds, an exposure of one second will give an *equally good result* if amidol is used to develop.

You *can* do it, "Cosmos," but don't take my word for it; give it a fair trial, and report the result.—I am, yours, &c., L. E. MORGAN.

17, *Philpot-lane, London, E.C., April* 25, 1893.

Answers to Correspondents.

*** *Correspondents are informed that we cannot undertake to answer communications through the post.*

*** *Communications relating to Advertisements and general business affairs should be addressed to Messrs.* HENRY GREENWOOD & CO., 2 *York-street, Covent Garden, London.*

PHOTOGRAPH REGISTERED:

Abraham Flatters, 6 Penshaw.—*Thirty photographs of cotton fibre.*

RUDD & CO.—The Convention group at Edinburgh was taken by an Optimus rapid rectilinear.

"DRY PLATES" for April contains an article by Mr. Cadett on "The Fixing Bath" of much practical value.

R. CHILDS.—The formula for the caramel backing solution is given at page 221 of the JOURNAL for April 7.

ROCKS.—It appears to us that the bottom of the picture is so poorly lighted that it is under-exposed. Could you not manage to throw a little more direct or reflected light upon it?

W. E. W.—Either the prints were developed with iron which was not removed, or they were acid when placed in the fixing bath. Anyhow, they show want of care in the manipulations.

J. GRAHAM.—1. We are of opinion that the combined bath will yield quite as permanent prints as the other. 2. The lens you mention will answer well for architectural work in addition to the other properties.

STAFFS.—Unless you have made the views copyright in the usual way, you have no redress against the lithographic piracies "made in Germany." If you had a copyright, you could proceed against any one selling the piracies.

T. R. (Bombay).—A difficulty is frequently experienced in obtaining density in some brands of extra-rapid plates. But by increasing the proportion of pyro considerably, and slightly the bromide, the trouble can generally be surmounted.

X. Y. Z.—We think that by substituting for the small lens C a triple achromatic, such as is employed as an eye-piece in the better class of opera and field glasses, there would not be any fringes of colour apparent. It would be worth while trying this.

R. R. C.—We are uncertain as to the nature of the effects desired to be produced, therefore cannot aid you. Bearing in mind, however, that the angles of incidence and of reflection are equal, you will be enabled to construct a multiple reflector, if it be this at which you aim.

D. E. GODDARD.—This week's report of the London and Provincial Photographic Association's meeting, and Mr. Cowan's paper in reply to Mr. Williams, published in another part of the JOURNAL, continue the subject of the determination of plate speeds.

J. P.—The markings on the negative look like hypo, which has recrystallised out through imperfect washing. You might try the effect of removing the varnish with alcohol, and of refixing in strong hypo, but we are not very hopeful that the negative could be saved in that or any way.

R. E. C. (Innsbruck).—So far as one can judge from the print, the negatives are much over-exposed. If all have received approximately the same exposure, treat them as being over-exposed when developing. Evidently the Alpine light has misled you. Still, with care, the negatives need not be lost.

ORTHO.—Instead of seeking for one of the aniline colours for giving to the prints the appearance of old engravings on Indian paper, try the effect of a decoction of coffee, strength according to the tint desired. None of the coal-tar colours occur to our mind at the moment that would answer so well as the coffee.

TISSUE.—When the bichromate bath becomes discoloured and frothy, as you describe it, it should be discarded and a new one made. It is not necessary to strengthen it as in the case of a silver bath, neither is it desirable to use the bath until it becomes in the state referred to. Bichromate of potash is cheap enough.

H. WADE.—1. The simplest way to add to the density of carbon transparencies is to treat them with a solution of permanganate of potash—say, ten grains to the ounce of water. 2. See answer to R. Fortune. 3. The ordinary sulphate of copper of commerce is the kind employed in making the bath for electro deposition.

B. BROWN, M.D.—In your preliminary experiments, confine yourself to low powers, say an inch or an inch and a half. The arrangement of the apparatus, as shown in the sketch, cannot be improved upon. Do not attempt objects with much colour till some little insight on the work has been gained. "Ordinary" plates to begin with.

W. E. PATERSON.—There may be two reasons why the enamel collodion dries with a crapy texture: First, the employment of a pyroxyline of an unsuitable kind; second, using solvents containing too large a proportion of water—*i.e.*, not strong enough. With a suitable sample of pyroxyline, and methylated ether of s.g. ·715 or ·720, and methylated alcohol of 66 o.p., a good collodion for enamelling paper prints will be obtained. For this purpose the presence of the mineral naphtha will do no harm.

M. L.—1. All the processes mentioned are capable of giving good results. As you have failed with them, you might employ the plan of placing a mirror at an angle of 45° with the lens when taking the negative. 2. The Kallitype process has answered well for portraits in this country. 3. Schirm's flash-lamp may, we believe, be obtained from Mr. Romain Talbot, Berlin. 4. Mr. Slingsby, of Lincoln, and many other portrait photographers, employ the flashlight very successfully in the studio. Messrs. Marion & Co. will supply you with information on the subject.

J. HIBNS.—Steel facing of copper plate is an electrotyping process, and its object is to enable a larger number of fine impressions to be obtained from the plate than could be obtained from the bare copper. In fact, by this process, the copper plate becomes almost everlasting. A coating of iron of extreme thinness and great hardness is deposited on the engraved plate, which prevents wear of the copper in printing. When the iron shows signs of wearing through, the coating can be taken off, leaving the copper in its original condition, and a new one deposited as at first.

T. O. J. says: "Can you tell me of anything that I can add to a solution of gum Arabic, which my hands use for spotting prints, that will keep it from becoming sour. I know that carbolic acid will answer the purpose, and I am using it, but the girls complain that they cannot use the lips for drawing the brush to a point with that in it."—A small proportion of alcohol will answer quite as well, and it will make the mucilage more palatable. Methylated spirit will answer, but perhaps young ladies will protest against its use. Anyhow, a very small proportion of the pure spirit will suffice.

C. MACER asks if the electric light, arc light, can be used for printing on the Ilford Printing-out paper; and, if so, what would the exposure be?—The light could be used, but it would necessarily make the printing very expensive in comparison with daylight, which costs nothing. The exposure will, of course, be dependent upon the power of the light used and the density of the negatives. From a commercial point of view—and it is upon this, we imagine, our correspondent's query is based—the thing may be considered as impracticable, except, perhaps, in an extreme case occasionally.

R. S. J. writes: "I have often seen it stated that professional photographers generally sensitise their own paper, because, on it, they get better results than amateurs do on what they buy ready-sensitised. For some time past I have been sensitising my own paper, using a fifty grain bath, and I much prefer it to that bought ready-sensitised; but I am much bothered at times with dark marbled-like markings on the paper when it is taken off the bath. One or two sheets will be so, and then all the others will be clear. What can be the cause?"—If the bath is allowed to stand in the dish, a scum forms on the surface, and, unless this is removed with a strip of blotting-paper, it will be taken off by the albumen paper. Skim the bath before floating the paper.

P. SEVILLE writes: "Can you tell me how to prevent the black spots which are on the enclosed photograph. It is printed on Ilford P.O.P. They make their appearance in the first washing water and by no after-process have I been able to get rid of them. One photographic chemist recommended to filter the water through a very fine flannel, but it made no difference. I have tried constant running water whilst washing them, but still spots appear. If the prints are allowed to lie still in the water for a moment, I have sometimes noticed a black deposit on them, which I have immediately removed; but every print so attacked has been quite spoiled. From this cause I have had spoiled as many as forty vignettes in one week. If you can suggest a remedy, I shall be exceedingly obliged to you."—The spots are due to particles of foreign matter, which coming in contact with the paper reduces the silver. These particles must be either in the water or on the surface of the print when it is immersed in it.

ROBERT FORTUNE writes: "Would you please answer the following questions? 1. After having developed a carbon print upon a sheet of collodionised glass, can you tell me how to dissolve away the collodion film without injury to the carbon print? 2. Can you tell me where to get a price-list of the copper plates, press, &c., necessary for photogravure? 3. Can you give me the formulæ for etching upon glass, commonly called a 'dull bite?' It is done by suspending the glass in the vapour of certain chemicals. I think it is a mixture of hydrofluoric acid and ammonia, but cannot say for certain. 4. Can you tell me where to get bitumen or asphaltum which is sensitive to light, and what is the solvent used after exposure to dissolve the parts which are still soluble?"—In reply: 1. Before the collodion can be removed, the print must be taken off the glass. Before applying the collodion, talc the glass; then, after the print is developed, squeegee a thin sheet of gelatine upon it, and allow to dry. Remove the picture, and clean the collodion off with a mixture of ether and alcohol. 2. Any dealers in printer's materials, such as Hughes & Kimber's, Winston's, and others. 3. Place some fluor spar at the bottom of an ebonite dish, moisten it with sulphuric acid, and place the glass to be etched over it. 4. Any wholesale chemists' Turpentine, to which sometimes a little benzole is added.

CATALOGUES have been received from G. W. Wilson & Co., Aberdeen, and W. Banks & Co., Bolton.

PHOTOGRAPHIC CLUB.—May 3, *Lenses for Copying*. 10, Members' Open Night. Saturday outing, May 6, Eynesford.

MESSRS. ARTHUR SCHWARZ & CO. point out that we omitted to print their name as agents for Dr. Andresen's chemicals in their last week's letter about settlement of, the dispute between the manufacturers of the amidol.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.—May 4, Technical Lecture of the Series—*Developers*, Mr. E. J. Wall, 11, Paper by Mr. W. H. Harrison, *Is the Present Construction of Photographic Studios Wrong in Principle?* 18, Monthly Lantern Night.

THE CENTRAL PHOTOGRAPHIC CLUB.—The Hon. Secretaries of the Central Photographic Club (Messrs. W. Fenton Jones, 12, King Edward-Road, Hackney, and C. H. Oakden, of 51, Melbourne-grove, East Dulwich) are open to receive applications for shares in the Club Company. The shares are 5*l.* each, 2*l.* 10*s.* being paid on allotment. All other communications relating to the Club should be sent to those gentlemen, and not to Mr. Thomas Bedding, who is no longer Hon. Secretary *pro tem.*

PHOTOGRAPHERS' BENEVOLENT ASSOCIATION.—Meeting held in the rooms of the London and Provincial Photographic Association, Thursday, April 20, Mr. Robert Beckett in the chair. Two applications for assistance were considered by the Committee.—In one case a loan of 5*l.*, together with a further sum in instalments, was granted. In the other case, the Committee instructed the Secretary to refer the applicant, who was a foreigner, to the consul of his own country, and to state that his case was one which the Committee did not see their way to relieve. The Rev. H. G. Morgan and Mr. J. G. Hudson were accepted as subscribers, and Mr. Walter D. Welford was elected a life governor. The Secretary reported on the fact that the proceeds of the Sandell Exhibition had been devoted to the Benevolent, and announced that Mr. Sandell had expressed his willingness to loan the whole of the pictures from that Exhibition, and to supply a number of catalogues gratis to any provincial society that would organize an exhibition in its own town and give the proceeds to the Benevolent Association. The following subscriptions and donations were acknowledged:—Rev. H. G. Morgan, 5*s.*; Atticus, 10*s.* 6*d.*; *Photographic Review of Reviews* Charitable Fund, 2*l.* 2*s.*; Hastings and St. Leonards Photographic Society, 2*l.* 2*s.*; *Photography* Prize Competition, 6*s.*; Mr. J. G. Hudson, 15*s.*; Mr. Thomas Bedding (THE BRITISH JOURNAL OF PHOTOGRAPHY), 10*s.* 6*d.*; and Mr. R. Hayward, 7*s.* 6*d.*

*** Owing to exceptional pressure on our space this week, we have been obliged to hold over several Society reports, letters, articles, and other interesting matter. We trust our numerous friends and correspondents who have been disappointed at the non-appearance of their communications will exercise their patience, for the reason given.

JOURNAL OF PHOTOGRAPHY.

No. 1722. Vol. XL.—MAY 5, 1893.

FOCAL PECULIARITIES OF WIDE-ANGLE LENSES.

Every one who is accquainted with the most elementary principles of optics as affecting photographic lenses knows that a deep meniscus lens will not, unless it be stopped down to a considerable extent, give an image at the focal plane any part of which is sharp, and that, the more pronounced the meniscus form is, the smaller will have to be the stop or diaphragm requisite to minimise the spherical aberration by which sharp definition is prevented. This applies, not alone to a single meniscus, whether achromatised or left uncorrected for colour, but is also the case when two such forms of lenses are mounted together so as to form a wide-angle, non-distorting objective.

When an objective of this class, single or compound, is focussed with its largest available aperture, say, for example, *f*-15, upon any suitable object, so as to produce the sharpest image of which it is capable under the circumstances, and a very small diaphragm is then inserted, disappointment is apt to be experienced at the small gain in sharpness that has resulted.

It is a common habit with those who employ lenses of this nature to focus with the largest diaphragm supplied, and then use one much smaller for making the exposure. For this there is a certain excuse which is plausible although not valid, viz., that a wide-angle lens of short focus admits an insufficiency of light to permit of any focussing being effected with a small stop, and that hence the largest one must be made to serve the purpose both of arranging the subject on the ground glass, and also of focussing; and it is reasoned that after this has been done the sharpness will be increased by the insertion of the small or working stop.

But it must be borne in mind that, when working thus, there are two focal planes situated at a certain distance apart, the one for the largest stop being closer to the lens than when the smallest one is employed. Hence a readjustment of the focus is imperatively demanded between the focussing with the large and the exposure with the small diaphragm. A clever casuist may say that, if he makes the image sharp with the larger aperture, the reduction of the aperture cannot make the image less sharp, seeing that the same rays by which the former was produced are utilised in the production of the latter. To which we reply, that we deny the *acme* of sharpness in the first case, on account of the amount of spherical aberration present, for, be the focussing effected with the utmost care, there are still transmitted rays which cross the axis at a greater distance than the mass of those by which the image is formed, and it is only when the lens is aplanatic (which no wide-angle deep meniscus ever is) that all the rays cross the axis at one point. We repeat what has already been said, that, in order to obtain the extreme of definition when employing only those attenuated rays transmitted by the small diaphragm, the focussing screen must be placed in the plane at which they cross the axis, and which, as we have said, is at a greater distance from the lens than is the case when the bundle of rays is larger.

Practice supports theory in this. We have just made a series of careful tests relative thereto, and have employed for the purpose a wide-angle deep meniscus combination of the most recent construction, and bearing an honoured name. The solar focus is eight inches, and the largest stop equals *f*-16. We focussed upon the meshes of a piece of rather fine network, such as that employed for window curtains, using a Ramsden eyepiece carefully adjusted and attached to the ground glass of the camera. The camera was thirteen feet distant from the network, which was erected so as to be backed by the sky. Having got the greatest sharpness capable of being obtained with the stop mentioned, we marked on the camera the stage to which it had been extended, and then "turned on" the *f*-32 stop and focussed again. There was a very marked increase in the definition of the lace, which was exceedingly crisp and sharp, the meshes being as if cut with a finely pointed graver. Another mark was now made on the camera. The *f*-16 stop was then made to supplant the *f*-32 one, and the image again examined, revealing now a serious falling off in sharpness. This was repeated several times, and established the fact that for the apertures mentioned there were two focal planes. On measuring the distance apart of one mark on the camera from the other, it was found to be three-sixteenths of an inch.

We have entered into this matter somewhat at length in order to enforce advice we have repeatedly given, and which is to the effect that, while the largest possible aperture of the lens is by far the most convenient to make use of when arranging the subject on the focussing screen, it is of vital importance where the highest degree of definition is desired that the focussing be effected when using the same stop as that by which the photograph is to be made.

When the lens partakes more of the aplanatic character than the deep meniscus that we have been describing, the same amount of difference in the focal planes does not exist, and we have seen lenses of the "rapid" class in which the focal plane with the full aperture and that with the smallest stop showed no marked difference between them. Lenses of this type, however, are not capable of including an angle of view so great as those of the deep meniscus form. Just observe the axial excellence of definition of the highest type of

planatic lens that is known—the object-glass of an astronomical telescope; by no amount of stopping down can its defining power be improved, but, on the contrary, it rather deteriorates. In it the amount of spherical aberration left uncorrected is practically non-existent. The external form of such a lens when made of ordinary optical glass is that known as crossed, which, while right for axial rays, is hostile to the transmission of oblique ones, for which purpose we must have recourse to lenses of meniscus form. The deeper the meniscus form the better is an extremely oblique ray transmitted, and hence the necessity of the deep meniscus for wide-angle lenses, which, on account of the aberration of sphericity, renders a small stop imperative.

It is no fault in the construction of such objectives as we have been speaking of that there is the difference spoken of between their foci when using a large stop contrasted with a small one. It is an optical necessity of their construction. We have known of more than one who made a speciality of copying fine line engravings of large dimensions who adjusted and focussed with a large stop on account of the superior illumination, and then inserted a small one, and who, failing to get the sharpness desired, blamed the lens, and laid it aside, whereas the fault lay with themselves in not knowing how to use such a lens aright. We hope that, from a perusal of what we have written, they will be able to do so in future.

A writer on the subject of focussing, eight years since, said: "To focus with the working aperture, as some writers recommend, is not only useless, unless the lens is imperfect, but it is practically impossible with the small apertures required for the rapid plates now used." We have adduced sufficient evidence to show the utility of the course recommended, and have only to add that if, owing to the feeble light transmitted through the smallest stop, correct focussing is not possible with its use, this can be ensured by the expedient of focussing with a large stop, and racking the camera out the extent necessary, and which has been previously ascertained by experiment, to ensure absolute definition by the small or working stop. Photographers should study the peculiarities of each lens they employ.

GUMS AND GLUES.

The query put by "T. O. J.," and replied to in our last, suggests the usefulness of a few hints on the use of gums and gelatines in their more mechanical aspects, so to speak, in relation to photographic manipulations. Acacia gum is so largely employed for the purposes referred to in our correspondent's query, that it is not surprising he has met with the commonly experienced difficulty. Any one feeling similarly troubled may with advantage act upon our suggestion of the use of a little alcohol, the best way of adding which preservative is in dilute solution in water, a thicker gum mixture being then made to avoid undue thinning. If alcohol be added direct, it will cause clots to form which will not readily redissolve. In making "gum water," which perhaps is done in every studio in the country, there are some minor precautions to be taken which will obviate the acidity or sourness for a time at least. First may be mentioned the advisability of dissolving the gum in perfectly cold water. Hot water is generally used, and the solution, in consequence, invariably decomposes in a day or two, especially in hot weather.

Those who have not adopted this method will be surprised at the difference in smell even when first made; there is an actual fragrance about the cold solution which is entirely absent when heat is employed. Then, again, it is quite unnecessary—a useless addition to the expense, in fact—to use, as some do, the powdered gum. Nice clear, clean, pale lumps should be chosen, though the kind sold under the technical name of "sorts," which includes white and coloured pieces, is quite as good, though not so pale in solution. An excellent plan to adopt is to make a quantity at once, and then place it in small bottles made quite full, and then well corked and kept in a cool place. So prepared, it will keep fresh quite a long time. There are many substances that can be added to act as preservatives, which are quite out of question, when the gum water is to be used for spotting, on account of their taste. Of the least objectionable, sulphate of quinine stands foremost, so very small a quantity being required; indeed, we doubt whether the bitter would be noticed. Gum water made very thick is a most useful and handy mountant, but its great drawback is the liability to cause a greasy appearance in the print wherever the finger is laid and pressed upon the gummed surface before mounting. It is stated that this effect may be got rid of by adding sulphate of alumina in solution, three per cent. of the weight of the solid gum being added.

An excellent substitute for gum water is made from milk; the caseine is precipitated by acetic acid, well washed till freed from acid, and then dissolved in a saturated solution of borax. We believe we are correct in saying that a solution of gum arabic or acacia was the first mountant used in dry mounting. We remember seeing it in use at Disderi's establishment in Brompton about twenty-five years ago, and some prefer it to this day on account of the ease with which it is made to adhere under what would be unsatisfactory conditions for other materials Perhaps, where it is prepared, it might for this purpose be better to use the formula given to us by a label-manufacturer in which gelatine plays a part. It is as follows:—One pound of gum arabic, one and a half pounds of gelatine, one ounce of sugar candy, six pints of water. The gelatine to be first soaked in a little water, and then melted in the rest of the water in which the gum and sugar candy have first been dissolved. The difficulty of dry mounting is that, if there is not complete adherence, the print may blister when heated by burnisher or hot process. Some blisters, however, that appear when first mounted may go down in the hot press.

Where a small pot of gum is handy for occasional instant use as a mountant, "gum water," as gum-arabic solution is usually termed, is a decided favourite; but we strongly advise a mucilage of tragacanth gum. This is strongly adhesive, and is free from the objectionable tendency of "greasing" the print where pressed by the finger, the effect not being due, of course, to grease; yet the appearance is just as though some oleaginous matter had been spilt there, and it has been a puzzle to many a one who has only occasionally used the solution. The drawback to the use of tragacanth is the great tendency it possesses to go mouldy. Many substances have been recommended to prevent this, the most successful being the essential oils—oil of clove, for instance. It has been stated that boric acid, which is so admirable a preventive of mould in many cases, will answer; but our own experience entirely negatives the assertion. We left a small pot of tragacanth, to which we had added boric acid, lightly corked in a free draught of air, and it was covered with mould in a fortnight. Salicylic acid preserved another sample for a much longer period, and a mixture of thymol and the latter chemical kept the mixture pure and clean till it dried up to the consistency of horn. The smell of thymol would to

some, perhaps, be objectionable, though others consider it very fragrant. We have left ourselves no space to refer to glues or gelatines in photography, and will therefore consider their properties in a future article.

A Large Negative.—Messrs. Werner & Son, of Dublin, have recently taken direct from life a negative 64×38. It is, we understand, to be exhibited at Chicago. Possibly it is the largest direct negative ever taken.

Silver Medal Awards at Philadelphia.—This country has secured a liberal proportion of the silver medals awarded at this great American Exhibition. The names of the fortunate artists are George Bankart, Leicester; John H. Gear, London; William Gill; Colchester; Karl Greger, London; Edgar G. Lee, Newcastle-on-Tyne, R. H. Lord, Cambridge; W. P. Marsh, Bognor; Charles Reid, Wishaw; Ralph W. Robinson, Red Hill; F. Thurston, Luton; G. West & Son, Southsea; W. Clement Williams, Halifax, and W. W. Winter, Derby.

The Royal Academy Exhibition.—The Royal Academy opened its doors to the public on Monday. It is surprising how comparatively few photographers consider it worth while to visit its annual Exhibitions, considering there is always something to learn therefrom. As usual, several of the pictures in the present collection are greatly indebted to photography. Especially is this the case with portraits. Of course, this is not mentioned in the catalogue. Just now, in addition to the Royal Academy, several other picture exhibitions are open. There is the New Gallery, Royal Society of British Artists, Royal Society of Painters in Water Colours, and others, all of which might be profitably visited by the majority of photographers.

"At Last, Colour Photography."—This appears on some pictures exhibited for sale at a printseller's shop in one of the leading thoroughfares of the City. The pictures are in colours produced mechanically, are very indifferent, and the announcement is certainly misleading to the general public. This is proved by the fact that on two occasions we heard persons discussing the merits of the pictures as if they really were photographs taken in their natural colours. One remarked, "They have been trying at it for years, and now they have got it," adding, in reply to a comment as to the mediocre character of the work, "Yes; but, now that they have found out the way, they will soon make improvements upon it." The public have so often been told that the discovery of taking photographs in natural colours has been made, that "at last" some are easily misled by the above announcement.

Success of the Eclipse Expeditions.—It is gratifying to astronomers to know that the two English expeditions—the one to the West Coast of Africa and the other to Brazil—have both been successful in their photographic work. A few days back Dr. Ainslie Common, secretary to the joint Eclipse Committee of the Royal Astronomical Societies, received a telegram from Mr. Taylor, who had charge of the Brazil expedition, saying that the negatives taken with the chronograph and with both spectroscopes have been developed, and that they are quite successful. It will be remembered that similar success, with like instruments, on the West Coast had previously been announced. Expeditions from other countries have also been, for the most part, highly successful. It is not always the case in these events that the weather is as propitious as it was on this occasion. The results will certainly be of great value to astronomical science.

Stripping Negatives.—A question was put at a recent meeting of one of the metropolitan Societies as to how to strip a negative from the glass without the film expanding. The replies given were, however, not very definite. Now, if the negative be developed with pyrogallic acid, and is afterwards well alumed, the film, when removed, will have very little tendency to expand. If, however, expansion does occur, the film can at once be brought back to its original dimensions by immersing it in alcohol. Indeed, in some cases, when very strong spirit is used, it can be reduced below its original size. When extreme accuracy as to size is imperative, it is advisable to protect the film from expansion while it is in a moist condition, either by coating it with a thick film of collodion or with gelatined and indiarubber paper. Then, when the stripped film is dry, the protecting medium can pe removed. Details of each method of working will be found in our ALMANAC for 1889. Both methods are worked commercially when stripped films are required.

Portraits and the School Board.—At the meeting of the London School Board last week, the question was asked by whose authority certain "hideous pictures" had been placed in the new Board-room. The reply was that the architect proposed to insert in the lunettes of the Board-room the effigies of Archimedes and other ancient personages, and it was suggested that "portraits" of persons who were, or had been, on the Board would be preferable. Had the architect's idea been carried out, there is little doubt that the portraits of "ancient personages" would not have been so closely criticised as likenesses as are those that have been substituted. However, the living prototypes can scarcely feel flattered by the portraits that are to hand them down to School Board posterity being designated as "hideous pictures." Many board and committee rooms are adorned by portraits of former members; but they are usually in the form of oil paintings or enlarged photographs, and not as "hideous pictures."

American Appreciation of English Art Work.—It is satisfactory to find that the works of some artistic photographers in England appear to be highly appreciated in America. The pictures sent by Mr. George Davison to the Philadelphia Exhibition were too late in being delivered until after the work of judging had been accomplished. This delay was occasioned by Custom-house red-tapeism, which surrounds with difficulty so many things that enter the United States. If, however, Mr. Davison has received no expression of opinion from the Judges, he is being awarded a not stinted amount of panegyric by the press, in fact the eulogiums on his work are of the highest order. The *Public Ledger* ranks Mr. Davison as the foremost exponent of the art side of photography in England, his work being now seen for the first time in America. From this paper we learn that it is Mr. Davison's custom to produce only one good print from a negative, so that each of his pictures is as unique in its way as a painting produced by an artist in colour. This is a trait in Mr. Davison's working of which we were not previously aware. The exhibits form a special loan collection, and are not entered for competition. Many of the examples are made without a lens through a pinhole aperture.

REDUCING OVER-PRINTED GELATINE PROOFS.

For many years a perfect method of reducing over-printed albumen prints without spoiling the tone has been a *desideratum*, and, so far as I am aware, up to the present time has not yet been achieved. The mere reduction is a matter of the greatest ease by a variety of methods, but these, without exception, act more or less injuriously upon the colour of the gold-toned image, and rob it of the charm that rendered the "photographic purple" such a popular tone.

With gelatine prints, however, the case is somewhat different, whether the image is the result of printing-out or of development, since the tone is almost invariably free from that warm tint that marked the albumen print, and which is so difficult to maintain under the action of reducing agents. The neutral black or cool grey tones of the modern gelatine print are, in fact, little, if at all, affected by such agents, except so far as lowering the strength of the image may affect its depth. This is especially fortunate, since the difficulty of stopping development at exactly the right point, as well as of judging the correct depth in the dim light of the dark room, is far greater than in examining the gradually progressing image of a direct print in feeble daylight.

In his anxiety not to overdo the development, the operator is apt to err on the reverse side, and to discover when too late that the print is spoilt by under-development; but, in the presence of an

efficient means of reduction, he may with safety, and even with actual advantage, allow the development to proceed beyond the depth desired, and then, after fixing, and in a good light, proceed to reduce it at his leisure, and with every power not only of carefully judging the right depth, but also of stopping the action instantly when the proper point is reached. A further advantage may also be claimed, namely, that the process of reduction also serves the additional purpose of clearing the whites of the print, and removing developing stains, usually a separate operation, so that it can scarcely be said that the introduction of systematic over-printing and reduction adds anything to the labour involved.

It is scarcely necessary to remark that there are a large number of different methods by which the reduction can be effected, but in making the selection of a perfect one, I should decidedly give the preference to one that consists of a single solution, that is to say, one that removes the excess of density in one operation, instead of requiring the application of a second solution to complete the process. Of the first class, the mixed solutions of ferridcyanide of potassium and hypo, or of ferridcyanide and sulphocyanide of ammonium may be mentioned as types, while the second class is represented by such applications as weak hydrochloric acid followed by hypo. So far as the actual reduction is concerned, nothing can excel the compound solutions containing potassium ferridcyanide, but they possess an unfortunate tendency in the direction of yellow stain—slight, it is true, but still sufficient to mar the beauty of an otherwise perfect print. Alum and hydrochloric acid—the ordinary clearing solution for negatives and prints—exercises a powerful reducing action if long applied, and is free from the tendency to stain, unless, indeed, it be applied to a very imperfectly washed print containing unremoved hyposulphites. But it has the disadvantage of converting a portion of the image into chloride of silver—a portion at least of which must remain in the print unless removed by a second solution.

However, by adding to the acid solution sufficient chloride of sodium to saturate it, it is converted into a one-solution reducer, the solvent action of the chloride of sodium sufficing to hold the small quantity of chloride of silver formed in solution, and to allow of its removal by simple washing. The solution as I have employed it is made as follows:—A hot saturated solution of common salt is made, and when cold, to each ounce of it two ounces of alum and half an ounce of hydrochloric acid are added. This solution acts slowly, but with great regularity, and its action is complete just when the print appears of the right depth. All that remains then is to wash thoroughly to remove the soluble salts and free acid.

Another reducing solution which is to be preferred in some respects to that of alum and hydrochloric acid is one composed of a soluble hypochlorite. This will be preferred by many, because it acts also as a hypo eliminator, perhaps the safest there is, since it converts any hyposulphites remaining in the prints into the least injurious compounds. Its chief fault as an eliminator consists in its reducing action on the image, but this ceases to be a fault when it is the effect sought. The hypochlorite may be used in the form of *eau de Javelle* or "Labarraque's Solution," formulæ for the making of which will be found in the pages of the ALMANAC, or it may be purchased in the form known as "Ozone Bleach;" these all consist of solutions of hypochlorite of sodium or potassium, not pure, it is true, but sufficiently so for the purpose in view, or the pure hypochlorite may be employed, though at a much higher cost.

The action of the hypochlorite upon the image is to convert it into chloride of silver—not hypochlorite—oxygen being at the same time disengaged; any hyposulphites remaining in the print from the fixing are, at the same time, converted into sulphates, and, in the case of the silver salt, eventually into chloride. Here, again, the necessity exists for some means of removing the chloride of silver thus formed; but this is easily effected, in the manner already described, by the addition of salt. In fact, in making up the reducing solution, it is only needful to substitute saturated solution of salt for plain water, adding sufficient of the hypochlorite to confer the desired energy.

The above are undoubtedly the best reducing solutions I have met with in the course of some years' experience, but it may happen that such a solution has to be made up in an emergency, when possibly the materials given above are not available. Nitric acid, however, finds a place, or ought to do, in every photographic laboratory; take a couple of drachms, say, of strong nitric acid, and dissolve in it a saltspoonful of salt, or, at least, let the strong acid take up as much as it will, and then dilute it with water to the requisite strength. This forms a complex solution, in which, in all probability, nitro-hydrochloric acid exists; at any rate, it converts the image into chloride in a far more perfect manner than hydrochloric acid, and is much to be preferred. It must be followed, however, by a fixing solution; but for this purpose I should strongly object to hypo, on account of the washing required after it. Considering the small trace of chloride of silver to be removed, a strong solution of salt, or, better still, of sulphite of soda, will be quite strong enough, and the products of decomposition, as well as the salts themselves, are far more easily removed than in the case of hypo. W. LINDSAY.

THE PICTORIAL MODIFICATION OF PHOTOGRAPHIC PERSPECTIVE.

[Society of Arts.]

EVER since I invented my system of reflected electric light, which I had the privilege of exhibiting in this room many years ago, and put aside for a time my palette to join the ranks of the photographic profession, I have been made to realise as acutely as any one the limitations, impossibilities, and shortcomings of photography. Not only have I felt them limiting my ambition while trying unconventional posing, but because of them it has often been painfully irksome to have to explain the restriction of my powers to a class of sitters whom I may fairly describe as the non-photographic type. These sitters—and most of them, I must confess, are of the fairer sex—are prone to lament that their hands (which they always try to hide), to say nothing of their heads, waists, and so on, come out much too large. Others, again, fancy themselves much taller and slimmer than they optically, or perhaps I may say, architecturally, really are, and I have always been compelled to admit that they are right—that is to say, visually right, artistically right—and that photography in their case could not do justice to one's visual impression. The invention which it is my privilege to submit to your notice this evening is, therefore, the outcome of necessity, and meets a great want, which all leading men in the profession, and many amateurs, have long and keenly felt.

THE "TRUTH" OF PHOTOGRAPHY.

On few subjects, I venture to submit, has there been of late so much discussion, so much debate, and so great a confusion of ideas as on that of the question of the truth of photography, and the value of its services to art, which latter have been most generously and freely admitted by the greatest masters of the brush amongst us. But, now that we are attempting to correct figure, portrait, and landscape photography, I think the time has arrived when we may usefully attempt to analyse it, and appraise it at its actual value; the more especially as I am convinced, from careful observation of the work of some of the best draughtsmen and painters of to-day, that the close study of photography is ruining their judgment, and vitiating their appreciation of the beautiful. Eloquent proofs of the baneful effects of the new creed, that photography cannot lie, appeal to us on every hand. Take up, for instance, the current number of the *Century Magazine*; here we find a draughtsman of the first rank permitting himself to draw horses in action as no other man has ever drawn them, as, I venture to add, no human eye has ever seen them. Obviously he has studied instantaneous photography, and honestly believes that he is taking a fearless and conscientious new departure in pictorial art in the cause of truth, oblivious of the fact that the camera registers a section of an action immeasurably more minute than the eye of a man can chronicle and convey to the brain, and therefore he depicts what he has never seen—depicts what is, to all practical purposes, an untruth; a state of affairs of which no human cognisance has, or can be naturally taken. Similarly, we see portraits nowadays painted under a like influence; time was, about half a century ago, when artists, obeying the behests of fashion, painted heads, hands, and feet absurdly small. Photography, no doubt, is responsible for the reigning reaction. The tendency of town dwellers—the professional class, artisans, tradesmen, &c.—who get little exercise for their whole bodies, and use their heads and hands only in the struggle to earn a living, is to beget a large-headed, small-bodied race; while those who, from early youth, get plenty of exercise—the privileged classes, the aristocracy, the agricultural labourers, and even the miners—are noted for their more symmetrical or classic proportions, and their well-poised, small heads.

We see at the Royal Academy, the Salon, and elsewhere, portraits disfigured by enormous heads, hands, and feet, looking for all the world as though their outlines had been traced from an enlarged photograph originally taken with a short-focus lens. We see figure pieces intended to carry us back to classic times, which would be delightful and perfect but for something which takes away their individuality, which makes them too familiar, almost vulgar; what is this something? It is, that we instinctively recognise in the figures the type of the modern town-bred model, or of the sedentary professional race, perhaps members of the artist's own family. It is not, however,

given to every painter of classic subjects to so appreciate and adore that perfect harmony of a classic form as to be able to be true to, and resist the deterioration of, his ideal through the constant contemplation of his models and the baneful influence of optically distorted photography.

Optical Truth and Visual Truth.

Science protests that photography cannot lie. Well, optically, it cannot. I have been trying to put my argument into a nutshell. I may not have succeeded, but here it is for what it is worth—"Optical truth is not visual truth." This may seem very much like a paradox, but the dictionaries are so singularly unaidful to me in my dilemma, that, for the sake of argument, we must let it stand for the present. The force of the statement is, however, one which the future must speedily recognise.

Optical truth, then, as far as photography is concerned, is the result of a mere mechanical impression on a plate, which is sometimes more wonderful and beautiful than anything the human hand could fashion; but which, on the other hand, is sometimes so brutal in its fidelity, and microscopically vulgar, as to give one a very disagreeable surprise.

Visual truth is a very subtle quality. Its appreciation depends on the observer's artistic sense and powers of comparison. I would go as far as to claim it as an hereditary quality which different people possess in different degrees.

There is a great distinction between it and optical truth, or the truth of the camera. The camera focusses every spot at the same instant, without favour or prejudice, uninfluenced by natural selection. The impression on the brain, on the contrary, is affected by all these things. The eye focusses only one portion of an object at a time, and, whilst the rest of such an object is within the diffused vision, the impression on the brain depends on the temperament and the more or less artistic environment of the observer, the brain instinctively and unconsciously recognises the quality of distance. In portraiture we have to please the family, the relatives, and the friends of the subjects—those, in short, who are most familiar with their appearance; and, in their case, the visual truth is the outcome of loving and friendly contemplation. The first essential for a successful portrait-painter is that he should be sympathetic, possess a great deal of the milk of human kindness, and love his fellow-man. These are the gifts that will enable him to approach his sitter in the family spirit. When he paints a portrait, say, of a sweet old mother, he unconsciously tones down and modifies the optical truth, and, guided by the visual truth, he accentuates the air of distinction and spiritual dignity which his own refinement enables him to see and appreciate. But the photographer, though he be a born artist, and ever so appreciative of these qualities in his sitter, is cribbed, cabined, and confined within certain limitations and poses. It is almost useless for him to study the work of the great portrait-painters, for the moment he copies an unconventional pose, say, with hand or foot extended towards the camera, he produces a libel, and I defy any one to judge of the actual size in proportion to the body of the extremities of a sitter when thus brought forward in a photograph.

It has been advanced by some that this distortion can be overcome by a long-focus lens at a long distance; but, although it does partially reduce it, the conditions are unnatural, and the portrait loses that subtle yet powerful effect which makes one see the sitter in one's very presence, what one might call a "speaking-likeness" effect, to obtain which it is essential the point of sight, whether optical or visual, should have been within a conversational distance. A long distance immediately suggests a theatrical effect, unsuitable for the portraiture of private people. Whether this view is correct, or would only occur to one having the knowledge and practice of these distances or points of sight, is perhaps open to discussion.

I will now give you a number of pictorial illustrations by magic lantern, showing the difference between optical and visual truth, produced without changing the lens in front of the camera or the distance from the sitter. I will also show you the wonderful possibilities of this new power by a single humorous illustration, using a photograph of Mr. Marshall P. Wilder, that quaint American humorist, for my subject. I will also take a portrait by my light in an unconventional pose, and correct before you its inevitable distortion, and afterwards give you, as well as I can, a scientific explanation of my invention.

The Problems to be Solved.

Before I had brought my invention to its present state of adaptability, I found I had to solve five problems:—

1. To reduce locally the size of a head or hand, or other portion of a figure, and to do it symmetrically, so as not to change the character or symmetry of a head or the expression of a face; or, in the reduction of a hand or waist, to reduce, if desirable, the width only, and thus give a slender instead of diminutive effect.

2. Having solved this first problem, how to find a way to make a number of corrections in one negative at the same time, and with such simplicity and rapidity as not to call for special skill or training, or materially lengthen the time usually occupied in focussing during adjustment.

3. To shorten or to lengthen a portion of the whole negative right across without distorting the rest, such as lengthening the waist or skirt of a lady's dress, or, in the case of a landscape, to vertically enlarge the middle distance or horizon while reducing the depth of foreground and sky.

4. To obtain with each lens a variable degree of the modification of the dimensions of the parts corrected, so as to avoid the necessity of employing a great number of lenses to form a working set.

5. To find a readily fashioned refracting medium, so as to enable one to make at will eccentric alterations, or even distortions, especially suitable for the purposes of caricature.

The first problem I solved by the interposition in front of the sensitive plate of a supplementary lens. Although I claim this interposition as part of my invention, the abrupt ending of the curve of an ordinary lens would not only throw a shadow or dark zone upon the negative, but the abruptly broken-off lines and shades on the outside of the zone would not tally with those on the inside. I therefore (and this is the germ of my invention), continually vary the curvature of my lens until it reaches the plane—in other words, where the circumferen e of a plano-convex lens would otherwise stop—it flows or graduates into the reverse or concave curve, or, if plano-concave, *vice versâ*, and thus gradually merges by a wavelike line into the plane, with the result that the dark zone before referred to, consequent on the use of an ordinary lens, is replaced by a perfectly natural gradation, leaving no evidence whatever of the correction having been made.

The second problem I solve by providing a number of small lenses, each constructed on the above-described principle, and means of invisibly and adjustably supporting them in the pencil of rays.

In problem 3, to enlarge a portion only, such as the distance of a landscape, or to lengthen portions, such as the skirt of a figure, I interpose a plate of glass, a portion only of which is of a cylindrical form, flowing gradually into a plane.

I solve the fourth by so arranging these lenses in the cameras as to be readily moved backwards and forwards, thus varying the amount of the reduction of any part by change of focus. About a dozen corrector lenses will thus be all that are required to form a working set for ordinary portraiture.

To solve the last problem, I have found a readily fashioned refracting medium; but, as it requires considerable artistic skill to use it, and there are many difficulties to be overcome in its practical use, I am not in a position yet to bring it to your notice. It is embodied, however, in my patents.

The Uses of the "Corrector" Lenses.

It is easily seen that to use these corrector lenses requires no special training, only an eye for natural or visual proportions. That it is readily abused and dangerous in the hands of the stupid and ignorant only proves its wonderful pliability and adaptability in the hands of an artist, and instead of there being any drawbacks to its use, such as an increased time for exposure of the plate, on account of passing through more glass, the fact that the rays of the image are converged upon the parts rectified increases the brilliancy of the image, and it is found that the time of exposure is actually decreased.

This new power has many possibilities, which you can readily imagine. I prefer at present to hide from you other evidences of its versatility in the domain of caricature, wishing only to advance the cause of that which is the more beautiful and true. In this I have been encouraged by Sir Frederick Leighton, than whom we have no greater exponent of the beautiful in form, and who on a recent occasion, when visiting my studios to investigate this invention, expressed not only his surprise, but his delight, at the startling artistic gain, and the consequent visual veracity of the images I am enabled to produce.

Experts in optics are apt to have no sympathy or ear for the claims of art, and some will, doubtless, declare that optical truth is the only truth, and any correction a distortion. I was, therefore, doubly pleased, when I brought this invention before the Camera Club the other evening, to receive the congratulations and praise of its President, Captain Abney, the most advanced scientific expert in photography of the day. Unfortunately, he is prevented from being here this evening by an accident.

In conclusion, I would point to the examples I have shown you, and ask if they do not furnish an irrefutable proof of my assertion that "optical truth is not visual truth."

Hereafter we shall be able to make pictures which will not only tell us the visual truth—the real truth to our minds and hearts—but also tell us something of the individuality of the photographer, thus raising one branch of photography another step towards becoming a fine art.

H. VAN DER WEYDE.

DISCUSSION.

The Chairman said that, in listening to Mr. Van der Weyde and seeing his results, and especially in seeing how he put his lenses on the plate of glass, one was forcibly reminded of Columbus and the egg, and wondered that no one had thought of it before; but all strokes of genius came out in that way, and the greatest simplicity often displayed the greatest genius. He was very glad that a landscape photograph had been included among the lantern slides, because he had no doubt that many present had seen Vicat Cole's "Royal Windsor," and no photographer could ever take Royal Windsor like that. He had looked at the place itself, and tried to imagine where one could get a view of it like that, and he was quite sure that the painter had etherealised it, and produced a picture which no camera could give. There had been, in fact, an alteration of the middle distance, and that the camera was powerless to do, unless with the aid of some such device as had been described, which he thought was destined to ally landscape photography more nearly to art than ever it had been before.

Mr. Traill Taylor said that they all knew Mr. Van der Weyde's great abilities, and must acknowledge the exceedingly successful way in which he had sophisticated these portraits. It was not a subject for a scientist, but for an artist, for an artist did not care whether a picture was truthful or not.

Mr. W. E. Debenham said that it was not necessary to say how much they were all interested in seeing these results, but those who felt as he did must protest against it being asserted that the instrument used was an optical corrector; it was, as had been said, a sophisticator, and he protested strongly against the expression that optical truth was not visual truth, and maintained that images obtained in this way were not visually true. The two expressions, optical truth and visual truth, were, in fact, interchangeable. There were three objects in using an arrangement of this kind, one being to change the character of the perspective. Now, photographic perspective was simply a representation of objects larger in proportion as they were nearer; in fact, as they appeared to the eye. If one stood near a long building, and looked at it sideways, the near wall might appear half as high again as the wall at the other end; but no one would call it a distortion to represent it so, and every painter would so paint it, just as it was seen, and as a photograph would give it. If they saw trees in the foreground, and in the middle distance, a near tree might appear perhaps three times as high as a tree in the middle distance; the artist recognised that, and it was so accepted. But, in representing single-figure pictures, artists had not been in the habit of representing the advanced portion of a figure larger in proportion. Now, pictures appeared to be for the most part judged, not by the beholder's knowledge, and by comparison with the original subject, but by comparison with other pictorial representations of similar subjects to which he was accustomed. A Chinaman was perfectly satisfied to see objects which he knew to be of one size represented of one size, although at different distances; they were accustomed, in buildings and in a general sense, to see nearer objects represented larger than more distant ones, but they were not accustomed to see single figures painted in that manner, and therefore, when a photograph showed a protruding hand larger, and one in the opposite direction smaller, it was said that photography distorted. It was said that a man's boots were not twice as large as his head, and so on. Of course, it would be an extraordinary position for a photographer to choose, and no artist would choose such a pose, but, if it were adopted, the true representation would be exactly as the photograph gave it. However, as people were not thoroughly accustomed to perspective in single-figure pictures, there was something to be said in favour of a sophistication to this extent, which brought the picture more in accordance with what they were accustomed to. The second point was that this contrivance enabled the photographer to make pictures more in accordance with the conventional ideal. It was said that sitters complained that their waists and heads were too large; he was not now speaking of perspective effects, when one portion of the body was nearer the camera, but of waists and heads generally being too large. Too large for what? Simply for the conventional ideal according to which they had been accustomed to see them painted, which, as Mr. Van der Weyde had told them, was considerably too small. Photography had, to a great extent, cured painters of that fault, and there had always been some too great and too genuine to pander to fancy and fashion in that way; but, at all events, it was very common to paint heads and waists too small, and hands also; and an arrangement of this kind enabled the photographer to satisfy those who wanted rather a conventional ideal than a truthful representation. Again, it was said that mountains appeared too small and insignificant; that, being objects of interest, they filled the mind and gave the idea of being larger than they actually were; but, if that were so, why should waists and heads, which were not objects without interest, be made smaller? In both cases it was simply a question of what would be most effective or pretty, not what was most in accordance with truth. Painters had been in the habit of flattering, it paid them to do so, and no doubt many sitters would be better pleased. If this plan enabled photographers to flatter vain women by making their heads and waists appear smaller than they were, no doubt it would be commercially successful; but do not let them lose their self-respect by flattering their sitters, in word as well as action, telling them that these smaller heads or waists were in accordance with optical, or visual, or any other truth, when it was simply in accordance with a conventional ideal. Optical and visual truth were essentially one.

Professor C. Roberts-Austen, C.B., F.R.S., said that he had no knowledge of photography, but he did not like to let a paper of such extraordinary interest pass without a word. It seemed to him that the author had guarded himself against any charge of inaccuracy by saying that optical truth, so far as photography was concerned, was a merely mechanical operation. It had been known for a long time that our impressions were not to be trusted—that seeing was not believing—nor could they believe altogether what they only felt. If they crossed their fingers and rubbed their nose, they would feel quite certain they had two noses; and a sophisticator, if it was to be called so, was, in such cases, absolutely necessary. His wife happened to be an artist, and he had heard her say, with reference to a figure, that it was not high enough, that it ought to be eight heads high, or whatever the number was. He did not like to think that what they had heard was mere sophistication. It seemed to him that the author had shown how, by taking thought, they might add cubits to their stature.

Mr. T. R. Dallmeyer said that it appeared to him that one of the remarks in the paper was a mere truism, viz., that photographic perspective and visual perspective were not the same. Photographic or optical perspective was a science, but the way in which they saw things was dependent on psychology, which was not a science, and he did not believe it ever would be. Although photographic perspective was a science, it did not correspond with what they saw in the physiological sense. He had been much interested in these experiments, though it could not be called anything but a clever device. The only case in which photographic perspective and psychology agreed was when the images were entirely on one plane; then they were identical. They knew that the best results in photography were when the whole image was as far as possible on one plane. Before this device (which would, doubtless, be largely employed for portraiture), it appeared to him that a man exercised his skill as a photographer in arranging the sitter in one plane wherever it was possible, and cases in which the feet or hands came forward were the exception. He was not an artist, but, from an artist's point of view, he should think that this flattering device was an exceedingly useful one, and would probably become very popular; but it was not at all true. He must insist on that, because he thought Mr. Van der Weyde rather misunderstood Captain Abney the other day. He welcomed, as they all did, any scientific application of an optical nature, but he felt quite certain that he did not mean to convey that the results thus obtained were of an order which could be classed as scientific. As to landscape, the only example shown was one copied from another photograph, a portion of which might be lengthened or exaggerated, according to the psychological view of the individual, and it certainly looked very much better; but he did not see how this method would work in actual practice. If they took the case of a tree cutting the horizon, and applied this method to it, the middle of the tree would bulge out. There were only certain subjects on which the process could be used, and it appeared to him that an immense number of these correctors would be required to produce the desired effect in a landscape.

Mr. Van der Weyde said that there were two reasons why this method was valuable; one, because it enabled them to give a better suggestion of true proportion than an ordinary photograph would, if one part of the object came forward; and that was a solid, artistic reason. The other was that it enable them to please their sitters. But these two reasons should not be mixed up. There was no reason to decry the whole thing because it might be abused. He remembered very well, in early youth, when looking at photographs of people he knew well, that it always struck him how large their heads looked. The impression generally conveyed was not that conveyed by the photograph, and he contended that, as a rule, the head should be slightly diminished in order to give the natural impression. In taking a lady playing a violin, it was very difficult to avoid distortion, and an unnatural pose had to be adopted.

The Chairman said that they would all agree that they were indebted to Mr. Van der Weyde for one of the most interesting papers they had had on the subject of photography. With regard to visual truth, he had long had very great doubts whether there was such a thing at all. He was quite certain that, if he and Mr. Van der Weyde both looked at the clock at the end of the room, they would receive very different impressions; his short sight would only enable him to see a blur where his friend would see the face distinctly. Visual truth, therefore, was a thing that no artist could attempt to arrive at. In the work to which he referred before, there was no visual truth at all; it was a purely artistic work from beginning to end. He concluded by proposing a hearty vote of thanks to Mr. Van der Weyde.

The vote of thanks having been carried,

Mr. Van der Weyde, in acknowledging it, said that he agreed with much that Mr. Dallmeyer had said, but he could not agree with much that Mr. Debenham had advanced, and he thought that gentleman had ignored portions of the paper which he (the speaker) considered were conclusive as to the necessity for an instrument of this kind. A picture should

always give a suggestion of the impression on the brain, and if it did not do that it was not a picture, but merely an optically true photograph. This instrument helped one to do more, to make an optical representation of it; it gave a better suggestion of what they had seen than had hitherto been possible, especially in the case of portions of the figure which came forward.

THE INFLUENCE OF THE HAND CAMERA.

[London and Provincial Photographic Association.]

The spirit of exaggeration is one of the necessary evils attending the development of photographic civilisation. For years hand-camera workers have been pushing to the front, and striving to make the general photographic public decent and respectably minded citizens. But the dawn of reason has only just arrived, and, though tardily admitted, the *raison-d'être* of the hand camera is now recognised. It is possible for the veriest fanatic to now address an ordinary society upon what, in his opinion, are the points of hand-camera work, that is, he can now do it without the sneers and quiet scoffs of the old-timers. So that, in venturing to address myself to the decent and respectably minded body of men that compose the London and Provincial Association, I feel that, whatever the criticism may be, it will be just and generous. Above all things, I am sure you will fight, when the time comes, with interest in, and appreciation of, the hand camera itself. The battle hitherto has been between a small body of earnest men determined to advance, whilst opposed to them were thousands of skirmishers, who were too busy with other things to pay much attention to the invading force. The battle-cry of one was, "We are here, and we've come to stay," answered impatiently by the skirmishers, "Tut, tut! run away, little boys, and play," or "Bother these folks, what can they do? what rubbish to trouble us!" The first sign of the dawn of reason I detected some time ago, when I heard that a member of the London and Provincial Association had actually agreed to look at a hand camera, and it was thought to be a reasonable supposition that, ere long, he might actually handle the monstrosity. And now—well,

"Do I dream, do I doubt,
Or is visions about?"

Of course I mean *visions* of hand cameras. I hope you will correct me if I am wrong, but I believe you actually have men now who *use* a hand camera. What has happened to the poor London and Provincial Association? Has it been having too much "spirits" of late?

I said at the commencement that exaggeration is necessary nowadays. If a man wants to sell his camera, he asks *5l.* 10*s.* for it, so that he can get *4l.* 10*s.* by "reduction in the camera." You may perchance imagine I am on the same tack, that I am claiming (or, rather, shall claim directly) a good deal too much for the influence of the hand camera, so that I can climb down a little to appease your wrath, and yet get pretty well all I wanted to. Personally, by the conviction of experience, I believe all I say. You may not; that is your fault. In a few years' time they will be accepted as facts.

The influences of the hand camera run in several directions. For convenience' sake I have classified them into two

Photographic,
Mental or physical.

By an "influence of the hand camera" I mean some power or incentive towards improvement, in which the hand camera has been the sole—or, at least, principal—factor. To make a definite start thereto, I claim that it has been of considerable use in improving photographic materials, apparatus, &c.

Speed of Plates.

Much interest has of late centered round the great efforts of some of our platemakers to obtain the maximum rapidity of emulsion. The makers would hardly do this unless to supply a want; that must be admitted. The point is, from what does the demand spring? I allege from the hand camera. But it may be said, instantaneous photography in the ordinary camera must not be overlooked. Certainly not, nor the fact that the reduction of exposure in a studio of portraiture, especially baby and child studies, for dimly lighted interiors, and for portraiture by artificial light, is a convenience the desirability of attainment of which, no doubt, has helped in the same direction. There are possibly other causes which I have not enumerated. I admit their power, but deny their importance as compared with the requirements of the hand-camera worker. You may mass all these factors in a lump, and still the hand camera towers above that lump as a mountain to a molehill. The increased speed of plates is due to the hand camera, and, whatever weight other considerations may have added, they have only been as a single black pin is to a full box of white. It is there certainly but it does not make us buy the box. If there be any gain to photographers by the increase of plate speed, to the hand camera the credit must be placed.

Apparatus.

In several directions the influence may be seen. In order to diminish the enormous disparity in bulk and weight between the ordinary and the hand cameras, the former have been cut down in every possible direction. A hand-camera worker grumbles at the unnecessary weight of his 10×8 ordinary. Result, improvements and new patents galore. The necessity of reducing the shutter to small dimensions, in order to go inside the limited space of a modern hand camera, has brought upon the market a number of small and ingenious shutters. Possibly some of these and other improvements in apparatus, such as lighter tripods, dark slides, and the use of aluminium, would have arrived in due course. But we've got them *now*, and the hand camera did it.

Small Work.

Although it cannot yet be said that the day of small work has arrived, yet I claim that we are now appreciating quarter-plate prints very much more than we did. This has been a gradual growth truly, but a *résumé* of exhibitions during, say, the last two years would certainly prove the existence of the growth. In the old days the reports were something like this: "Mr. Blank shows a frame of snap-shots, which, as such, are very good." "As such," indeed; that is where the blind bigotry crept to the front. It was usual in those days to term them "snap-shots." Never mind if evidences of composition, careful treatment, and individuality were visible in the prints—that did not matter. They were snap-shots—no more, no—well, I cannot say no less, as no further degradation of photography could be then imagined. They were taken in a hand camera, and that damned them for all time. But now—they are snap-shots no longer, but prints the same as the rest. The influence has carried us towards the recognition of merit in the smaller sizes of prints, so much so that ordinary quarter-plate and 5×4 are constantly represented.

I'll admit that we have not yet reached rock bottom on this question, for, undoubtedly, small work does not receive its full meed of recognition; nor can it be said that hand-camera work is yet free from enemies. Even now, some puffed-up, unmitigated egotist of the high-art school waxes wroth occasionally, and provides padding for one of the photographic publications. He is usually one of those to whom photography must mean "art" or nothing. Well, we hand-camera workers do not suffer very much; I presume we have the proverbial duck's back. Anyway, Mrs. Artist Partington has no broom capable of keeping back the tide of the hand camera. Personally, I consider any man, who believes that photography is entirely concerned with art, science, or, indeed, any *one* branch, to the exclusion of every other, may safely be written down an ass. Hobbies may be ridden to the death, but they must not be allowed to order all others off the road.

Increase of Photographers.

Another very powerful influence is that of increasing the number of photographers. I don't think it can be denied that the principle of "You press the button, we do the rest," has increased th number of workers considerably. Many hundreds of the outsid public, to whom the very mention of a camera, tripod, lens, &c., would have frightened into fits, have bought a hand camera, to do "button-pressing" for themselves. Many of these must have been seduced into our ranks; for the step, from having "the rest" done by some one else to the doing of it themselves, was one of the easiest transition. Upon this point let me not be misunderstood. I cannot claim that all these "button-pressers" have become photographers (this is a terse way of putting it), but certainly a good many have been so pleased with their new hobby that they *have* made the plunge.

Better Posing of Figures.

This is another influence I claim. Of course, I know full well that all good photographers pay, and have paid, every attention to this matter; but my point is that the hand camera has stimulated effort in the same direction amongst the lesser workers. Let us suppose a case, of Smith, a half or whole-plate man, and his friend Brown, a snap-shot man. Smith is a careful worker of several years' experience, whilst Brown is but a beginner. Upon a comparison of results, Smith finds that in all his pictures there is too much staring at the camera if he introduces figures in the scene. He finds in Brown's shots, poor though they may be either artistically or technically, that, at all events, every one is not rooted to the spot, looking at the camera, and having the appearance of plaster-of-Paris images plumped down into the landscape, wishing they hadn't come, and wondering how they ar

going to get out. He takes the lesson to heart, and improvement in this respect follows. I am not saying this without authority, for I have seen the change in the work of many of my friends.

Illustrated Journalism has benefited considerably by the hand camera, as witness the reproductions of shots in the *Pall Mall Gazette*, the *Westminster Gazette*, and other up-to-date periodicals. The hand camera gives the power of depicting life and incident, which to the ordinary camera are impossibilities. This leads me to my last point in this section, but it is in no way least. Indeed I would lay considerable stress upon it. It is the influence of

Life and Character Studies.

As photographers we ought, I really believe, to feel a considerable amount of shame at the neglect of such a fine opportunity. If so be a hundred years hence it may be asked what has photography done, is the reply to be that it has produced pictures (at least the art photographer calls them so, though the painter will in no wise admit the fact), and pictures only? Certainly not. We can point to its use in astronomy, microscopic, medical, and many other directions, including the preservation of historic buildings and spots of interest. But will it not be asked at once, "Why did you not with the ample means at your command preserve for us the dress and fashion, the characters and incidents, the every-day life and bustle of the street?' Are we to answer that we sat at the feet of art masters who taught us so much about the diffusion of focus, the rules and canons of art, the composition, light and shade, freedom of treatment, idealism, realism, impressionism, and a few more "isms," that we either had no time, or were afraid to descend to such commonplace work as the life and character of the present century? I trust not, and sincerely hope a better account of our duty can be given. Here with the hand camera we have the opportunity of portraying for posterity life, life with its joys and sorrows, its sunshine and shadow, its comedy and pathos. The hand camera can in many cases do this better than the artist, and at all events we can do very much more in a given time. I have on many occasions fallen foul of photographic survey work, especially when any limitations of size or anything else debar hand-camera prints. Because that means the exclusion of life and character, which I firmly believe will have much more interest for future generations than these old mills, river banks, abbeys and castles, churches and public-houses (interior and exterior of each, of course), wandering brooks, &c. These may be stamped with the individuality of the artist; they may have clouds skilfully printed in from another negative; they may show the stream from the artist's house looking south, from the west, from the east, with the artist's house in the distance, and from round the corner; they may be sharp all over or sharp nowhere, but there is no life about them. Certainly, a farm labourer, say, may be introduced into the stream picture, but he will have his best go-to-meeting clothes on, be gracefully posed, and wear an expression upon his face a conjunction of care whether the cow is likely to get into the field, if this operation will keep him later at work, and whether he'll get a copy of the print. We may also be able to show studies of natives taken in the studio, with impossible backgrounds and sitting upon papier-mâché rocks, or standing in the street spruced up for the occasion, carefully posed, erect and manly, wondering what would happen if the show "bust."

After all, is there no art in the portrayal of life and movement? Is there no art in depicting the emotions and feelings by the expression upon the countenance? Are we to shut our eyes to the pathetic or humorous side of living nature? Must all art consist of dead tree-trunks, printed in clouds that run over the trees and landscape as if they were not quite sure just where they ought to be, and streaks of sunlight caught on the spree?

Must we produce representations of nature in an intoxicated state, or, as Captain Abney expressed it, "makes one perfectly sick to look at?"

No, good army of hand-camera workers, let not your hearts be troubled by this high art falutin. Keep steadily on the way of life and character, which is one of the hand camera's strongest directions of work, and the future will bless you equally with those who portray nature rubber-stamped with their own originality or eccentricity.

I have wandered slightly from my subject, but the influence of the hand camera is, and must be still more, felt in the direction of immortalising the men and women of to-day.

Mental and Physical Influences,

I now come to a somewhat more difficult subject to tackle, viz., the influences, physical and mental, of the hand camera. I don't expect you will agree with me upon some of the points at all, for the reason that, until a man has become a really earnest worker of some experience, these influences can hardly be understood. The hand camera, to my mind, exercises a considerable power of education, both mentally and physically. At all events, I have so found it. As the two points are so interweaved one with the other, it will be necessary to treat them together. The directions I refer to are principally increased speed of artistic perception, improving the vision, and quickness of action and decision. It is, perhaps, true that the class of work principally undertaken by each worker will make this point of lesser or greater importance. One who goes in for street work or rapidly moving objects will benefit more in these respects than the landscape worker. I still hold the opinion that successful hand-camera workers are born rather than made. Nevertheless, I cannot lose sight of the educational power of actual practice, for, speaking personally, the hand camera has quickened my thoughts and actions to a not unimportant degree. Speed in work and thought in these go-ahead times is not to be sneered at, and I do positively assert that I can work at greater speed, think, and decide more quickly than before using a hand camera. Take the question of focussing rapidly, and, to illustrate it best, let it be tried on a full-size focussing screen upon an approaching object. A few trials will prove how much more quickly it is possible to decide when actually sharp, and to fire the shutter, than it was at first. The whole question of thought and action following therefrom is quickened. To illustrate this, let me mention another capital test, that by electricity at the Aquarium, a test of vision and action. A pistol is held in the hand and a disc is watched. At a certain time a definite object passes this disc, and the task is to quickly fire the pistol, an electric arrangement of a black band registering the time that elapses between seeing the object and firing the pistol. Take any ordinary photographer (he must not be a shooting man, however), pit him against an experienced hand-camera worker, and the difference in the fractions of the second will be startling. Nay, further, let the hand-camera worker first try after a month or two's absence from the camera, and then, second, after he has been with it in the streets that day. He will be struck with the improvement. I therefore claim that the hand camera so improves our vision, our thoughts, our actions, in the direction of speed as to materially alter even a man's character. He decides and performs the result of the decision more quickly. He becomes sharp, prompt, and decisive, and past hesitations vanish. The hand camera therefore has considerable influence in altering the mould of the man.

I am ready to admit that the second division of influences may not appear of very much account, but am, nevertheless, convinced that, even if that is so, it is because I have not the ability to put these considerations before you properly. They wander afield somewhat from photography into other domains of study, with which I cannot claim much acquaintance as yet.

In conclusion, I claim for the hand camera the following points:—1, Increasing speed of plates; 2, Improving apparatus generally; 3, Causing greater attention to small work; 4, Increasing the number of photographers; 5, Naturalness of posing; 6, Aiding illustrated journalism and the study of life and character; and 7, Improving mental and physical action.

The paper is no weak-minded, cover-all-the-ground sort of attempt, but may almost be termed a fighting one. It is not hedged in with "buts" and "perhaps" and admissions or concessions, so as to prevent discussion or criticism. I have said what I believe and what I am prepared to defend from any honest enemy. And in that spirit I offer it to-night in the words of Hamlet,—

"Our thoughts are ours; their ends none of our own."

W. D. Welford.

RETOUCHING.

[Richmond Camera Club.]

I am given to understand that you expect of me something more than a lecture, and will not be content with less than a demonstration. You prefer to see things done rather than talked about, and I will try to make my paper as practical as the nature of the subject admits. It must, however, be remembered that retouching is emphatically not a demonstrative art. Good retouching is essentially modest and retiring, its very existence is unsuspected by many who admire the results produced by it, it is the Cinderella of the photographic arts, and its lot is generally to work without recognition or acknowledgment. I do not suppose I can act the fairy prince and raise it by anything I can say to-night to honour and esteem amongst amateur photographers; but I should be glad if I could, at least, cause you to consider whether a very useful, and in portraiture I might almost say an indispensable, art is not neglected more than it deserves to be. My own experience gives me grounds for assuming that it *is* neglected by amateurs, because, although I have met with amateur photographers excelling in many branches of photography, I have never met with an even passably good amateur

retoucher. The professional photographer, on the other hand, is very fully alive to its advantages, and is generally supposed to love it "not wisely but too well." How is this neglect to be accounted for? Are amateurs deterred by the apparent difficulty of the work, or do they look askance at retouching as an illegitimate tampering with the truth of a photograph?

The Degree of Skill Required.

If you examine carefully the work of a really competent retoucher on a head that has required clever treatment, it is quite possible that you may feel a little discouraged at the evidence it shows of a high degree of skill, which it is perfectly evident must be difficult to acquire. It must seem to the average amateur photographer that the time and patience necessary to attain such great proficiency would not be worth the while, and that he would do better to confine himself to landscape and subjects where want of retouching is not so apparent. But, after all, the proper study of mankind is man, and I suppose there never was an amateur, however ambitious, but who cast longing eyes on portraiture. Luckily, retouching is an art that pays good returns for small investments of time and thought spent upon it. A very little skill, if supplemented by intelligence, can be made of great use, and I feel perfectly sure that the most casual amateur would not find that any time given to learn the rudiments of the art was spent without result. If you are careful and resolute not to put any work on a negative you do not know will be an improvement, however little work you are able at first to do will be of advantage to your picture, even if it is confined to removing obtrusive defects or blemishes on the skin, or mending up neatly mechanical defects in the negative. Even such humble work as this will often make a negative satisfactory that could not be acceptable without it. If you learn how to get a suitable surface on your negative to work upon, and a properly pointed pencil to work with, you can get thus far without much difficulty; and I hope to-night to be able to teach so much to everybody here who cares to learn. As soon after as sufficient delicacy of touch is acquired to, if necessary, work on the negative so finely that the touches do not show when printed, further progress can be made towards retouching a head more completely. I have, besides, heard of conscientious photographers being deterred from practising retouching by an exaggerated respect for the truth of a photograph. But the inviolable truthfulness of a photograph is an unconsidered idea; an average photograph is, in fact, one mass of inaccuracies, and its irregularities are only too apparent to any one examining it with the slightest care.

In comparing a photograph with the object presented by it, the most noticeable variation of the photograph from the object, as seen by the eye, is generally its failure to render colour. This we are, of course, prepared for, and, I am sorry to say, even retouching cannot make good the omission, and for this reason we are not concerned with it to-night.

Modification of Tone by Retouching.

There are, however, other particulars in which photography seriously falls short of an ideal expression of the object photographed, and in most of these retouching can render very material assistance. Take, for instance, the modification of tone by colour, and this, in itself, is sufficient to prove the utility of retouching. Colour exercises a seriously disturbing influence in the rendering of tone by a photographic plate, and no object, in which there is a great diversity of colours, can be rendered in a photograph in its proper relation of tones.

In a photograph, reds and yellows will be represented much too dark, while the colours at the other end of the spectrum, the blues and violets, will be lighter than they should be. The introduction of isochromatic plates has lessened this fault, but the correction has only been partial and incomplete.

An engraver rendering an oil painting, or an etcher working from nature, is able to put aside colour altogether, and to express his subject by the proper relation of its tones to one another. If he gets a red or a blue together, it makes no difference to him; he expresses them simply as tone values, and according to their depth and intensity as seen by the eye. In a photograph everything is distorted by the influence of colour: a red and a blue together send their relative tones flying wide apart, and so exaggerated and untrue that the merest novice in retouching could see the inaccuracy, and to some extent correct it. Consider for a moment the effect of the colouring of the human face on a photograph.

Here we have an object with such varied colour and tone that it is almost impossible to get a passably truthful representation on a photographic plate. Take a fair subject with a high colour and a freckled skin, and, if you want to make a bitter and implacable enemy for life, show your subject the result untouched. Every freckle and imperfection in the skin that in life are not noticeable, and in the reduced size of a cabinet or carte photograph could not be seen at all, stand out harshly and obtrusively, and the unfortunate subject looks as if a charge from a shot had been distributed over his or her face. The glowing colour in the cheeks, again, which in life would be a charm, is rendered in the photograph as a shadow, and gives an unnatural hollowness to the cheeks and a sunken appearance to the face; the hair, again, being a warm tone, is sure to be rendered darker than it should be, while the eyes, if blue or cold grey, are lighter.

The effect in extreme cases is horrifying, and in all cases inaccurate. A photograph is often described as "justice without mercy," but this should only be when it is retouched, in its untouched state it is generally "justice without mercy" with the justice left out. Of course, I have put here an extreme case; some of us may be fortunate enough to keep through life the bloom of youth on our complexions, and preserve a skin unsullied by freckles or blotches, but we should then feel all the more keenly the flagrant injustice of representing the face blotched and uneven by the variations of colour in the skin unseen by the eye. An interesting illustration of the effect of colour on the skin was reported in the photographic press some months ago, when the photographs of a sitter in the earliest stages of fever revealed indications of the disease on his face long before they could be detected by the eye.

But even if there was no colour to deal with, although the tonality of photographs of most subjects would be much improved, it would be very far from perfect. It may be possible to make a negative from a subject in monochrome in which the tones shall have true value, but it is extremely difficult, and depends on the exposure being timed with great accuracy, and the development being carried on with the greatest skill. If it is under-exposed, the tone will be hopelessly extended and grades lost at both ends of the scale, some being smothered in the shadows and others lost in the lights.

Again, take the form of an object in its simplest expression as shown by its outline. Here we have no colour to confuse the form, and the shape does not depend on gradations of tone, but even under these simpler conditions we are not sure of getting an accurate representation by photography.

There is the distortion of the lens to be taken into account, and in an object having much depth the front or part nearest the lens will be of an exaggerated size compared with the part more remote, especially when the lens used has not much depth of focus.

Most Negatives Improved by Retouching.

I have reminded you in this way of some of the shortcomings of a photograph, because, unless it is clearly seen how imperfect a photograph must necessarily be, there is no excuse for meddling with it. But, whether you photograph landscape, figure, or portrait, you will seldom take a negative that could not be considerably improved by intelligent retouching.

For portraiture, indeed, it is absolutely indispensable, and the professional portrait photographer owes his very existence to it. Before it was understood that a negative could be worked upon, freely and successfully with a lead pencil, portraits were almost invariably taken of small size, generally of full length with tiny heads too small to show the imperfection, and photographs of this period are generally found to have been clumsily posed full length, *carte-de-visite* size.

The advent of retouching brought an immense extension of business to the photographer. Now large heads are generally made in almost the other extreme, and there is not a photograph sent out by any photographer of repute that is not from a negative that has been through the hands of the retoucher, and generally to its great advantage.

An Example.

Let me draw your attention for a moment to an example I have here. It is not an extreme case, but it will serve. It is a negative I picked out from only a few I looked through, and is an every-day subject with the retoucher.

The lady is not suffering, as at first sight she appears to be, from the ravages of some fell skin disease. You will notice she has rather a pleasant, smiling expression, not appropriate to one in pain. It is, in fact, nothing half so serious; she has merely been out in the sun, or has used the wrong soap—the one that is not matchless for the complexion—and has got a few freckles. Slight imperfections, barely apparent to the eye, but which are maliciously rendered by the lenses as great blotches and splashes having a perfectly horrifying effect. I have retouched the negative and made another enlargement from it, and I think you will agree that it is not only a more pleasing portrait, but also much more convincing as a likeness. The retouching is not flattery, it is an act of simple justice. I will willingly acknowledge that, like all useful things, the practice of retouching can easily be carried to excess; it must be confessed that it is often used in such an illegitimate manner as to call down upon the art sharp and well-deserved criticism. A fashionable photographer will think nothing of carving away a substantial piece of a lady's waist if it is not in the same proportion as that of a figure on a fashion plate. He will straighten a nose, as a matter of course, if it happens to be a little too *retroussé* or pronouncedly Roman, tint grey hair, and entirely eradicate wrinkles and marks of age of all kinds.

The Materials Necessary.

The cost of the materials necessary for retouching need deter no one from commencing. A 1*d.* pencil, or, if price is no consideration and you are inclined to be luxurious, say, a 4*d.* Faber or Hardtmuth, some arrangement in the shape of a retouching desk to support the negative, and a little medium, that can be made up for a few pence, is all that is absolutely necessary. The pencils I generally use are Hardtmuth IIH or HHH leads in screw holder. These or Faber's best pencils are very even and free from grit, and take a very fine point without breaking. They may be obtained in almost any number of H's according to hardness, and perhaps a beginner would find it easier to get on with a rather harder pencil at first; but a softer pencil saves time when the touch has

become light enough to use it. When you have got the right sort of pencil, the next thing is to get the right sort of point on it. This is one of the first difficulties of the beginner. An extremely fine point is absolutely necessary for such delicate work, and it is worth taking pains to obtain. I make a point about an inch or rather longer, tapering down regularly from the thickness of the lead to the sharpness of the finest pointed needle. The quickest way to sharpen is to rub down first with fine sand paper, and finish on a piece of ground glass or opal glass. The gelatine or varnished surface of a negative is too smooth to work upon, and offers no bite to the pencil; it is necessary to prepare it in some way. To my mind, the most comfortable surface to work upon is obtained on a good hard varnish, by grinding the surface with pumice powder. This gives a luxurious surface compared to the usual surface given by a medium.

The varnish must be fairly tough and well baked after negative is varnished. The grinding down must be done with some care, or there is a danger of scratching or cutting a hole in the negative, especially if the pumice is not fine and free from grit.

A little of the pumice should be taken on the tip of the finger and rubbed carefully on the parts to be worked upon. With a little practice any surface can be obtained to suit the subject, from a rough surface with a tooth like drawing-paper to a fine surface that will only take the pencil in light, fine strokes. I much prefer this surface to any other I have tried, but it has, unfortunately, a serious drawback, the density of the part rubbed down is very slightly increased. In retouching a face, the very slight increase in density is generally imperceptible, and when the negative is thin may be a positive improvement. When the face to be retouched is already on the dense side, it is better to use a medium.

There are a number of suitable mediums sold for the purpose. The medium I generally use is made of one drachm of powdered resin to two ounces of turpentine; it is very easy to make, and answers as well as any other.

The disadvantage of mediums compared with a surface prepared with pumice is that they are generally more or less tacky, and tear off the fine point of the pencil, and the bite cannot be regulated so conveniently. However the surface is prepared, it will not take the pencil freely enough to bring up quite transparent places in the film to the density of the lights, and when very transparent places have to be dealt with, such as holes in the film, dust spots, and other similar defects, it is best as well covered with the pencil as possible, and strengthened to full density with water colours mixed to match the tint of the negative stippled on neatly with a fine brush.

A retouching desk is required to support the negative in a convenient position while retouching. The desk should be firm, and capable of being arranged at an angle so that the light may be reflected through the negative from a reflecting surface arranged beneath. Desks sold for the purpose generally have a mirror for reflecting the light; but, unless the light is very weak, it is reflected too strongly by a mirror, and white paper makes a much better reflector, and has more mercy for the eyes. A good desk will be fitted with frames to hold different-sized negatives, and a hood to screen the eyes of the retoucher from light other than that passing through negative.

When we have these few requisites, we are ready to commence.

The Usual Method of Retouching.

I propose now to show you, as well as I am able, the usual method of retouching a portrait head with pencil, and afterwards I propose to call your attention to retouching methods more suitable to landscape photography.

It is a very difficult matter to illustrate portrait retouching to an audience, and I am trying a novel way. I have here a negative bromide enlargement of a head to life size. That is, an enlargement made from a positive transparency instead of from a negative. It is a choice subject, from a retoucher's point of view, and I am sure that the need of retouching is perfectly obvious to everybody who can see it. I am afraid I should exhaust your patience if I tried to retouch it in anything like a finished manner; but, if you can bear with me for a few minutes, and imagine it is the negative of a small head, and that you are looking through, instead of on to, it, I will show you how I should commence it. When it is necessary to retouch a landscape negative, the need for working upon it is generally from the same causes that call for retouching in a portrait, viz.:—

The modification of tone by colour, the defective rendering of gradations of tone through under or over-exposure of whole or parts of the negative, or faulty development, distortion by the lens, &c.

The method of working is, however, different in landscape; it is generally necessary to deal with larger surfaces, the delicate niggled work of the pencil must be exchanged for something broader.

The most useful retouching when broad patches are required to be lightened or darkened, such as an under-exposed foreground against an over-exposed distance, is done on the back or the glass side of the plate with the stump, or with coloured varnishes, or with colour applied with the brush. There are great advantages in working on the back of the plate; there is no risk of spoiling the negative, as any work put on, if not satisfactory, can be wholly removed or can be worked upon or corrected by scraping with a knife; and, besides, the retouching, being separated from the printing surface by the thickness of the plate, prints softer and permits of rather coarser working. Suppose we have a tree trunk in the foreground which is rather under-exposed, and which, before the distance and denser parts of the negative are printed, has darkened into a black stripe without shape or rotundity, it is an extremely easy matter to work upon it from the back of the negative and make it print as light as desired to bring it into proper tone with the rest of the picture. This can be done by coating the back of the negative with matt varnish, or covering it with *papier minérale* (a transparent paper sold for the purpose) and stumping a tint over it with a lead. If, however, it is necessary to make a very decided alteration, sufficient density cannot be got with the lead, but with tinted varnish a black object can be modified to numberless tints—to white if necessary.

The varnish may be made up with collodion and thinned with ether, and tinted to the required density with a few drops to the ounce of a strong solution of aurine. Pour it over the back of the plate so as to cover the part to be modified, and as soon as it is dry scrape it away where it is not required. The same plan may be adopted to help parts of a negative too dense to print.

Take, for instance, the gleam of sun on water. Very frequently the negative will print with a hard, white, chalky light, omitting altogether the delicate tones that approach the high light. Although they are apparent in the negative, the picture would be over-printed before they were printed out. If, however, the negative is varnished all over, the back with a suitably tinted varnish, and the varnish over the light removed by scraping with a knife, the difficulty would be overcome. This method of treating a negative is extremely simple, and I think can be used with great advantage and effect by every landscape photographer. I do not mean in order to make poor negatives presentable, but there is hardly a negative produced that could not be made more truthful and more beautiful by judicious and intelligent retouching. It puts in our hands a power akin, although remotely, to that of the painter, who can arrange the tones of his picture according to his feeling and judgment.

PATENTS COMPLETED.

Improvements in Apparatus for Taking Instantaneous Photographic Pictures.

No. 10,353. Georges Philibert Charles Maroniez, 101, Rue Faidherbe, Boulogne-sur-Mer, France.—*March* 4, 1893.

My invention has for its object improvements in apparatus for taking instantaneous photographic pictures, the movement of the shutter and the changing of the sensitive plates or surfaces being effected by a single movement of a knob or handle.

The apparatus consists of a box or camera forming a dark photographic chamber, provided with a lens adjustable by a rack and index, so that the exact position and focus can be determined beforehand.

Behind and against the front of the camera is a shutter in the form of a disc, revolving always in the same direction. It is provided with two opposite openings, which pass in turn in front of the opening of the lens, and it is mounted upon an axle having a toothed wheel, operated by a coiled spring, which can be wound up with a key when required, so as to afford a considerable number of exposures.

At right angles to the diameter of the disc on which the openings are made, and at its circumference, two catches are arranged which serve as stops. For this purpose they act in combination with an escapement or anchor piece pivoted in the upper part of the camera.

This escapement is held back in its normal position by a spring, one of its teeth being down and the other up, so that the first engages with and holds one of the stops upon the disc, and prevents the latter from turning.

When, by the action of a bar or pusher moving longitudinally and provided with a tappet, the escapement is turned on its centre, the tooth described is released from the disc, which makes a semi-revolution, uncovering the lens as it does so. The other tooth of the escapement, which is now down, then stops the other stop upon the disc, but when the pressure upon the pushing bar is released it is returned to its normal position by a spring, and the escapement takes its original position, the second stop upon the disc being released, but being immediately caught by the other tooth of the escapement, where it is held in readiness for another exposure, and so on as often as may be desired.

In order to change between each exposure the sensitive surface, which may be either glass plates or films of any convenient size, they are contained in frames or discs of thin metal slightly concave to give elasticity, and having their edge turned over to hold the plate or film.

These frames are arranged one behind the other in the back of the camera, and are all pressed forward by a spring. They are supported below by two guides, allowing a slight amount of play, and the front frame is pressed against two pieces of metal, which project very slightly above the ends of the guides, and have their projecting ends rounded.

In the middle of the upper part of the camera is arranged a longitudinal bar or spindle, turning in bearings, and having upon its front end a toothed pinion gearing with a rack upon the pushing bar already described, so that, immediately after the shutter has operated, the pinion and spindle are made to make a quarter of a turn.

The spindle carries two curved teeth at right angles to each other in end view, and one somewhat in advance of the other, the forward tooth, which, in its normal position, is inclined downward and curved to the left, serving to release the front sensitive plate and frame. For this purpose it is combined with a stop at the end of a flag spring, which presses it down, and against which, in this position, the top edge of the first or front frame presses.

By the revolution of the spindle by means of the rack, the front tooth rises to the left, and, having made an eighth of a turn, comes against and presses up the spring and stop, pushing the latter into a recess in the top of the camera, so that the top of the front frame is released, and being pushed forward by the spring at the back, and by an angular spring described presently, falls forward (turning upon its lower edge), and, guided by two curved guides in the body of the camera, falls flat upon the bottom of the latter, where it is held by two springs in the sides.

At the same time that the forward tooth upon the spindle has moved up, the corresponding back tooth has moved down, and prevents the next frame from falling forward.

When the pressure upon the pusher bar is removed, the spindle is brought back to its original position by a spring, and the next frame is pressed forward and held in position ready for a fresh exposure.

The back tooth upon the spindle operates a wedge-shaped piece at the end of a flat spring, which tends to force it down. This piece has a notch, into which the said back tooth engages, and raises the wedge into the recess at the top of the camera. When the tooth is lowered, it releases the wedge, which is forced down by its spring, its edge entering behind the frame which has just been exposed, and driving the upper edge of the latter forward so that it falls over as already described, even in case the camera is inclined somewhat backward.

Inside the camera, at its right and left sides, are two vertical springs of thin steel metal split into strips of different lengths, the thickness of, say, three superposed frames being left between their successive ends, which are bent somewhat outward, so that the frames as they fall easily press them back, but are afterwards prevented from rising from the bottom, or being displaced, even if the camera is turned in any direction. An opening in the bottom allows these exposed plates to be removed without disturbing the others.

The pushing bar is provided at its end with a spring cam, which, at each operation, advances a ratchet wheel one tooth, the wheel having a number of teeth corresponding with that of the plates, and having an exterior index hand which can be brought back to zero by a button, and indicates automatically the number of plates exposed.

The pusher bar itself, which actuates the entire mechanism, is of brass, having a rack cut in it to fit the toothed pinion on the spindle, and it is also provided with a pall which in its forward movement actuates the escapement. This movement is so arranged that the escapement is released after the first part of the stroke, during the remainder of which the teeth upon the spindle disengage a frame as described and cause it to fall to the bottom of the camera, the two movements being in succession and not simultaneous.

The pusher bar is operated by a cam having an exterior thumbpiece which can be worked without shaking the camera. By turning this thumbpiece a quarter of a turn, the cam is turned and forces forward the pusher bar, which starts the escapement and the spindle. A safety catch prevents the thumbpiece from being accidentally moved.

When the pusher bar is brought back by its spring, the whole of the parts take their original position ready for a fresh exposure, and all the required movements are made with great rapidity by a simple pressure upon the thumbpiece, so that a large number of exposures—say, twenty a minute—may be made without interruption.

From its simplicity of construction and operation, only a simple pressure upon the thumbpiece being required, the apparatus may be safely used by persons inexperienced and without knowledge of photography.

Improvements connected with Photographic Cameras.

No. 8067. Samuel White Rouch, 180, Strand, London.—*March* 18, 1893.

Instead of the narrow piece made removable, which was detachable from the baseboard which folded over so as to protect the focussing glass, as described in my patent (No. 1448, April 11, 1878), I now make this removable narrow piece much broader, so as to extend nearly from side to side of the baseboard, and have it attached thereto, so as not to be removable, but to slide in and out within defined limits by means of a rack and pinion. The front of the camera, by which the lens is carried, may, as in my former arrangement, be attached to this travelling and adjusting piece at either of its ends, so as to provide for either a short or long extension by the bellows body of the camera to provide for the including of wide or narrow angles of view; and, whereas the former narrow adjustable travelling board had one rack only, my improved one is fitted with two—one at each side—thus ensuring steadiness and parallelism of motion.

Attached to the back of the camera is a repeating back adjustment (already known in some other cameras), by which, instead of one single picture the full dimensions of the camera, two of smaller size may be taken side by side.

To provide for the increased raising and lowering of the lens in the camera, the front slides in grooves at each side, and at its bottom ingress of light to the camera is prevented by a folding gusset arrangement of leather or similar material attached respectively to the solid front of the camera and the movable lens-carrying front, by which arrangement light is totally excluded, even when the movable front is considerably raised.

This camera may be used for the production of either enlarged or reduced pictures from any negative or cliché by the following means:—It is erected on an elongated table or base, and, its front being removed, the front of another, although not necessarily similar, camera is inserted thereon, by which both are thus attached together. This latter, to permit of the facility of extension, has two independent bellows bodies, each fixed to the central frame. An enlarging or reducing lens is fixed in any convenient place in the latter camera, which has an independent ground glass on which to focus the enlarged or reduced image, and the means for holding the negatives or cliché.

After the camera has been focussed, and to prevent its being thereafter removed or disturbed, a quick-threaded screw, acted on from the side, jambs the adjustment and renders it temporarily rigid.

Improvements in or relating to Apparatus for the Exposure, Separation, and Storing of a Pack or Series of Photographic Films.

No. 2566. Joseph Thacher Clarke, Boston, Massachusetts, United States of America, at present residing at 3, College-road, Harrow, Middlesex.—*March* 25, 1893.

The chief purpose of my invention is to provide an apparatus, of the type customarily described as a "changing box," by means of which a pack of sensitised films or like flexible sheets may be exposed in connexion with an ordinary photographic camera, and may thereafter be transferred *seriatim* to a light-tight receptacle, where they are stored in another pack or series. Certain features of my invention—notably the differentiating indicator wheel, the interlocking pressure board, and the means for attaching the selecting devices to their supports—are, however, directly applicable to photographic film-changing apparatus of other types, such, for instance, as a self-contained hand camera. This adaptability will be readily understood from a description of my improved changing box for photographic films, and will, moreover, be especially referred to hereinafter.

My invention is more particularly intended for the manipulation of films notched upon two of their sides and arranged in alternate sequence, as described in Letters Patent, No. 23,315, of 1892. A pack or series of such notched films may be exposed, separated, and stored in my improved changing box without the intervention of carriers or sheaths, and without previous separation of the films by the photographic operator. Means by which similarly notched films may be selected and separated *seriatim* from a pack or series have been described by me in Letters Patent, No. 11891, of 1890, where they are referred to by the numerals D 12, and the separating device which I employ in my present invention, is, in principle, identical therewith.

My improved changing box consists of two receptacles. The first of these (which will hereinafter be referred to as the dark slide) contains the pack of unexposed films, and is provided with a rebate or with catches for attachment to ordinary photographic cameras, in the same manner as are the double backs which are in every-day usage for the exposure of glass dry plates.

The second receptacle (hereinafter called the receiver) is adjoinable to the dark slide, face to face, by a light-tight fitting, and serves to store the exposed films which are transferred thereto.

The faces of both dark slide and receiver are closed by light-tight shutters which may be withdrawn for the respective purposes of making the photographic exposure, of transferring the films from one receptacle to the other, and of removing the exposed films. The dark slide has an opening at its back to permit of the insertion of the pack of unexposed films, together with a spring follower or backboard serving to press the films forward against the selecting and separating devices which hold the foremost sheet in register.

For the purpose of making an exposure upon the foremost film in the dark slide the procedure is as follows:—This receptacle is attached to a photographic camera in the same manner as an ordinary double back; the shutter of the dark slide is withdrawn; light is admitted to the camera lens in the customary way, and the shutter is replaced. The dark slide is then detached from the camera and adjoined, face to face, to the receiver, being held in an approximately horizontal position, face downwards. The shutters of both dark slide and receiver are withdrawn together, and the film-separating mechanism is operated by means provided for this purpose upon the outside of the case. This releases the exposed film and allows it to fall into the receiver. The shutters are thereupon replaced, and the receptacles separated. These operations may be repeated as many times as there are unexposed films in the dark slide. When it is desired to remove the exposed films for the purpose of development in the photographic dark room, this may be readily done by withdrawing the receiver shutter.

Improved Photographic Magazine Changing Box for Plates and Films with Roller Slide Shutter.

No. 6355. Carl Grundmann, Leipzig, Saxony, German Empire, Nicolaistrasse 41.—*March* 25, 1893.

This magazine changing box is provided with a plate-changing device which renders it possible to use the same, as other ordinary dark slides, direct with the camera, and also allows the same to remain fixed to the camera during the changing of the plates, that is, while transporting the exposed front plate to the rear.

The changing of plates is greatly facilitated by employing my invention.

A further improvement relates to the arrangement by means of which the slide or shutter, which serves for exposing and also for changing the plates, moves in a semicircle round the box forming the plate magazine, and for that reason does not protrude from the apparatus during the use of the same.

It is, furthermore, very advantageous to employ a light-tight bag fixed to the

box for temporarily holding the plate during the changing, as the folds close to the box when not in use.

A great saving of space and a very compendious form is the result.

The connexion between the box forming the magazine and the attached bag is formed by two slots made in one of the side walls, one of the slots being towards the front near the shutter, the other to the rear of the last plate, both slots being protected by the bag.

The exposition and changing of plates is carried out in the following manner :—

After fixing the changing box to the camera, the safety spring attached to the lid is pressed down and bolted, and a roller-slide shutter moved in the direction towards the bag.

In this manner the front plate is laid free to be exposed, and at the same me the frames, which carry the plates or films in the box, moved so far forward by means of the pressure of a spring that the front frame will be in the focus of the lens and in the position which the shutter has previously occupied.

If the shutter is moved in the opposite direction to the aforedescribed, when the exposition is ended, the front frame, with the exposed plate, will be simultaneously pushed through the forward slot into the bag, from whence the same can be moved by hand through the rear slot into the changing box behind the other plates.

By means of a ruby glass let into an opening of the lid, the succession of the frames, which are provided with consecutive numbers, can be observed.

Improvements in Photographic Apparatus.

No. 9535. James Douglas Lysaght, 7, Crescent, Queenstown, co. Cork, Ireland.—*March* 25, 1893.

My invention applies more particularly to that class of photographic apparatus known as hand cameras.

It provides a means for accurately focussing the image previous to exposure.

To accomplish this, I provide a plane mirror, preferably silvered on its upper surface, to reflect the image projected by the lens on a piece of ground glass inserted in the top of the camera. This mirror is attached to a plate which slides in grooves on a frame in the same manner as the sliding stage of a microscope, being actuated by a rack and pinion. The frame is so constructed that it forms an angle of 45° with the ground-glass screen.

To obtain a suitable chamber or hood to enclose the ground-glass screen, I provide two flaps or doors, hinged to the top of the camera—one of these doors is fitted with side wings. When in use for focussing, these doors or flaps are raised by rods, to be hereafter described, and form a focussing chamber, the width of aperture of which is capable of adjustment.

To enable the operation of focussing to be effected in the most satisfactory manner, I provide means, to be hereafter described, to open the stop or diaphragm of the lens to its fullest extent at the same time that the doors of the focussing chamber and mirror are raised.

To accomplish these combined movements, I connect the pinion that actuates the mirror by means of a train of wheels to a vertical slide furnished with a rack. At the upper end of this slide suitable rods are fitted connected with the flaps of the focussing chamber.

A lever handle outside the camera connected with a toothed wheel inside in gearing with the train of wheels above mentioned actuates the apparatus.

The stop or diaphragm of the lens is moved as follows :—I attach a roller to the shaft carrying the wheel and lever handle ; to this roller one end of a cord or chain is attached, the other end being secured to the knob or projection from the stop, this stop or diaphragm being preferably that known as the iris. A spiral or other spring fixed between the side of the camera and the knob of the stop serves to bring it back to any required position. An adjustable pin or screw permits of any degree of adjustment of size of aperture.

For use with my invention I prefer that form of exposing shutter known as the roller blind, fitted as close as possible to the sensitive plate or film.

The claims are :—That one movement of the lever handle in one direction raises the mirror and the doors of the focussing chamber at the same time, opening the stop of the lens to its full aperture, thus enabling an accurate focus to be obtained by means of the usual rack and pinion attached to the lens or camera, and the reversal of the handle lowers the mirror, closes the doors of the focussing chamber, and returns the stop of the lens to any prearranged position.

Improvements in Photoographic Camera Shutters.

No. 9820. Conrad Beck, 68 Cornhill, London, E.C., and Joseph Thacher Clarke, Boston, Massachusetts, United States of America, at present residing at 3, College-road, Harrow, Middlesex.—*March* 25, 1893.

Our invention relates to photographic shutters of the type described in Clarke's Specification, No. 20,852, of 1890, in which the movable plate or shutter, revolving in one direction only, is of a circular shape, with a single exposure aperture, the size of this aperture being increased or diminished by a secondary or auxiliary semicircular fan or stop attached to the face of the main shutter disc in such wise as to obscure a greater or less portion of the aperture thereof. With an auxiliary stop of this nature, the exposure aperture in the shutter disc may be varied from the narrowest radial slit to a concentric zone extending to a length of 180 degrees.

In shutters of this type, the exposure aperture, whether narrow or wide, has hitherto been so arranged as to pass immediately in front of the lens on the shutter being set in action : the auxiliary stop, *i.e.*, the semicircular obscuring plate attached to the main shutter being moved, in the act of increasing the aperture, in a direction contrary to that in which the shutter disc is revolved.

It has been found in practice that this arrangement does not give the greatest possible latitude of exposure, inasmuch as the shutter disc, when released, revolves with a gradually accelerating motion. Thus the narrowest available slit, being immediately adjacent to the lens aperture, was passed in front of the lens at a slower speed than was any portion of the zone situated at greater distance from the lens. It is obvious that the result of this acceleration has been to decrease the variability and range of the effective photographic exposure, which was thus not directly proportionate to the aperture displayed in the shutter disc by pushing aside the auxiliary stop from the zone.

Our present invention not only obviates this disadvantage, but profits by that very acceleration in the rate of travel which has been observed in the movement of the circular shutter disc. We obtain this advantage by so constructing the auxiliary semicircular obscuring plate that it is moved, in the act of increasing the aperture, in the same direction as that in which the shutter disc revolves. According to this arrangement the narrowest available slit is situated not immediately adjoining the lens aperture, but at a distance of one hundred and eighty degrees therefrom. In other words, all that portion of the aperture zone which is obscured by the auxiliary stop has to be passed across the lens before any light is admitted. Thus the largest possible aperture is passed across the lens at the slowest average speed, whilst the narrowest aperture is passed across the lens at the most rapid speed. By this method of constructing the obscuring plate that acceleration in the motion of the shutter disc, which has hitherto been a drawback, is rendered actually advantageous.

The change in the operation of the obscuring plate involved in our present invention naturally leads to certain alterations in the details of the shutter. As no time exposure is possible without the introduction of an entirely independent detent, the secondary or retaining click, with its lifting apparatus, described in the before-mentioned Specification, No. 20,852, of 1890, is omitted. It has, furthermore, been found economical and otherwise advantageous to replace the screw cap attachment, which was at first employed for the purpose of holding the obscuring plate against the shutter disc by a light spring clip of thin metal affixed to and revolving with a shutter disc, and capable of exercising sufficient pressure upon the two plates to prevent their relative position from being unintentionally altered.

A New Maoazine Camera.

No. 6243. Samuel Dickinson Williams, Moorlinch House, Clytha Park, Newport, Monmouthshire.—*March* 28, 1893.

According to my present invention I form my camera with a double bottom, that is to say, with a platform stretching about half the length of the camera, and raised parallel above the floor thereof so as to leave a space between sufficient to enable a sensitised film or sheet to pass along. The films or sheets or other sensitised surfaces, hereinafter referred to for brevity as films, are packed and rest with their edges downwards upon this platform, and are maintained in this upright compact order and position by means of spring pressure applied at the front and on top. On the sides of my camera I arrange a system of wheels or pulleys with endless chain bands or cords passing over them, and I connect the pulleys and bands on one side with similar pulleys and bands on the other side by cross pieces or carriers bearing spring hooks, clips, or grippers. The system of pulleys and bands occupies on each side of the camera a rectangular-shaped position or approximating thereunto, so that when set in motion the above cross pieces travel in continuous rotation right round the body or pack of films as they rest or stand on the platform, that is to say, starting at the back, passing under the platform, then round the front, over the top, and on the back again. The spring grippers take hold of the bottom edge of the film, but I prefer to use films with holes in at the bottom edge into which the spring hooks or grippers carried by the cross pieces engage at the proper moment, by being made to pass over a ledge or guide piece situated at the required point on the inside in the back at the bottom of the camera. The continued motion in the same direction of the travelling band enables the cross piece thus to carry the film under the bottom of the platform and up into a vertical position in the front, when, having arrived thereat, the spring hook or gripper is again made to pass over a corresponding ledge or guide situated at the required point on the inside in the front at the top of the camera, and thus becomes disengaged, leaving the film in the front in proper position for exposure, the spring pressure at the front and the springs at the top of the films adjusting same in their place and preventing the front film from becoming deranged in position.

I prefer to furnish my system of pulleys and bands with four of the cross pieces referred to, as by that means I am enabled to have a film which has been already drawn from the back, always waiting at the bottom of the camera ready to be drawn up in front. I provide for the separation of the films or sensitised sheets, in order that the hooks or grippers of the carriers may take to one and one only each time by the following device. At the end of the platform which supports the general body of the films, I arrange on a suitable shaft a screw consisting of a cam-shaped thread with knife edges, such thread being of a pitch just fine enough to admit only one thickness of the film or sheet which is being used, the travel of the thread beginning from nothing increases by reason of its cam shape so as to gradually insert itself automatically between the last film at the back and the general body of the films, and at the same time by reason of the natural angle of the thread pushes the film so separated outwards and over the edge of the platform, where it is in a position to become engaged by the hooks or grippers of the cross carrying pieces. For the protection of the body of films during exposure of the one in position, I arrange in front of the general body of films a dark curtain, or flexible dark slide, or screen, working on rollers mounted upon or in conjunction with an endless band, which forms a sort of skeleton or hollow frame alternating with the dark slide in such a way that for a certain travel of the rollers the dark slide is behind the film when in position for exposure, and for a certain further or reverse travel after exposure, the dark slide is withdrawn therefrom to a position in front of the film, and the skeleton or hollow frame aided by the spring pressure referred to permits the exposed plate to join the general body of the films, and the next movement brings another film up in front, but at the same time the screen rollers have also made a further travel and brought the dark slide into position behind it. The screen rollers are geared with the system of pulleys and driving bands, so that the motion derived therefrom connects the screen in a manner suitable to produce the effects required. I arrange my camera with suitable shutter mechanism, and this also I connect by contacts or gearing, or other mechanical connexion, with the shaft of the screw cam or system of pulleys and screen rollers, so that, when a film is

about being changed after exposure, the fact of the same being done shall automatically set the shutter, I arrange a suitable spring catch for releasing the same by hand either for instantaneous or time exposure, or, where necessary, I omit such device for independent working and make the continuous travel of the system of pulleys and cross carriers, or the general action of the mechanism as described; set the shutter and release it as fast as the films are brought into position. I arrange a driving band on a driving wheel or pulley on the side of the camera gearing into the system of pulleys and cross carriers, or I drive the general movement from the screw shaft by suitable gearing, from which it will be seen that the continuous rotary motion of the driving handle and the general arrangement and mechanism as described will enable the films to be exposed in rapid succession until the charge of films or sheets in the camera be exhausted.

Improvements in Photographic Cameras.

No. 10,167. John Featherstonehaugh Parsons, Siddington House, Kingsdown-parade, Bristol.—*March* 25, 1893.

This invention, which relates to photographic cameras—more particularly hand cameras—has for its objects to obviate certain disadvantages appertaining to cameras as hitherto constructed and fitted.

According to this invention, in its relation to the use of films, the latter, instead of being, as heretofore, in a continuous roll, are separate, and each film is carried on the face of a mount of cardboard, paper, or other suitable substance, to which it is attached. The mounts carrying the films are piled on end, and at the base they are separately hinged to a common foundation of tissue paper or other suitable pliable material. The pack of mounts and adhering films thus arranged in book form is placed on a shelf in the camera, and a spiral or other suitable spring is brought to bear on the back of the pack, which thereby tends to advance towards the lens, but is restrained by a stop situated at each side of the camera. When an exposure has been made, the said stops are operated so as to release the foremost film of the pack and to retain the rest. The camera is then tilted forward, and the released film descends on its hinge, face downwards, until it is arrested by the spring of an indicator. The operator then turns a rod by which a vane, arm, or frame, is brought to bear on the back of the mount and forces it past the indicator, by which latter the descent of the film is indicated to the operator. The film descends to the floor of the camera and is detached at the hinge from the rest of the pack, which, under the influence of the spring behind it, has advanced to the extent of the thickness of a mount. After exposure of the now leading film of the pack, the actions above described are repeated, and so on for each until the whole pack has been exposed.

When, at any time, it is desired to take out a film or films from the camera, a slide in the latter is opened, and the film or films removed without waste of film, such as is entailed with the use of rolled films, and without disturbing the unexposed films.

According to this invention, in its relation to the use of sensitised glass plates, the latter are arranged in a pack of frames or cases placed on end and hinged at the base, which is inclined, by webs of paper, parchment, or other suitable material, to a common foundation. The pack of frames or cases carrying the plates is placed with the inclined base downwards on a correspondingly inclined part of a carrier in the camera, the longest frame or case being in front, that is, facing the lens. To the carrier is attached one end of a spring constantly tending to draw the carrier towards the lens. A rod, furnished with suitable restraining stops, prevents, at the will of the operator, any forward motion of the carrier. The stops are so arranged that, when one plate has been exposed, and is allowed to fall on its hinge, the plate immediately behind it is prevented from descending with it. As each plate is used and lowered, a holder, connected to a spring, acts in conjunction with the stop rod, and holds the plate on the bottom of the camera, where they lie, face downwards, one exactly over the other, a result due to the inclined base of the pack and the inclined part of the carrier, which is advanced to the extent of a plateholding frame or case at each change of plates. The changing is effected by one manual motion only.

This invention consists, further, in an improved shutter for the lens. The shutter is composed of two sliding plates so shaped as to present, when moved apart, a diamond-shaped aperture. The plates, which are contained between guides, are normally kept closed by a spring of indiarubber or metal. To open the shutter, pressure is applied to the outer ends of two hinged levers, which, on being pressed inwards at the said outer ends, and consequently forced apart at the inner ends, cause the plates to recede from one another and from before the lens. With this form of shutter no setting is necessary, and instantaneous and time exposures are made without altering the shutter or the motion by which exposure is made. Moreover, light is first admitted at the centre of the lens, which is also the last point of closure.

Mr. Edward A. Rice has sent us a sample of his "Reliance" retouching medium, and which, after giving it a trial, we find to quite bear out the name that has been given to it, for it gives a responsive surface to the touch of the pencil, whether applied with a hard or a delicate pressure. It dries quickly, and is ready for use within two minutes after application.

An Automatic Rocker, invented by Messrs. Pittar & Thompson, is ingenious. Two small pans are balanced on a pivot, in such a way that, when one is filled by the stream of water flowing in, the weight causes it to oscillate, and the water to flow out, the other pan now taking its place. This reciprocal action imparts movement to a balanced false bottom in a tray adjoining, and on which is laid the negative to be washed. Old photographers, who were acquainted with the washing machine of Cornelius Hanbury, will recall the similarity of the means for effecting the oscillation, but this one differs in certain respects from the one of former times.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

April 28,—Mr. J. J. Briginshaw in the chair.

The Influence of the Hand Camera.

Mr. W. D. Welford read a paper on this subject [see page 279.]

Mr. R. P. Drage thought that, although some hand-camera workers might secure nine or ten pictures out of twelve exposures, they were only a drop in the ocean, and that as regards the wasting of plates the hand-camera men had the pull.

Mr. W. E. Debenham, as to Mr. Welford's claim that the hand camera tended to quicken a man's perception and readiness for carrying out a train of movement in a rapid manner, thought the use of the hand camera might in that respect be compared to certain games of skill. As to the speed of plates having been quickened by the demand for rapid plates for the hand camera he (Mr. Debenham) thought that a mistake. He had used as rapid plates (of his own make) ten or twelve years ago as were obtainable commercially now.

Mr. G. Austin thought that the hand camera as a companion on walking tours passed the time very pleasantly.

Mr. J. S. Teape corroborated Mr. Welford's remarks as to the necessity of speedy action when photographing in crowds of people. The hand camera had certainly increased one's power in that direction. He did not agree with Mr. Welford in his reference to the articles on art, which appeared in the journals, as "padding." They were of great use at times and no check should be used against their appearance. Photographers had learned a great deal from them.

Mr. T. Bolas thought such articles useful from the point of view of awakening thought, even though the articles might themselves be valueless.

Mr. Simpson, of New York (a visitor), said he had been travelling for three years and had carried a hand camera all the time and wished to say something in its defence as it was abused on both sides of the Atlantic. He used a whole plate camera for landscape work but if one travelled with any baggage it was too cumbersome. He had taken 1200 negatives with the hand camera in the course of his travels, and showed lantern slides from them made on Carbutt's lantern plates which were three years old.

Mr. J. H. Avery thought that, if photography was to take up a position as a fine art, it would not be due to the hand camera.

Mr. R. Child Bayley asked, if Mr. Welford regarded articles on art as padding, why such a large proportion of the articles in his paper were on artistic subjects?

Mr. P. Everitt said that if any camera sinned in giving drunken architecture it was the hand camera. As to the speed of plates being influenced by the hand camera, he thought the assertion was altogether wrong. He (Mr. Everitt) did not believe it for one moment. It was due to competition on the part of platemakers to supply the public with what they wanted, and to claim it as due to the hand camera was a piece of cheek. Professional photographers required quick plates and the increase of speed was as much due to the use of large plates as small. Mr. Welford's sneer at articles on art cut against the paper he had just read.

Mr. J. Nesnit detailed some recent experiences with a fixed-focus hand camera which had resulted in failures.

Mr. S. J. Beckett said the hand camera was an advantage when travelling, and showed results he obtained with one which he could not have got with a stand camera, or even at all.

After further observations Mr. Welford replied: Too much had been made

of the waste of plates in the hand camera; there were just as many failures with the ordinary camera. Having instanced the utility of the hand camera in street work from his own experience, he said most of the arguments used against hand cameras were the usual arguments of non-workers.

A vote of thanks to Mr. Welford closed the proceedings.

Hackney Photographic Society.—April 25, Mr. R. Beckett in the chair. A print of uneven colour was shown and a question was asked as to the reason. A reply was given that the toning bath was out of condition. Mr. ROBERTS asked if after developing in pyro a plate can be put into amidol for further detail. Mr. DRESSER said it was like jumping from the frying-pan into the fire, and was not altogether advisable. Mr. PUTTOCK asked how to remove pyro stains from the hands. Mr. BECKETT said one way was to wash in 1:4 hydrochloric acid. The HON. SECRETARY asked Mr. Dresser how he removed amidol stains from the hands. Mr. DRESSER said they cannot be removed, must wear off, but washing in the dark was a good plan as the light caused an action on amidol. Mr. HUDSON had been experimenting with developers for snap-shot work and gave an excellent formula, an admixture of eikonogen and quinol with caustic potash. Mr. DRESSER then gave *The After-work of the Hand Camera*. Although he treated very largely upon this subject, he was drawn into other questions upon the hand camera, for which he is so well known, and gave among other details the following:—The chief point was a good lens and shutter and he advised a shutter working between the lenses, roller slide or films, objected to magazine form owing to the tendency to stick. A good eikonogen formula for snap-shots is:—Eikonogen, 1 ounce; sulphite soda, 5 ounces; carbonate of potash, 1 ounce; caustic soda, 1½ ounces; water, 30 ounces; and for use take 1 ounce of solution and 1 of water. For fuller exposures he would add bromide and redevelop by adding a little hydroquinone. He had been experimenting with metol, but did not find it quite so good as amidol for short exposures. His amidol formula was:—I. Amidol, 1 ounce; metabisulphite potash, 1 ounce: water, 10 ounces. II. Carbonate of potash, 1 ounce in 5 ounces of water. III. 10 per cent. solution bromide potassium. For bromide work he would use 1 ounce of I. and II. and 1 ounce water, adding bromide for full exposures. He used in enlarging the incandescent light, but care was necessary; one light was placed behind the other, as better illumination was given. Mr. A. BARKER asked whether it was necessary to have a rising front and swing back to a hand camera. Mr. DRESSER was of opinion a rising front only was necessary. In answer to other questions Mr. Dresser preferred a four and a quarter or a five inch lens, he would develop with amidol until he got detail, and then wash and finish with hydroquinone.

Birmingham Photographic Society.—April 25, Mr. W. Jones in the chair. —An extremely fine set of slides by Mr. Hendren, a member of the Society, were shown on the screen. They comprised beautifully selected landscape and architectural bits, and were instances of most careful and successful composition. Mr. Hendren gave most interesting descriptions of the places and styles of architecture; he also instanced the different results of various methods of development by sometimes showing two slides from the same negative. This was of great interest to members. A plucky slide of a warm brown tone was, in most instances, preferred by the lecturer.

Brighton Natural History and Philosophical Society (Photographic Section).—April 21, Adjourned meeting.—The new rules regulating competitions in the Society were adopted. The subjects also for the competitions being arranged for the ensuing year. Dr. W. Harrison owing to pressure of engagements was compelled to resign the office of Hon. Secretary. The following gentlemen were elected as officers and committee for the year:—*Chairman:* Mr. J. P. Slingsby Roberts.—*Committee:* Messrs. D. E. Caush, W. Harrison, C. Job, W. W. Mitchell, H. V. Shaw, C. B. Stoner, and A. H. Webling.—*Hon. Secretary:* Mr. G. Foxall.

Halifax Camera Club.—April 25.—Mr. A. STEWART gave a interesting paper on the subject of *Lenses*. In the course of his remarks Mr. Stewart said that without the use of a lens, but simply by means of a pinhole, an inverted image is formed on the focussing screen by the rays comiug in a direct line through the pinhole from the object. In this case there is no focus, everything being in focus at whatever distance. The use of a lens is to utilise other than straight rays, and, according to its focus to regulate the angle of view included and the size of the image, as well as to give greater sharpness. When a lens is used, objects at different distances from the lens are not brought to a focus at the same point; and, in order to overcome this, stops are used, which tend to equalise the focus. The focus of a lens depends on its curvature; the greater the curvature, the shorter the focus. The rapidity of a lens is influenced by the size of stop used, and also by the number of reflecting surfaces in the lens. A short-focus lens gives more depth of focus than one of longer focus. Objects at a greater distance require less exposure owing to the fact that more rays of light come from distant objects. Mr. Stewart also spoke of the faults of lenses, and also of the special uses of the different sorts of lenses.

Liverpool Amateur Photographic Association.—April 27, Mr. J. Sirett Brown in the chair.—Messrs. H. Jennings, Stanley, Rimmer, James Wilson, and David Robinson were elected members of the Association. Mr. J. T. Norman-Thomas reported on the excursion to Ince Blundell Hall and Park, which was thrown open to the members, by Mr. Charles Weld Blundell, on Saturday, April 15. About one hundred ladies and gentlemen were present. Mr. E. M. Tunstall gave his lecture, entitled, *Picturesque Holland*, illustrated by over one hundred slides, made from negatives taken duriug August last year. An excursion to Chester and River Dee to Eaton will take place on Saturday, May 13 next.

Photographic Society of Ireland.—April 27, Professor J. A. Scott (President) in the chair.—Mr. J. A. C. RUTHVEN, C.E., Hon. Secretary, read a paper and gave a demonstration, entitled *Tips in Woodwork for Amateurs*. The subject formed a very interesting lecture, which was ably handled by the lecturer, who appears to be an adept in the theoretical as well as the practical use of all tools required in woodwork. After having successfully explained the use of the wedge, the axe, chisel, and other tools, and illustrating on the blackboard the splitting effects of these various instruments, Mr. Ruthven entered into the practical part of the work, and showed how planes, chisels, and other implements should be used, and referred to the manner in which amateurs were always inclined in using the saw to cut through the wood in drawing the saw up as well as down. The cut should only be made in the down stroke. Various methods of wood-joining for camera-making were also shown. After the demonstration, those present had the privilege of examining a splendidly constructed bench equipped with British and American tools of the newest and most approved description.

FORTHCOMING EXHIBITION.

May 5–6 ..... *Forfarshire Photographic Association. Hon. Secretary, W. J. Anckorn, West Port, Arbroath, N.B.

* Signifies that there are open classes.

Correspondence.

☞ *Correspondents should never write on both sides of the paper. No notice is taken of communications unless the names and addresses of the writers are given.*

THE PARVIN TELE-PHOTO OBJECTIVE.

To the EDITOR.

SIR,—*Credat Judæus*, indeed!

You say, "*We are afforded no clue as to its optical nature.*" Again, emphasising this, in reference to the particulars of the lens given, "*That little conveys no optical information.*" Further: "*True, we are put in possession of some of what we may call its externals.*"

Now, Sir, for the "externals" and the paragraph "that conveys no optical information!" Here it is:—

"For example, in a 7 × 5 objective, the combination positive lenses are 6½ inches focus, the negative single lens is 6 inches focus, and these are mounted in a tube of 2⅝ inches long. The diameter of both lenses is 1$\frac{3}{32}$ inches."

What more information is wanted? The only thing lacking is the said "externals," or shapes of the lenses.

The *Phrenology* of lenses is not the *Science* of optics. The telephotographic lens was founded upon the latter, and its theory is fully explained in my paper read before the Society of Arts on March 1, and still further at the recent Camera Club Conference. In the latter I treated, as being simpler, a fixed system, such as Mr. Parvin claims to have "invented," showing, for the first time, the rationale of how, with a comparatively *weak* negative posterior lens, a fixed system can have a short "back focus," with the advantage of a considerably longer "equivalent lens."

In Mr. Parvin's selection, and taking the *separation* at 2⅝ inches, as quoted, the lens must give an image equal in size to that of a lens of 18·3 inches focus, but would only have a back focus of 10·9 inches; if there be no diaphragm, it would work at full aperture at an intensity of *f*·16·7.

Again, if the lens be reversed, the back focus would be 26·4 inches, but still the same equivalent focus of 18·3 inches.

Mr. Parvin has adopted the principle I first introduced into photographic lens construction, but in a much more limited degree, and, moreover, without the advantage of varying the amount of magnification and covering power.

The question is, whether the amount of magnification given in his case is worth a special construction.—I am, yours, &c.,

25, *Newman-street, W., May* 1, 1893. THOMAS R. DALLMEYER.

"THE PHOTO CORRECTOR."

To the EDITOR.

SIR,—It appears to me that Mr. Van der Weyde's new method of modifying or "correcting" the ugly and inartistic proportions of things as they often appear in photographs has scarcely been received with that enthusiasm which it deserves, considering that it presents us with an additional means of "bending," so to speak, photography to our will, and thus removes one of the great disabilities under which we have hitherto laboured. If by using a lens of sufficiently long focus, or by taking a station point distant enough from the picture plane, we obtain what is called "wide-angled" perspective, and this gives us a picture free from those apparent disproportions which we meet with in pictures taken under opposite conditions, well and good. In such a case the "corrector" need not be employed to correct the perspective, but it has another use, the value of which seems to me, as I mentally cling to the idealistic in art; inestimable. In the discussion which followed Van der Weyde's demonstration of his invention at the Camera Club Conference he made the weak and apologetic admission that there was *money in it*, as, by altering the proportions of any part of the human body, we can flatter our sitters, and thus secure additional custom and remuneration. This is true, but is immensely overshadowed by the much more dignified and noble consideration, that, by thus being enabled to adapt the proportions

of our model's figure to an ideal standard, we become possessed of one of the powers most prized and most exercised by all the great artists of antiquity.—I am, yours, &c. FRANK WILCOCKSON.

20 *Orde Hall-street, Lamb's Conduit-street, W.C., April* 29, 1893.

AMIDOL.

To the EDITOR.

SIR,—I have been away from home, and only just read the inquiry of "Cosmos."

The report of my lecture was very condensed; the actual words I used were as nearly as possible as follows:—

"For photo-mechanical and lantern plates I was able, when using amidol, to reduce the exposure to about one-third the time required for the very restrained pyro developers recommended by the makers of the plates. No doubt this was principally due to the very small quantity of bromide necessary to be used with amidol."

I further said I had not tried amidol for general work, so would not express any opinion of its capabilities for other than copying and lantern slides.

"Cosmos" asks what proof I can give for my assertion. All my exposures were made by the aid of a Watkins actinometer.

The actinic value of the light and the aperture of lens become very simple matters, and I have only to estimate and record in my note-book the subject-number.

I find this plan a very simple and accurate one, as I can, without any difficulty, in any light, give to another plate a corresponding greater or less exposure, as I desire, and only by varying the subject-number.

I have now developed about five dozen plates with pyro and the same number with amidol, on one series of similar drawings, and I have found the subject-numbers for amidol are about one-third of the corresponding ones for pyro. Notwithstanding this, I find the time required to develop with amidol is also much shorter than with pyro.—I am, yours, &c,

2, *Craven-terrace, Ealing, May* 2, 1893. H. W. PEAL.

ART IN PHOTOGRAPHY.

To the EDITOR.

SIR,—Referring to your note signed "F. B.," page 269, I should have thought that you would have long ago discarded the idea of mixing oil with water. Art in photography is about as vexatious as amateurs and professionals. The first one (artist) will not admit in his exclusiveness that any art is at all possible without *him*, and the second one (amateur) that any improvement is possible without *him* also. The only difference is that the artist is educated to the art, while the amateur is born so; that is, at least, the reasons given to the lower class of mortals that do not understand what they so well try to impress upon the few or many uninitiated. From all the articles on art in photography as against art in painting that have been published I have gleaned the following:—An artist, however poor in art he may be, will never turn out anything but there will and must be in it some artistical merit. Bad design, bad colours, bad posing, bad everything, yet artistic. Now, a photographer, however well chosen the subject, well lighted and well finished the result, is never artistic—at least, from an educated artist's views. Why not let this matter rest a while now? I, for one, would rather (uneducated as I am) have a fine photograph than a poor painting. I may be wrong, but I am pretty sure that, however educated an artist may be, he will not average in taking photographs more than one real fine view out of a dozen, and ditto the artistic photographer. Of course, they may not admit this readily; but, nevertheless, they will show you always very few of the results of their work, carefully omitting mistakes and failures. It is human nature only, after all. They all do it.

I have tried several makes of films lately, and, as you object generally to giving names, I do not think that the results obtained would be very interesting to your readers. With one English firm I have always very fine results, while with the others I have uneven ones, such as frilling, no intensity, and disagreeable lifting of the gelatine while printing. I have also tried lately some American films, which have a rough or ground back to them. Having given what I think a correct exposure, I found the picture come up pretty quick; but the film (developed with pyro) was fearfully stained yellow, and the back of it same way, so that it takes a whole day in full sun, and with this fair weather, to get one print. I wish you could tell me how to get rid of this yellow stain, if possible.

I wrote you some time ago in regard to the Exhibition at Chicago, and the failure I met with in regard to obtaining an answer from the head of the photographing department. Do you know of any one that has met with better success? and if so, please let me know how he managed it, so I may do the same.—I am, yours, &c., A. LEVY.

Asnières, Seine, May 1, 1893.

"AMATEUR PROFESSIONALISM."

To the EDITOR.

SIR,—During the last few days the town of Malton has had the honour of a visit from two individuals with a camera and other appliances for photography, and who profess (as so-called amateurs invariably do) to call on schools for the purpose of taking groups of children, &c. During the course of their canvas of the town I had the honour of a call from them at my studio, and, on asking their business, the principal operator said they had called on me to ask if I would grant them the loan of my dark room, in order to change plates and develop. This, certainly, was a poser; but, when I afterwards asked them whether they were professionals or amateurs, they answered that they were *both!* This was a conundrum indeed, which I could not solve, and so I politely told these "amateur professionals" that I must decline to accede to their request, and they immediately meandered from my doorstep.

Since the above took place these two gentlemen have billed the town, announcing that they were prepared to take all kinds of photographs at a certain hotel in the town at stated prices, &c. So much for their amateurism. I mention this simply to show what dodges some people will resort to in order to hinder the true professional members of the trade from earning a livelihood. The public ought to put their foot on such bastard professionalism, which contributes nothing towards the rates and taxes of a town.—I am, yours, &c., PROFESSIONAL.

May 2, 1893.

"ALBUMEN *VERSUS* GELATINE PAPER."

To the EDITOR.

SIR,—So much has been said in condemnation of albumen that I would like to be allowed to repeat that permanent albumen prints can now be obtained as of old, if professionals will pay the necessary attention to their production that is required.

To use good paper with strong salting solution, and sensitise with strong silver.

With such paper, when printed and toned, and fixed in *freshly* made hypo, and thoroughly washed, pressed, and squeegeed after each change of water for two hours, will do more good than to allow the prints to remain all night in a tub or tank.

Above all, do not entrust the washing to boys who do not understand the nature of hyposulphite of soda, who hurry through their task in order to get away from it.

Time only can prove whether gelatine prints are permanent, but silver prints made so long ago as 1856 are good now.

Can as much be said of gelatine prints? Apart from the curling and stickiness of the latter, hyposulphite of soda cannot so effectually be removed from gelatine as from albumen.

The good old collodion wet-plate process was to be superseded by gelatine plates, but it is valued more than ever in process work, and by many professionals; and, much as albumen has been maligned, it is not doomed yet! It is being improved upon daily, and will not be discarded for gelatine.—I am, yours, &c., W. H. HUNT.

May 2, 1893.

To the EDITOR.

SIR,—In your JOURNAL of last week, I see "B. B." complaining of dirt spots, &c., on gelatino-chloride paper, due, I should think, to dirt and dust flying in the air. The scraping is caused by having the burnisher too hot. I have enclosed print printed and toned in the ordinary way, and burnished by the common bar burnisher. I have only taken to P. O. P. for two months, and I think I can say that I have hardly spoilt one print, which I cannot say of the albumen.—I am, yours, &c.,

S. W. R. BROWN.

Chateau Studio, Boulevard, W.-S.-M., May 2, 1893.

Exchange Column.

*** *No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance. The full name of the advertiser must in all cases be given for publication, otherwise the Exchanges will not be inserted.*

Will exchange No. 2 Kodak, complete with case, instruction book, and about thirty unexposed films, for Beck's Frena hand camera.—Address, J. E. RIDDALL, 2, Elm-park, Brixton Hill, S.W.

Wanted, three dozen quarter-plate double dark slides for hand cameras; will give, in exchange, Coventry tricycle, tangent wheels, for two riders.—Address, F. WRIGHT, Photographer, Northampton.

Wanted, backgrounds or head and body rest, in exchange for English lever silver watch or quarter-plate camera, lens, tripod, &c.—Address, J. E. OATEY, Photographer, Wadebridge, Cornwall.

MR. WILFRED EMERY, of 24, South-street, Baker-street, W., has sent us his trade price-list, from which we gather that he undertakes printing in bromide, carbon, platinum, and silver. His prices for these and for retouching appear to be moderate.

Answers to Correspondents.

*** *All matters intended for the text portion of this* JOURNAL, *including queries and Exchanges, must be addressed to* "THE EDITOR, THE BRITISH JOURNAL OF PHOTOGRAPHY," 2, *York-street, Covent Garden, London. Inattention to this ensures delay.*

*** *Correspondents are informed that we cannot undertake to answer communications through the post.*

*** *Communications relating to Advertisements and general business affairs should be addressed to Messrs.* HENRY GREENWOOD & Co., 2 *York-street, Covent Garden, London.*

B. O.—So long as the jars are clean, they may be used any number of times for emulsion boiling.

PYRO.—1. A letter addressed to the firm, Berlin, is sufficient. 2. The Autotype Company, Oxford-street, and Gerson & Co., Rathbone-place.

R. BLAGDEN.—If a choice of position is open, by all means have a north light for the studio. Such an aspect will be far the easiest for a novice to work with.

S. W.—The firm of Bourquin ceased to exist many years ago. A lens bearing that name, though it may be a good instrument, has very little commercial value.

AMIDOL.—You will observe that Mr. Dresser recommended the amidol formula for bromide work given at page 28 of the JOURNAL for January 13. This may meet your purpose.

PHOTOS wants information as to the best means to recover gold and silver from a combined toning bath.—The metals will be thrown down if potassium sulphide be added, avoiding an excess.

BUCKLE.—A matt surface on carbon prints can be produced by squeegeeing them, while still wet, on to a ground-glass plate that has previously been waxed to prevent them adhering when dry.

T. A. R.—We cannot endorse your idea that the public do not expect photographs to stand for more than a year or two. If you act upon it, you may possibly find that your business will not endure for a much longer period.

E. D. J.—It would be useless for you to write either to the Secretary or the General Manager of the Crystal Palace Company for permission to photograph in the building or grounds, as they have no power in the matter. The exclusive right has for many years been leased to Messrs. Negretti & Zambra, and for which they, we believe, pay a high rental.

H. W. H.—1. To copyright a photograph, you must fill up a form describing the picture, and deposit it at Stationers' Hall, with a fee of one shilling. The form costs a penny. Our publishers undertake registrations at a charge of one shilling and sixpence each. 2. No duty is payable in America on cameras or other apparatus when taken there for personal use.

T. CROSBY asks if, in the wet-collodion process, the ordinary ferrous oxalate developer, as used for bromide paper, could not be used instead of the sulphate of iron and acetic acid as given in the ALMANAC? No. Wet-collodion plates can only be developed with strongly acidified developers, such as those given in the different formulæ for the collodion process.

SPOTS sends a number of mounted prints which, he says, became covered with fine spots within a few months, though they were produced with every care as to washing, &c. He asks if we think the mounts are the cause?—The spots are, no doubt, caused by the bronze powder used for the lettering. Particles of it are sparkling all over the cards. Avoid bronze lettering for the future.

L. B.—You have been misinformed, or have confused matters. For a mirror simply for reflecting light through a negative in the enlarging apparatus, common glass, silvered at the back, is all that is necessary; but for a mirror to be placed at an angle of forty-five degrees in front of the lens, for producing reversed negatives, an optically plane surface, which is silvered on the face, is required.

N. D. R.—Two thicknesses of canary medium, with a small fishtail burner, will be quite safe with ordinary plates, but it will not do with the orthochromatic ones. When these are used, the medium should be supplemented by ruby glass, and the plates shielded from the light as much as possible. Your case is by no means exceptional. A deep red light is very painful to many people, and often produces headache if worked in for long.

OTHELLO.—1. Chadwick, of Manchester, makes a stereoscopic partition on the spring roller-blind principle, which possesses certain advantages over any other that we have seen. It is always tightly expanded, no matter what focus of lens is used. 2. A partition must extend to the plate, but it is not necessary it should do so to the lens board. All that is required is that no light from the one lens shall find access to the plate covered by the other.

W. REDMONT says: "I want to try the lime toning bath, and have sent to all the chemists in this small town to get hypochlorite of lime, and cannot obtain it. One said there is no such thing, and the other two say they do not keep it, yet I see it often mentioned in the photographic journals. Is it difficult to make, and how, as I am anxious to try the lime bath?"—If our correspondent will send for "chloride" of lime, or bleaching powder, from the nearest oil shop, he will obtain what is requisite. It is a little surprising that the local druggists do not know what hypochlorite of lime is, though they doubtless have it in stock under the other names.

G. SAYERS says: "I have a wide-angle doublet bearing the name of Ross. It is said to cover the whole-plate size, and is of very short focus. But the largest aperture is exceedingly small, as compared with the size of the glasses, which makes it too slow for my purpose. If I had the opening enlarged to, say, *f*-6 or *f*-8, would it then do for a hand camera?"—No, unless pictures of the fuzzitype order will suffice. With lenses of this class a small aperture is necessary to overcome the spherical aberration always present.

R. CLAYTON writes as follows: "I have several plain, flat oak frames, that had become very dirty. I glass-papered them up, first with rather coarse, and then finished them with very fine, paper; they then looked as good as new. I then gave them a coat of the "best oak varnish," and, although it was carefully laid on, the surface has become quite rough to the feel, and looks wretched. Can it be the fault of the varnish, or what?"—This experience is by no means exceptional in varnishing oak and some other woods. The varnish appears to draw up the grain of the wood. However, the thing is easily rectified. With a piece of fine glass paper rub the surface smooth again, and apply another coat of varnish.

SENIOR asks: "1. Is it necessary to put iodide of silver in the bath for collodion negatives, and what would be the results with and without? I find it rather dear and not easily obtained. 2. I have a Winchester bath that has gone quite yellow with about three weeks' work. I put it down to the collodion being old, but perhaps you would give me your opinion, with remedy."—1. Yes. If the solution is not saturated with iodide of silver, it will dissolve it from the film, and thus leave it thin. It is not necessary to purchase iodide of silver for the bath, as the addition of a few grains of iodide of potassium to the solution of nitrate of silver will precipitate it, when the excess can be filtered out. A drachm or so of collodion will answer the same purpose. Some iodise a bath by coating a plate with collodion and leaving it in the solution one or more hours. 2. The bath ought not to become yellow unless something has contaminated it, and that is scarcely likely to be the collodion. Remedy, add a small quantity of carbonate of soda, and then expose to sunlight for a few days. Filter, and make slightly acid.

A PHOTOGRAPHIC SOCIETY has been started at West Kirby, of which Mr. J. Maurice Jones, of Bank House, is Hon. Secretary.

WEST LONDON PHOTOGRAPHIC SOCIETY.—The forthcoming Annual Dinner has been arranged for at the Frascati Restaurant on May 9.

NEWCASTLE-ON-TYNE AND NORTHERN COUNTIES' PHOTOGRAPHIC ASSOCIATION.—Outdoor meeting, May 10. Train leaves Newcastle for Brompton Station at 8.15. J. Hedley Robinson, leader.

PHOTOGRAPHIC CLUB.—May 10, Members' Open Night. 17, *Testing the Speed of Plates.* Outing, Saturday next, May 6, Eynesford (Kent). Train from Holborn Viaduct at forty minutes past two.

THE last number of the *St. James's Budget* is illustrated exclusively by process blocks, some being line and others half-tone reproductions of drawings or photographs. Several illustrations of life in Japan are very interesting.

Process Work, No. 2 (Penrose & Co.), will be found a useful sheet and price-list for those who make, or desire to make, experiments in photo-mechanical processes, as its publishers make a speciality of the appliances for this class of work.

ASHTON-UNDER-LYNE PHOTOGRAPHIC SOCIETY.—From Monday, May 15, to Thursday, May 18, there will be an Exhibition, in the rooms of the Society, of over one hundred photographs of *The Land of the Broads*, kindly lent by the Great Eastern Railway Company.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—May 9, Ordinary Meeting, at 8 p.m. A paper, on *Some Uses of Moving Sensitive Surfaces*, by Captain W. de W. Abney, C.B., R.E. *On the Use of Tinfoil as a Support for Photo-lithographic Transfers*, by Captain A. M. Mantell.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.—May 11, Paper by Mr. W. H. Harrison, *Is the Present Construction of Photographic Studios Wrong in Principle?* 18, Monthly Lantern Night (last of the season). 25, Members' Open Night. June 1, Paper by Mr. P. Everitt, *The Angle of View.*

WE gather from the *Australian Photographic Journal* that the free-portrait dodge is rife in Sydney, N.S.W. The local press has denounced it, and there is a notice placed prominently on the show-cases of the leading photographers throughout the city, drawing the attention of the public to the fact that in England and America the free-portrait system is denounced as a "fraud" and a "swindle."

THE illustrations in the *Idler* have lately been so excellent that the portrait of Mr. Robert Buchanan and his favourite dog in the May number of our versatile contemporary, strikes a hostile chord on account of the very commonplace and inartistic pose. It is suggestive of the Saturday afternoon efforts of tyro who has hitherto devoted his time to the technical rather than to the art side of photography. It is a "front elevation" of both man and dog. But amends are made in a sitting figure of the *littérateur*.

No. 1723. Vol. XL.—MAY 12, 1893.

THE RAPID DRYING OF GELATINE NEGATIVES.

Given a good light, and there was no reason why, in the former days of wet collodion a sitter could not be shown a proof, unfixed of course, of the negative which had been taken of him before he left the studio, and that without unduly detaining him. After being fixed, the washing of a collodion negative was effected in a brief period of time compared with a gelatine one, and the drying before a clear fire was still more quickly done.

Gelatine, on the contrary, does not quickly yield up its fixing salts even to a stream of running water, although this time may be considerably reduced when the washing water is applied in the form of a spray from a rose jet and under a high degree of pressure. We have been surprised at the rapidity with which a jet of tepid water—not so warm as to affect the gelatine surface—eliminated the hyposulphite of soda from a negative and with such a degree of thoroughness as to stand a delicate test for its presence, such as the iodide of starch. But it is the drying rather than the washing of the gelatine negative we have at present to consider.

This operation is much abbreviated by the removal of surface water by mechanical means. The back may be dried at once by the application of a soft towel, after which it is laid down on a padded board and a piece of cambric spread over its surface, with a pad of blotting-paper supervening. Gentle pressure is then applied either by a roller or by the hand. This operation, if properly done, leaves the negative surface-dry. On no account ought the blotting-paper to be placed directly in contact with the surface of the negative, as numerous little fluffy hairs will become adherent, and their perfect removal is not always readily effected.

It may be thought that the texture of the cambric will be indented by the pressure into the soft surface of the gelatine. So it will, but after complete drying it totally disappears. We have intentionally selected cambric with a pronounced pattern in it, and have applied a needlessly strong degree of pressure, one by which the pattern was rendered plainly visible on the gelatine; but it invariably became invisible upon drying.

Having removed all surface moisture by the method indicated, complete desiccation is attained with a surprising degree of rapidity by the adoption of either of the following means:—That by immersion in a dish of alcohol is so well known as only to require mentioning. The alcohol has such an affinity for water that the very small quantity remaining absorbed in the film is quickly abstracted, and in consequence the drying may be effected by heat if necessary, or by the rapid evaporation of the alcohol.

What we consider a more economical, if not, on the whole, a much preferable, method of drying is by a centrifugal machine, which we have had constructed for experimental purposes. Four arms, or more if desired, emerge from a pivoted spindle mounted vertically, and capable of being rotated with great velocity by means of a long horizontal rod geared with the spindle at the inner end, and terminating at the outer end by a winch handle. On these projecting arms are mounted frames or sheaths, into which the plates to be dried are dropped. The rotation of the handle causes the arms to revolve rapidly, and the impact of the air carries off all moisture. We have found that it is better to set the plates at a slight obliquity rather than in directly facing the line of the circle of rotation. We believe that, if some of our enterprising dealers would have this apparatus made and supply the public with it, there are few professional photographers who would care to be without it. Instead of the toothed wheel and pinion a simple pulley and band may be employed with equal effect for causing the rotation.

An analogous means for effecting the rapid drying of a negative from which the surplus water has been removed is to submit the surface to a jet of air directed by a rubber pipe connected with a foot bellows. In such trials as we have made with this system we found that the best means of applying the air current, as might have been anticipated, is to direct the jet at an acute angle to the plate when lying flat upon a table.

Here, and in connexion with our subject, it may not be amiss to speak of a plate, the result of a discovery of Mr. T. C. Roche, of New York, introduced over a dozen years ago by Messrs. Anthony & Co. of that city, under the designation of "The Tropical Plate." The special characteristic of this plate, which we think is not now manufactured, was that by special treatment in its preparation the gelatine was rendered quite insoluble even in very hot water, and that in consequence both the fixing and the subsequent washing could be conducted with fluids heated to very many degrees above the ordinary temperature with a commensurate reduction of the time necessary when these were cold. Added to this was the possibility of drying the negative by heat after being flooded over with boiling water. As to the method of preparation of these plates we cannot speak definitely, as it was held a secret, although several methods of imparting insolubility to gelatine are known to every one who has studied the subject. There is, however, no doubt as to the abbreviation of the whole system of finishing a negative up to the stage of placing it in the printing frame for proofing that is capable of being attained by the adoption of one or more of the suggestions we have here thrown out.

STRIPPING AND REPLACING NEGATIVES WITHOUT THEIR EXPANDING.

Allusion was made last week to a question put at a meeting of one of the Societies, as to how a gelatine negative could be removed from the plate and yet retain its original dimensions. We then briefly referred to two methods of procedure, but the subject is really one, now that so many reversed negatives are required for mechanical processes, that may with advantage to many be dealt with more in detail; and especially so, as on several occasions we have received complaints that negatives, which have been supplied to have mechanical prints made from them, have been returned to their owners, sometimes in film form or on glass reversed, and sometimes also with the image of a larger size than it was originally. In this condition the negatives were, of course, of no use for the purpose for which they were originally taken, namely, silver printing.

There is no reason whatever why, if necessary, a negative should not be taken off the plate, utilised as a reversed one for any purpose that may be desired, and then be replaced on the glass and returned to its owner without even his suspicion being raised that it has in any way been tampered with. If a "pyro" developed negative be thoroughly alumed, there is but little tendency of the film to expand when it is taken off the glass. But this condition cannot always be depended upon, as some gelatines behave differently from others. Therefore, to make sure of its retaining its original size, the film before its removal should be secured to some medium that will prevent its lateral expansion. Reference was incidentally made last week, as just mentioned, to two methods of working as given in the Almanac for 1889, each of which answer well in practice. The one is by Mr. A. Pumphrey, and the other by Mr. H. J. Burton, and it will be seen that each of them is based upon the property of hydrofluoric acid loosening the film from the glass. Here is a brief description, slightly modified, of each.

The first method is this:—The varnish is removed, supposing the negative to have been varnished. Next, a thin film of plain gelatine is moistened in a dilute solution of hydrofluoric acid—one part acid to sixty of water. This gelatine film is secured on paper by a coating of indiarubber. The dilute acid softens the gelatine, and makes it very adhesive; it is then attached to the negative, which may be readily done with the aid of a squeegee. The acid in the film passes through the negative, and releases it from the glass. It is then lifted off, and pinned to a flat surface to dry. The paper is then stripped off, which can easily be done when it is dry by moistening the back with a little benzole. We thus get the negative in pellicular form of precisely the size it was when on the glass, and which can be restored to glass at any time if desired.

Here is the other method, which is really given for repairing broken negatives:—Instead of paper being the resisting medium, in this case collodion is the one employed. The negative, denuded of its varnish, is placed on a levelling stand, and coated with thick collodion, such as that used for enamelling prints. This is allowed to thoroughly set—say, for ten minutes or a quarter of an hour. The negative is then immersed in a dish of plain water until the collodion solvents are washed away, known by the film losing its greasiness. Then a few drops of hydrofluoric acid are added to the water, and the dish gently rocked. In a short time the film will begin to detach itself, when the plate should be at once rinsed with clean water. Another plate—and, for convenience of working, somewhat larger than the negative—which has previously been coated with plain gelatine and dried, is then placed in the dish, and the released film, after being turned over, is floated upon it, removed from the water, and allowed to dry spontaneously. We have now a reversed negative, ready for printing from, cemented to a rigid support by gelatine, with an intervening film of collodion.

We will now suppose that, after the negative has served its immediate purpose as a reversed one, it is desired to restore it to its original state—say, for silver printing—this is how it may be done:—Take a clean glass plate, again a little larger than that now holding the negative, and coat it with a solution of gelatine, this time containing a little chrome alum, and dry. Next place the plate in tepid water until the gelatine is softened and feels slightly slimy, and remove to cold water; then place the negative in a dish of water, to which a few drops per ounce of hydrofluoric acid have been added, until the film shows signs of being released. It is then rinsed with clean water and floated on to the plate with the softened gelatine, of course again reversing it; remove, and allow to dry spontaneously.

The negative is now non-reversed, as at first; but it has upon its surface a film of plain gelatine and also one of collodion. As the gelatine that cements the negative to the glass is insoluble in warm water by reason of the chrome alum, the former can be sponged off with warm water, and, after drying, the collodion can be dissolved off with alcohol and ether. The negative is then varnished, supposing it to have been varnished before, and the glass cut to the original size. We have now the negative just as it was in the first instance, and none the worse for the treatment it has received.

It might be imagined that, if the collodion film were formed thicker, there would be no necessity to attach the negative to the glass, and this is the case; but, on the whole, it will be found safest in practice to proceed as directed. Then the negative, when dry, is always attached to a rigid support, while, when it is in pellicular form, with only the collodion to retain it, there is always a tendency to cockling, unless the latter is abnormally thick.

EXPERIMENTS WITH MULTIPLE-COATED FILMS.

Since we wrote on this subject a few weeks back the interest in multiple-coated films has been on the increase, and several experimentalists have, like ourselves, been endeavouring to investigate the functions of the separate films in so far as they affect halation and latitude of exposure. The importance of the inquiry seems to increase as we go deeper into the subject for fresh facts and suggestions are constantly forcing themselves on the attention and raising new issues in the inquiry.

For instance, it is pointed out that, as each film or layer of sensitive gelatine is thoroughly dried before the next is applied, the two "are not in chemical or even in mechanical contact," the latter portion of the statement, however, being, we think, a little difficult to maintain. Supposing, however, that the films are not in chemical contact—and in the instances we are about to relate they are still less likely to be than in the case of double or triple gelatine films—we should like to find an explanation of the following result.

In the course of some experiments with combined collodion and gelatine films a layer of collodion emulsion was spread upon an ordinary commercial gelatine plate, this method being adopted as the easiest for obtaining a double film the constituents of which were of widely different character. In one experiment, by mistake an unwashed collodion emulsion was employed, the fact being only discovered in consequence of the

great falling off in sensitiveness. But here is the remarkable part of the matter; the collodion emulsion employed, if exposed *per se* without washing, would be perfectly incapable of forming an image under development owing to the excess of soluble bromide it contained: yet, when exposed in contact with a sensitive layer of gelatine, although the exposure had to be vastly increased to properly impress the gelatine film, still an image was produced on the collodion film as well, as was shown by the difference in density when the latter was removed. The exposure given—some three or four times that necessary for the gelatine film alone—was still all too short to impress the collodion emulsion even had it been washed; but, as we have said, in the condition in which it was employed it was utterly incapable of receiving a developable impression with any exposure.

To place the matter beyond all question, a portion of the gelatine film was carefully and completely removed from a plate by scraping, followed by warm water. The whole plate was then coated with the same unwashed emulsion, so that a portion of it presented a compound film of collodion and gelatine, while the remainder consisted of collodion alone. Upon exposure and development the image upon the double film was of the same character as already described, namely, it was partly or mainly on the gelatine, and slightly, though quite distinctly, upon the collodion. Upon the plain collodion portion of the film, on the other hand, there was not the slightest trace of any image, although the development was intentionally pushed to the stage of incipient fog.

The result points certainly to the conclusion that it is an erroneous supposition that the films are not in some sort of chemical contact, but how the image on the collodion film is formed is an interesting question that is open to argument. At least, we may drop the assumption, as, indeed, we seem to be forced by other facts to do, that the different films are inert towards one another, except in so far as they act as light-screens, absorbing a portion of the light that passes through them. It seems more reasonable to take the view, as presented by the experiments of Captain Abney some years ago, that one film does very materially affect the other in development to such an extent, indeed, that in some instances it is found that, if a second film be coated on top of another after it had been exposed, on development an image will be produced upon the unexposed film.

This appears to be the only explanation of the experiment we have quoted. We can readily imagine that, on proceeding to develop the compound film, the excess of bromide contained in the collodion will be absorbed by the swelling gelatine underlying it, which will in this manner, as well as by the upper film of collodion, be powerfully restrained or retarded. Mr. W. K. Burton has shown that the effect of bromide in the developer is merely to retard development, not to destroy the image; hence, as we have shown that it was necessary to give three or four times the exposure required by the bare gelatine film, the latter must have received a very full impression, and during development may be taken to represent a store of pent-up force capable of reacting on the practically insensitive film above it; or it must be borne in mind that the collodion film, containing, as it does, the unremoved decomposition salts, as well as the excess of bromide useful to its due keeping, is, if not absolutely insensitive, at any rate sufficiently so to bear full exposure in the camera without giving the least sign of image on development, though, on re-exposure, a perfect picture can be produced. For all practical purposes, therefore, the collodion film in this case must be taken as insensitive or unexposed.

Not so, however, in the case of a washed emulsion. When such a film is applied above the gelatine film, the exposure of the latter is not greatly increased, though the time of development is the latter effect, being, we imagine, rather mechanically produced by the overlying collodion film than by any chemical slowing action. Under the head of mechanically produced we may include the slowing produced by the absorption of light in passing through the film, though, as a matter of fact, this is so slight as to be not worth considering. But the retardation of development by the collodion film is a different matter, and that that is purely mechanical may be proved by coating a plate with plain collodion instead of emulsion, in which case there is neither light arrested nor any chemical agent introduced to act upon the sensitive film. Yet the same impervious varnish suffices to render development a comparatively slow process, and also to raise some uncertainty as to whether there is really any loss of sensitiveness, or only retardation of development.

The compound film produced when the washed emulsion is used gives a similar result to that from the unwashed emulsion, so far as the development of an image upon the upper film is concerned. But in this case it is with a shorter exposure, and still too short to impress the collodion emulsion itself, except perhaps in the extreme high lights, as the sky of a landscape. We have, indeed, simultaneously exposed a compound film and one of collodion emulsion alone to an open landscape with clear sky, and on development the sky was the only portion visible on the collodion plate; in the compound film, however, the whole of the image was impressed upon the collodion portion, as was easily proved by the difference in density when a portion of the latter film was rubbed away.

In this instance it would certainly be supposed that the effect of the collodion film would be to give an image showing greater contrast than that given by the gelatine plates alone, but such was not the case. Two plates were exposed side by side—or rather a plate divided into two portions—one of which was coated with collodion emulsion, the latter receiving a slightly longer exposure than the other. On development—not for the same period—as, owing to the slowing action of the collodion, that was out of the question, but until as nearly as possible the same general density was obtained, the two images were practically identical so far as gradation was concerned, or at least it could be said that there was an entire absence of any suspicion of stronger high lights in the compound film.

But—and here is the noteworthy point in the matter—when a portion of the collodion film was rubbed away, the image on the gelatine film underneath showed decidedly less contrast than it had done previously. We do not refer to merely decreased density owing to the removal of the upper image, but the sky had lost noticeably more density than had the other portions of the image; indeed, the extreme high lights in the stripped portion of the image were thinner than the half-tones.

The explanation of this, it seems to us, is not far to seek, and, if this action occurs between two films of collodion and gelatine, it is even more likely to occur or to come with greater force when two or more films of gelatine are in question. Bearing in mind what we have said about the slowing action of the collodion film upon the development of the underlying gelatine film, and also the well-known fact that a collodion image

develops with great rapidity, it might be expected that *the sky* of the picture on a compound film would develop at once on application of the developer, or within a very short period, and that there would then be a long wait until the solution reached the gelatine below. This, however, is not the case, for the first indications of sky did not make their appearance for fully five minutes, and the remaining portions of the picture then followed with perfect regularity. Thus we must believe not only that the upper film exercises an influence on the development of the under one, but also that the converse is the case; otherwise, seeing that the sky of the collodion film had had sufficient exposure to produce a developable impression, that impression would have been produced in less time than five minutes, unless it had been held back by the gelatine film underneath it.

When development did commence, it commenced from the surface—that is to say, in the collodion film. This much is evident to the eye, but is capable of easy demonstration, and has since been proved by means which need not here be detailed. That being the case, as the silver is reduced in the collodion film, bromine is given off, and either directly or in combination with the alkali of the developer, as bromide is present to act upon and restrain the corresponding portions of the gelatine image lying underneath and in contact with it. In other words, as the high lights of the collodion image are developed, the bromine evolved goes to restrain the high lights of the gelatine image and weaken them.

Although the compound films with which our experiments have been made are totally different from, and, in fact, diametrically opposite in principle to the Sandell double and treble-coated films, still we think the same kind of action may be traced in both. For instance, with an ordinary short exposure, the bromine given off by the high lights of the rapid top film hold in check those of the second film, and contribute to the softness which is so remarkable a feature of these plates. Again, with longer exposures, it is possible to trace the action of one film upon the other, and to explain the freedom from halation so obtained in a far more intelligent manner than by supposing it to result from mere opacity of film.

Photographic Salon, 1893.—We have received from Mr. Alfred Maskell a notification of a proposed "Photographic Salon," for which the Dudley Gallery has been taken. Its nature will be ascertained from the following:—"An exhibition of photographic pictures, to be called the Photographic Salon, will be held at the Dudley Gallery from October 9 to November 11, 1893. Careful consideration will be given to all pictures entered for exhibition, and a selection of works of pictorial merit only made by a Committee. Foreign as well as English photography will be represented. The aim of the organizers of this, the first Photographic Salon, is to inaugurate a series of exhibitions (which it is hoped may be annual ones) bringing before the public the best productions of photography solely from the pictorial point of view. No awards are offered, and no charge made to exhibitors. The usual charge of 1*s.* will be made to the public for admission. Arrangements will be made for the sale of pictures, if desired, and a commission of fifteen per cent. will be charged on sales effected."

Photographic Competition at the Welsh National Eisteddfod.—We may remind our readers that at the Eisteddfod, which takes place at Pontypridd in August next, photographic competitions will be held in the following classes:—1. A set of not less than six or more than twelve photographs illustrating the coal industry from cutting to shipment. Prize, 5*l.* 2. A set (not less than six) illustrating the industries of Wales. Prize, 5*l.* 3. Six instantaneous photographs of a football match in its various phases. Prize, 2*l.* 4. Landscape. Prize, 1*l.* 5. Architectural photograph. Prize, 1*l.* Photographs should be sent to the General Secretary, Pontypridd. The adjudicators are practical photographers, and, as the prizes are to be in money, there is every incentive for a keen and interesting competition among that large class which regards honour as not incompatible with profit.

A Constant Light for Spectrum Work.—In a paper of importance on certain absorption spectra by Dr. W. Lapraik, he refers to the desirability of having a source of light as constant as possible, and at the same time of sufficient illuminating power. With this idea a quick-combustion petroleum lamp having a circular wick was used. This gave a very powerful light equal to forty-eight candles (British measurement). He used electric light, and also sunlight reflected from a heliostat, but did not find any material difference between the absorption spectra so obtained and those by the petroleum light.

Mr. R. P. Drage and the London and Provincial Photographic Association.—Our readers will learn with regret that Mr. R. P. Drage has resigned the Secretaryship of the London and Provincial Photographic Association, a position which he has filled for the past three years. The "L. & P.," as it is familiarly known, takes rank as one of the principal technical photographic Societies, its reported discussions and proceedings being, as we are aware, read with deep interest throughout the world. Mr. Drage's services to the Association have been of such a thorough-going nature, by persistent hard work and unfailing courtesy to members and visitors alike he has rendered himself so agreeable, and has contrived, week after week and month after month, to bring matters and papers of such interest for discussion before it, that he is certain to be much missed. The best wish we can extend to the Association is that Mr. Drage may have a worthy successor in the office he has so ably filled.

Carbonic-acid-free Ammonia.—The uncertainty as to the composition of any particular sample of ammonia solution required for development is always a stumbling-block in the way of those who would make photographic operations as exact as possible. In estimating the strength, by ascertaining the amount of acid it will neutralise the difficulty if the presence of carbonate comes in, for it is well known that, though carbonate of ammonia preceded liquid ammonia for use in development, the latter in bromide dry plates is much more powerful than the former. Hence a simple suggestion by Herr J. Hertkorn, in the *Chemiker Zeitung*, will be of value in regard to this particular source of uncertainty. He recommends that some lime-water (quite free from turbidity, of course) should be added to the suspected sample of ammonia, and the mixture then boiled. If turbid, the presence of carbonic acid is shown; but if it remains clear, or only very slightly turbid, the sample is free.

Temperature Limit of Light Sensitiveness.—Dr. Dewar, in a lecture on the magnetic properties of liquid oxygen, referring to the extremely feeble energy displayed by the oxygen molecules at extreme low temperatures, said they seemed to be drawing near what might be called "the death of matter" so far as chemical action was concerned. Liquid oxygen, for instance, had no action upon a piece of phosphorus and potassium or sodium dropped into it, and once he thought and publicly stated that at such temperatures all chemical action ceased. That statement he remarked in this later lecture required some qualification, because he had found that a photographic plate placed in liquid oxygen could be acted on by radiant energy, and at a temperature of 200° C. was still sensitive

to light. This fact is of considerable importance as regards the actual result of light action on a plate, for it is well known that chemical action goes on less quickly in solids than liquids, and that a solid dry plate should be influenced by light at this extraordinary low temperature would be a fact that the old advocates of a mechanical rather than a chemical action as the result of light would not be slow to take advantage of.

Lightning Photographs.—A note on two such photographs taken at Sidney was read at the Royal Meteorological Society's last meeting, and the writer gave an explanation of certain effects. The two photographs referred to were taken with a half-plate lens mounted in a whole-plate camera, and as a matter of course showed distortion at the edges. For example, while the lights of street gas lamps were white specks in the centre of the plate, they were crescent-shaped at the edge. The lightning flashes also were distorted, and we have specially referred to this matter on account of the suggestions in the paper that the so-called "ribbon flashes" may be accounted for by this distortion. It is quite obvious that, if accurate depicting of lightning flashes is to be obtained, every care should be taken that neither coma nor astigmatism should play any part in the obtained results. On every account, therefore, it would be advisable, when setting the camera up on the chance of securing flashes, that a lens with as flat a field as possible be employed, and that it be well stopped down. It appears to us that the lightning flash is of such brilliancy, that no matter how small the stop employed the appearance would be recorded brief, as is its duration.

Phosphorescent Zinc Sulphide.—In a recent number of *Comptes Rendus* this substance has been proposed as a photometric tandard by M. C. Henry. The original investigations by which Mr. Warnerke established the usefulness of the instrument which bears his name are on record, and will not be found out of accord with the most recent investigations. M. Henry's results show that, within somewhat wide limits, which correspond with luminous saturation, the quantity of light emitted by a surface of zinc sulphide, rendered luminous by exposure to magnesium light, is independent of the distance of the light or its duration, and of the thickness of the layer of zinc sulphide. He states that the law governing the loss of luminosity is always the same, though the material itself may have such different characteristics as it would probably have after being prepared by different experimenters by different methods. The actual law is expressed in the formula $i^m (t+c)=K$, when M is taken as ·598, and c as 28·35. It holds good for thicknesses of layers varying from ·45 to ·9 mm. Within these limits of thickness the maximum intensity of the luminosity is not influenced by the length of wire burnt, nor by the distance it is held within a limit of 15 cm. of length, and of 28 of distance.

STUDIO-BUILDING.

III.

At this stage it might be well to refer to an aspect of the subject that has caused me the receipt of several letters. How much of the roof should be glazed, and how low should the side lights extend? Here, again, it would be better to reply on broad general principles rather than fix a hard and fast line. Thus if it be remembered that when the blinds and screens used are of good design and construction it is—so far as the actual illumination is concerned—quite immaterial so long as there is a sufficiency of light area. For instance, if the whole roof and sides were glazed, the lighting could be made to assume any character and come from any direction merely by arranging the blinds suitably. But, unfortunately, there is something more to be considered than the illumination only; we have to think of the sun's heating rays as they affect the sitters' comfort. So that here the indications are all in the opposite direction, that is, to restrict the amount of roof area to be glazed. When large groups are to be taken, or on occasions where difficult subjects requiring quick exposures are in hand, the need for most light will be experienced, and the artist will feel he cannot have too much; but, as a line must be drawn somewhere, a fair principle to act on will be that not more than one-half of the roof in a ridge roof, that would be the whole of one side, should be glazed; the rest should be quite opaque, slated by preference, to keep out the sun's heat. This latter point is of such supreme importance that no essay or instructions on studio-building can be complete without a thorough consideration of its bearing. The possibilities of building a studio on a low level against a lofty building at its south or west, influence this point to an important extent, as before referred to, and if two sites, of equal merit otherwise, were under consideration, that which provided an already formed sun-screen in this manner should unhesitatingly be preferred. This subject will be referred to again in a final chapter on screens and blinds.

The glazing of the whole length of one side of a roof may to some appear excessive, but it must be borne in mind that it is the light furthest away from the sitter that has to be relied upon to equalise the illumination on groups, which may possibly extend across the whole breadth of the studio, also a studio to seat the sitter at either end is the present groundwork of our remarks. Of course, a similar effect could be obtained by glazing a portion only of the opposite side of the roof, though, unless carefully done, and its position well chosen, such a method would lead to that cross lighting of the subject which on a face is so ugly and inartistic.

Some photographers prefer to make the roof opaque for about two feet from the end, and the plan has many advantages. Its chief disadvantage is that there is then an insufficient control over the lighting of the backgrounds. When they are lighted from overhead, and the light aperture screened from the sitter, the effect of the background is but slightly interfered with. However, the main light may be controlled by blinds in any special way, while, if the lighting of the background depends on that of the sitter, very unfortunate results may be unwittingly obtained. The relative disposition of the lights and darks may alter the whole chiaroscuro, and cause possibly, for example, a usually light background to come out quite dark in the negative.

As to the side lights, little need be said. If they are continued to about three feet from the floor, that will be quite as low as would ever be necessary, and when too low it could be blinded. Side lights, however, are often useless, owing to the light from sky to sitter being arrested by contiguous buildings. Obscured glass of course, as advised, should then be made use of.

We have now arrived at an advanced stage with our studio erecting. The walls are built, the roof is on, and the sash-bars are ready for glazing; and this is a point on which many photographers are in doubt: whether to use plain glass, rolled plate, hammered plate, or obscured glass. Instead of answering the questions that have been put directly, it will be better to discuss the general principles or the governing conditions which may be looked to for guidance in coming to a decision. From a given beam of light direct from sky to sitter—using the word sky to indicate either clouds or the unclouded azure—least light will be removed by the interposition of plain glass; rolled and hammered plate come next; and obscured, *i.e.*, smoothed, or ground glass in the given circumstances robs the beam the most But there are other conditions. According to the situation and construction, the strength of the sheets is matter of greater or less importance. Ordinary window glass can be had of a strength of fifteen, twenty-one, and twenty-six ounces to the foot. The same holds good with obscured glass. The varieties of plate may be had, practically, of any thickness. Under all ordinary circumstances, where no violence beyond the forces of nature is anticipated, glass of the thickness of that represented by twenty-six ounce is sufficient. In the course of a long experience I have seen the results of many hailstorms, and have never found glass of that thickness injured even by the heaviest fall. The country is occasionally visited over narrow belts of a few miles by hailstorms when the stones are of extraordinary weight; but, though I have seen the windows of private houses facing the direction of a storm literally riddled with hailstones, I have never

yet had a roof pane of that weight broken. It is well to note that the best English glass should be used. There is a cheap kind of foreign sheet on the market, which, though fairly thick, I have been credibly informed is far inferior to a thinner make of the kind I recommend. It is not only said to be more easily broken by hail stones, but is also liable to crack *in situ* through slight expansions of the sash-bars from wet or heat, or from trivial strains of the supports through painters on the roof, or slight warping of the timber used.

As my object is to give, and only to give, my personal experience, I may here say I have had no experience whatever of metallic sash-bars. I should have a prejudice against them, owing to the need for experiments in lighting arrangements, necessitating the use of nails and screws for suspension, and the impossibility of obtaining such support when metal framework was employed.

To assist in coming to a decision as to whether glass plain or obscured should be selected, it may be said that every studio builder should ask himself why he should have other than plain glass. In any situation where the studio is liable to being overlooked it will, of course, be a necessity. But granted a free, unobscured light, there is nothing to gain by making the glass translucent rather than transparent. But many studios are built in situations where surrounding buildings intervene and prevent a free light entry; then translucent glass may be a decided benefit. The rule to adopt is for the artist to place himself in any situation in the studio where a sitter may probably be placed, and look round at his sky light and side light. If he sees nothing but clear sky, he will receive most light from the use of clear glass. If, however, in his line of sight buildings are visible, then obscured or other similarly acting glass will bring more light to the sitter. Supposing a studio to be painted internally dead black, and all the unglazed roof covered over, except such parts as would only permit a view of buildings to be seen by the sitter, then—at any rate, speaking for the face—he would be almost in perfect darkness, except the building were painted or otherwise light in colour. If, then, clear glass were put in the sashes, the darkness would remain unaltered. But if obscured glass were made to take the place of plain, a great difference would be observed. Those beams or pencils of light which in the first would from other directions penetrate the roof, illuminate the walls or floor and not the sitter, would be dispersed or scattered, and so many would reach the sitter as to give a fair illumination to his features.

These are the conditions under which portions of a roof might with advantage be glazed. In the studio with very steep roof that I described, and which was built in the old wet-collodion days, I used ground glass for the lower panes, owing to my being shadowed over by an exceedingly lofty building at some distance away. Standing at the sitter's end, in all positions where I might expect to place him, I looked through the empty sash-bars, and got the carpenter to mark, with a pencil, the limit on the bars through which I could see bricks and mortar. These I had glazed with obscured glass; where sky only was visible, I used clear glass.

G. Watmough Webster, F.C.S.

CONTINENTAL NOTES AND NEWS.

Ammonium Hyposulphite.—M. Ch. Hermitte writes in the *Revue de Photographie* that the ammoniacal odour given off by ammonium hyposulphite with which several Continental photographers have been experimenting as a substitute for sodium hyposulphite, may be obviated by the addition to the solution of a small quantity of chlorate of potash. This, however, does not apply to all samples of the new hypo that are prepared, considerable variations in its quality being experienced. M. Hermitte recommends the following bath:—

Water	1 litre.
Ammonium hyposulphite	150 grammes.
Chlorate of potash	10 „

Negatives fixed in this bath are said to be beautifully clear, and in the quantity of solution mentioned fifty to sixty half-plates may be fixed. M. Hermitte finds an hour's washing in running water sufficient, but recommends for greater safety a longer immersion.

A Platinum Toning Bath for Silver Prints.—The following bath is recommended by a foreign contemporary:—

Water	500 c.c.
Sodium chloride	35 grammes.
Tartaric acid	8 „
Sulphate of soda	6 „
Chloroplatinite of potassium (12 per cent. solution)	8 „

The salts are dissolved in the order named. The bath is said to give tones much resembling those of platinum prints, and to keep well.

Photography and the Falsification of Documents.—It is stated that the Russian Government has instituted a photographic laboratory in connexion with the Courts of Justice, the principal object of which will be the verification of the authenticity of legal and other documents. The laboratory, it is further said, has already done signal service to the cause of justice in this way.

Hypo in the Metol Developer.—Herr Schmidt, of Wiesbaden, finds that hypo in the metol developer acts as a retarder instead of, as is generally the case when it is added to the developer, an accelerator. He uses it in the proportion of from 30 to 40 drops of a hypo solution 1 : 100 per each 30 c.c. of metol solution.

Society Outings in France.—The plan of photographic instruction in the field, which seems of late to have been adopted by several English photographic societies, is being followed in France. On Sunday, April 9, the Société d'Etudes Photographiques met in the gardens of the Trocadero, Paris, under the direction of the President, M. Balagny, for the purpose of photographing a certain view which had been previously decided upon, the development of the plates being subsequently conducted at the President's house. Under experienced direction such a method should be a useful source of knowledge to young photographers.

Salted Gelatine Paper.—"Violette," in *L'Amateur Photographe*, publishes a plea for plain salted gelatine paper (*à la* albumenised paper) which could be sensitised and used according to the requirements of the individual, and he claims that, by its use, better tones than is the case at present could be obtained, that toning would be more rapid, and that yellowness, which is more or less evident with commercial sensitive gelatine papers, would be minimised, inasmuch as the elements of deterioration would be absent.

Sulphocyanide of Ammonium in Uranium Toning.—Professor Rodolfo Namias, in the *Rivista Scientifico-artistica di Fotografia*, recommends the addition of ammonium sulphocyanide to the uranium toning bath as a solvent of the ferrocyanide of silver and potassium which, he says, is formed in toning, and to facilitate the deposition of the uranium ferrocyanide upon the image. The following is the formula he employs:—

A.—Potassium ferridcyanide	2–3 grammes.
Water	1000 c.c.
B.—Uranium nitrate	10 grammes.
Ammonium sulphocyanide	50 „
Acetic acid	10 c.c.
Water	1000 „

Equal parts of the solutions are taken for use.

Purifying Eosine.—Eosine, which is employed in orthochromatic photography, is not always found in commerce of a sufficient degree of purity for photographic purposes. The following method of purifying it is given:—Dissolve 20 grammes of eosine in 700 c.c. of boiling water, and, after dissolution, add sulphuric acid 1 : 10 until no further precipitate of bromofluorescein is formed. The liquid is separated by decantation, and the salt washed and dried. The purified eosine is insoluble in water, but is soluble in alcohol.

The Aero-carbon Light for Printing-out Purposes.—With a celloidin paper and a negative of normal density M. Kowarzik finds that by using the aero-carbon light he can obtain developable images in from 20 to 30 minutes, and under a thin negative in 20 minutes, while a dense negative takes from 40 to 45 minutes. With gelatine paper 15 to 20 minutes suffices, but platinum paper requires from 3 to 5 hours. The printing frame is placed within a few inches of the source of light.

PHOTO-LITHOGRAPHY.

[Photographic Society of Great Britain.]

The purpose to which photo-lithography is applied with special advantage is the reproduction of a subject where only two tones, as black and white, without intermediate gradations, are required. True, there are photo-lithographic processes in which the half-tones of the original are broken up into a kind of grain, which gives the idea of half-tones, as do the fine lines of an engraving. The present paper and demonstration will not include these processes, nor be concerned with many of the variations that have been made in the practice of photo-lithography; but an endeavour will be made to clearly show throughout a practicable working method, such as the writer has used with success, and, in the main, such as he has known to be employed in printing works turning out large quantities of excellent work.

The absence of half-tone, and the consequent separation of the gradations of the original into two tones as dissimilar as can be obtained, is, in most of the cases for which photo-lithography is employed, not only no drawback, but a positive advantage. An engineer's tracing, for example, has to be copied. There may be pencil markings, traces of erasure, some amount of soiling, and lights and shades from the cloth lying irregularly, or being creased. In any of the ordinary photographic methods these defects would be reproduced, but in a process devoid of half-tone everything must be either black or white, and so representations of soils and creasing, if not strong enough to show as black, will be got rid of.

The General Principle of Lithography.

The general principle of lithography depends upon the fact that a porous stone imbued with water, especially water containing mucilage, does not readily take to grease, and *vice versâ*. If a drawing be made with greasy matter upon a lithographic stone, and the stone be then well wetted, a roller charged with greasy ink will deliver its ink on to the drawing, but not on to the surrounding moist parts of the stone. A paper laid on the stone and subjected to pressure will pick up sufficient of the ink to represent the drawing, and the stone may be rewetted and inked up again for as many prints as may be wanted. Certain additions to the process have been found necessary, and will be described; but this is the main principle.

The first thing necessary in photo-lithography is to have a negative, the shadows of which are really clear. It is also desirable to have dense lights, but this is not essential. Wet collodion is recognised as being the best negative process for the purpose, though, for coarse lines from a clear black and white original, some gelatine plates may be made to serve. I always use wet collodion, and I believe that to be almost the universal practice in commercial establishments. It is of course much easier to get a suitable negative from a pure black-and-white subject than from one in which blacks and whites are deficient in purity, and some establishments insist upon having a drawing made with Indian ink and on Bristol board. However, it is often necessary to copy a subject which presents greater difficulties. I have here a letter more than twenty years old, written to me by a well-known artist. It is rather soiled and creased, and the ink (which, of course, was of the ordinary kind) has faded in parts. Illustrating some of the words is a pen sketch, which I have selected as the subject for the demonstration. Of this I have made two negatives (wet collodion). One, which is of full intensity and shows the paper as of fairly solid opacity throughout, looks, to those not aware of the special quality required, to be the better. It is, however, a full half-tone negative. The lines where the ink is still black are transparent, but in other parts, where the ink has been thin or has faded, there is a good deal of deposit. Such a negative is not suited for the present purpose, for, although by deep printing on the sensitised transfer paper the faint lines might be made to show, there would then be a spreading and thickening of the more transparent lines. The second negative, which is of the kind required, shows the lines throughout as clear as the margin. The white of the paper is not so good, every soil and irregularity shows strongly, but these

c

an be masked out; or, if they print sufficiently to take the ink on he transfer, can easily be cleaned off the stone.

Preparation of the Photo-lithographic Transfer.

The principle concerned in preparing a photo-lithographic transfer is this:—Certain organic substances, such as gelatine and albumen, combined with a bichromate, undergo a change when exposed to the light, in virtue of which they are no longer soluble, and do not even absorb water. When, therefore, a film of bichromated gelatine is exposed under a negative, a greasy ink may be made to adhere to the parts affected by light, whilst the unaffected parts when imbued with water will not take the ink, or will permit it to be removed.

Paper prepared with gelatine for photo-lithographic transfer is an article of commerce, but if preferred can be made at home. The paper should be of firm, good quality, or it may split up in manipulation. Gelatine such as is used for photographic emulsion, tolerably hard, may be swelled in water, and dissolved by heat. The strength may be conveniently one to ten, and the solution must be warm enough to allow of easy flowing. Floating in a dish is best, but means must be taken to keep up the heat during the time the requisite number of sheets are being floated.

The paper is sensitised by immersion in a bath of bichromate. Bichromate of potash is generally used, and it has been recommended to use a solution nearly saturated, about an ounce and a half to the pint. I have more generally used a rather weaker solution, about an ounce to the pint, and have even got good results with half that strength. The objection to a very strong solution is the rapidity with which the paper goes bad. It is generally advised to add ammonia to the sensitising bath until the deep orange colour becomes changed to a yellow. I have not found this an improvement. When the paper is softened in the bichromate solution, it may be hung up to dry; but a plan which I much prefer is to squeegee it on to a sheet of talced glass, and leave it to dry there.

There are several advantages about this method:—

1. The surface is fine and smooth, and the paper may consequently be pressed into more intimate contact with the negative.

2. For the same reason the ink may be applied more evenly, without having to be forced into the depressions of the grain of the paper.

3. The sensitised surface of the paper is kept out of contact with the air whilst drying, and until it is required, when it may be stripped and taken direct to the press.

4. The paper being dried in an expanded condition, and applied in that state to the negative, there is very little, if any, distortion from expansion of the paper by moisture when applied to the stone.*

The objection that I have heard raised to drying on talced glass is that there is a tendency for the paper to stick, and, in short, to refuse to strip. I have never known this occur since finding that ease of stripping depended entirely upon a vigorous rubbing in of the talc. Take a little powdered talc (French chalk) and with a cloth rub a clean glass hard until the surface appears to be matt nearly all over. It may afterwards be rubbed until polished again, but the effect remains. The grain of the matt is so fine that it is of no consequence, and the plate may be used many times in succession without any further rubbing or application of talc being required. All loose talc is, of course, dusted away before use.

The paper, stripped from the talced glass, is printed from the negative in the usual way. The exposure is not long, and may be judged to be sufficient when the lines show as a clear brown on a yellow ground. The ground may even print through to a certain extent, as a faint image may be made to part with the ink whilst the stronger parts retain it.

Inking the Transfer.

The print taken from the negative is covered with a thin film of transfer ink. This may be done in various ways. A very good plan is to roll up a lithographic stone with a thin film of ink, and then lay the transfer on it and pass a few times through the press, reversing the stone to ensure equality of pressure. Another plan is to roll on to the transfer paper direct. The end of the paper may be turned over the edge of a piece of glass so as to reach the back. The glass is then laid on another glass, and so the paper is held during the rolling. In either case the first thing is to get a thin, even coating of ink upon a roller. A special ink is used, containing a large proportion of fat. It is sold as lithographic transfer ink, and being very stiff requires a little thinning before use. For this purpose lithographic

* To make up for this distortion, it is customary with some photo-lithographers to take the negative somewhat smaller than is required for the finished print; but then, as paper expands unequally when wetted, it will be necessary to note which way the paper is to be cut, and even then the result will only be of the required size in one dimension, and will exceed or come short of it in another.

varnish is commonly used; some, however, take a fat oil, such as palm oil, and others turpentine. The diluent, whichever it is, is worked up with the ink by a palette knife on a stone, and then by repeated rolling; the stone and the roller are evenly coated. It is desirable that the coat of ink on the transfer be thin, or the fine lines may hang together. The image should just show through the ink.

The roller used is an ordinary lithographic leather roller, which, however, should be of fine texture. For very fine work some use a velvet roller. Small subjects, and, indeed, larger ones if time is not an object, may be coated with ink by a pad of linen or other rag merely, and the use of a roller may be dispensed with until the transfer is on the stone. The pad should be first dabbed with a little ink on a stone or piece of glass until it will distribute a thin even film of ink.

Placing the Transfer on the Stone.

When the transfer is inked, if turpentine has been used as the diluent, it is left for some time, say, twenty minutes. With other diluents it may be proceeded with at once. It is laid in water, or merely floated on, face upwards. This is perhaps the best way, but then no water should be allowed to get on the face in parts, or these will be less strong in the image than the rest. When the gelatine has absorbed sufficient moisture (which can be told by the unexposed portions being raised a little above the lines), the transfer is laid on the slab, held down as before described, and the roller passed over it a few times. The ink will now, for the most part, leave the whites, and the blacks will be strengthened. The transfer is next sponged with water until the spaces between the lines are perfectly clear. Sometimes the rolling off is omitted, and sponging alone is relied on. The transfer is then partially dried and put on to the stone, or, as is often done, it is dried and damped again by placing it in a moist blotting-book. The transfer is best put on to the stone the same day as made. If kept several days, it may refuse to take properly. The stone, having been cleaned and polished with snake-stone used with plenty of water to prevent scratching and dragging, is, after drying, and sometimes slight warming, laid on the bed of the press. Warming is necessary if the stone is colder than the air of the room, as in that case a film of water may be deposited. The damp transfer is put in place face downwards. Some thicknesses of paper are placed on it, and it is then passed a few times through the press, the stone being reversed and the back of the transfer redamped half way through the process. A corner is lifted to make sure that the impression has taken well on the stone, and then, after damping the back of the paper, it is pulled off entirely. If there is a difficulty, warm water is used. The stone is sponged, and then gum water is rubbed all over. This helps to keep the whites clean, and the lines from spreading. The gum water should be allowed to dry, and then the stone is sponged, and ink from the transfer is reinforced by rolling, or rubbing with a pad, with ordinary lithographic ink slightly thinned with varnish or turpentine. If a pad is used, enough ink should be taken up to show as a smear. Before touching with the pad, thick gum water is poured on to the stone, and rubbed in at the same time that the ink is strengthening the deposit on the lines.

Preparing the Stone.

The stone has to go through a process called etching, which, however, does not dissolve it to an appreciable extent, but cleans it up. Before etching, the image is protected by being dusted over with finely powdered resin. The excess of resin is lightly dusted off, and the surface of the stone is sponged. If there are any blemishes in the way of ink on the stone where not wanted, they can be removed at this stage by a scraper, or a narrow slip of snake-stone. Sometimes powdered talc is used instead of resin. The etching fluid is a very dilute solution of nitric acid. The strength of the acid is determined by its effect on the stone. If effervescence takes place in from five to ten seconds, the acid is about right for strength. After sponging off the acid the stone is again gummed and dried.

The stone is now again sponged, and the ink, which has been clogged by the resin or talc, is washed off with turpentine. The stone is again sponged clean, and, a little thick gum water being first poured on, the image is partly brought back by rubbing with a pad of linen that has been touched on to the inky slab. The stone is once more sponged clean, and wiped with what is called the damping cloth, which, as its name implies, is always kept damp enough to leave the stone moist. The damping cloth is a material of a soft muslin character, without any dressing in it. What is called butter cloth, such as is sold for the purpose of wrapping round rolls of butter, is suitable; enough to make a good handful—say, a yard—is sufficient.

Printing.

The stone is next inked up by rolling with the ordinary lithographic ink, slightly thinned with lithographic varnish. The amount of ink left on the image may be regulated by the thickness of the coat on the inking slab, by the dilution or softness of the ink itself, and by the manner of rolling. Heaviness and slowness of rolling deposit ink freely, whilst lightness and quickness tend to remove it from the stone and clean up the lights. A piece of paper is laid on, the tympan lowered into place, and the print made by pulling through the press. The first print may be a little weak, and yet, after about a dozen pulls are taken, it may come up of full strength.

After each print is pulled, the stone is damped again before re-inking. Wiping with the damping cloth is generally sufficient. If the stone itself appears to take the ink in places, rubbing with a sponge will generally clean it; but, if there is a difficulty, clean it off with turpentine, and, after sponging with water, bring back the image by rubbing with a cloth, charged with thinned ink as before directed, taking care that there is some thick liquid gum on the stone at the same time.

Of course the assistance of a practised lithographic printer will save some failures, and be of great use during the first essays in the printing part of the work. It would be perhaps as well at first to confine oneself to making the negative, and from that the photo-litho transfer, and hand the latter over to a lithographer for printing from. If only one or two prints are required, it may suffice to make the photo-litho transfer, and consider that as the final result. At all events, this will afford good practice for those commencing to work the process.

W. E. Debenham.

AMIDOL FOR DEVELOPED PRINTS.

I have made some thousands of bromide prints, and used some hundreds of gallons of ferrous oxalate developer during the past ten years. Recent events, however, have worked a change. Ferrous oxalate has been an old and valuable servant, but I am afraid it will now have to be deposed and be considered practically defunct. "Requiescat in pace."

For printing in bromide—and one is almost compelled to adopt this method when days are short and leisure scanty—I find amidol to be a particularly satisfactory developer. Things are getting simplified nowadays, for we are able to develop out negatives and prints in the same solution, and fix them side by side in the same bath, while we can (and it is a good riddance) say good-bye to the acetic-acid clearing bath. The developer made several months ago, viz., amidol 1·0, soda sulphite 10·0, water 48·0, was used. I have not met with any trouble so far with reference to the keeping qualities of this new developing agent. A solution, ten per cent., of potassium bromide was also prepared. Exposure of the bromide paper should be full and ample, the addition of a few drops of the bromide solution keeping the development well under control. The whole arrangement is quite easy, the requisite exposure ascertained by a trial print, the remainder are exposed, and may then be immersed in a bath of clean and very slightly (at this time of year) warmed water.

One part of stock developer is put into another dish with two or three parts of water, and bromide solution *ad libitum*. The prints may be developed singly or in batches, are then transferred to a dish of clean water, and thence to the fixing bath; afterwards, a thorough washing to complete this stage of the operations. This is of the first importance to thoroughly elimidate the hypo—hence fixation should be complete. Then, after thorough washing, a final bath of hydrogen peroside and water, about one ounce to the pint should be resorted to; then a final rinse in water. The *tone* of the developed print is quite pleasing, and leaves little to be desired; but if we wish, various colours, more or less rich and warm (and rather *less* than more, by the way), are easily produced. If the print be, and this is, perhaps, preferable, on *thin* paper, I don't know of anything better than the old mercury bath, followed by a wash in ammonia water or a solution of sulphite of soda. One advantage I find in the use of *mercury* is that no lessening of density results. Whatever intensifier (?) is used, the subsequent washing is to be ample. We may then safely immerse the print in the alkaline solution.

Eder & Toth's bath may be used, *e.g.*:—

Ferridcyanide potassium	6 parts.
Nitrate of lead	4 „
Water (distilled).....	100 „

followed by a thorough washing, then the print toned by various chemicals. It seems, having in view the exposure, density, and length of time in the mercury bath, or Eder & Toth's, possible to get an extraordinary variety of tone; in fact the process is extremely in-

teresting experimentally. At the same time it would require very careful working to get a dozen prints exactly alike. If toning be resorted to I have a liking for the lead and ferridcyanide bath. The print should be fully exposed and over-developed, this bath taking "a lot out" of the print. After bleaching and washing we get, with a ten per cent. solution of cupric sulphate, a really good reddish brown, and very often the print will be the better for a second dip in a bath of weak ammonia water. *Washing* in water, not to be lengthy, follows, a piece of cotton wool helping at this stage to get a thoroughly clean surface, and the prints are then suspended to dry. For opals amidol should be very suitable: in fact, looking at the ease of working, keeping qualities of the solution, and the fact that a clearing bath is not a necessity, to say nothing of colour of positive, one is inclined to ask what further use have we for ferrous oxalate? J. PIKE.

CENTRAL PHOTOGRAPHIC CLUB,

FLEET-LANE, LUDGATE-CIRCUS.

HON. TREASURER: John Howson, "Brockenhurst," Ilford, E. Executive Committee: Messrs. Birt Acres, R. Beckett, Thomas Bedding, Austin Edwards, Thomas Fall, T. E. Freshwater, John A. Hodges, E. J. Wall, and H. Snowden Ward.

The following circular is in course of circulation:—

The want of a photographic club and institute with a permanent home in a central position of London, and easily accessible from the principal railway termini and by the chief omnibus routes, has been for some time felt, and, after several meetings of gentlemen interested in the matter, two public meetings have been held, and it has been decided to at once supply the deficiency.

Numerous premises have been seen and reported upon by the Executive appointed at the first public meeting; and it is proposed, and negotiations are on foot to secure premises at the above address, consisting of basement, ground, first, and second floor, at what is considered a very reasonable rent. In the basement twelve dark rooms could be fitted up, and leave sufficient space for setting up apparatus for enlarging by artificial light. The room on the first floor, after structural alterations, will be sufficiently large to seat 230 persons. It is also proposed at first to provide a smoking-room and library, and other club conveniences. It is proposed at first to utilise the refreshment-rooms in the Memorial Hall-buildings, with which communications will be made. The excellence of the usual catering and the moderate charges have, after actual experience, been highly spoken of. This arrangement will be terminable at any time, and the Club Committee can take the supply of refreshments entirely into their own hands. While the social element will be a strong feature in the proposed Club, technical photographic meetings, demonstrations, lantern entertainments, exhibitions of pictures, apparatus, &c., will be held at stated times.

All gentlemen interested in photography will be eligible for membership.

The subscription for town members, *i.e.*, those residing within twenty miles of the Club, will be 1*l.* 1*s.* per annum, and for country members 10*s.* 6*d.* per annum. The first 500 applicants will be admitted to membership without payment of an entrance fee, which has been fixed at 1*l.* 1*s.* for town members, and 10*s.* 6*d.* for country members. About 250 applications for membership have been received. Life members will be admitted on payment of 10*l.* 10*s.*

A number of rules drawn up and published in the photographic journals for the week ending April 15, 1893, were adopted at the public meeting held on the following Monday. It is anticipated that the Club will be opened early in July next, when a working Committee will be appointed and the necessary bye-laws and regulations drawn up. Every effort will be made to make the club a home, and rendezvous and resort for all those interested in photography, whether residing in London or in the country, and a representative force in each of the many branches of modern photography. We shall be pleased to receive applications for membership, and will, on application, furnish any further information that may be desired.

It is proposed to form a limited liability company, with a capital not exceeding 100*l.*, divided into 5*l.* shares, of which 2*l.* 10*s.* will be payable on application; to take the lease of the premises and to furnish and fit up the same for the use of the club. It is particularly pointed out that all who are interested in the advancement of photography should take shares to assist in placing this cosmopolitan and much-needed club on a sound basis. We shall be pleased to hear from gentlemen as to taking shares, and will forward a prospectus on hearing from you.

W. FENTON-JONES, Hon. Sec. Hackney Photographic Society, 12 *King Edward-road, Hackney, N.E.*

Joint Hon. Sec.

May 1, 1893.

"PHOTOGRAPHY APPLIED TO JOURNALISM."

[Brixton and Clapham Camera Club.]

ON Tuesday, the 18th ult., Mr. T. C. Hepworth, F.C.S., gave a lecture on *Photography applied to Journalism*. The lecture, which was illustrated by means of fifty-seven specially prepared lantern pictures, may thus be briefly summarised.

The lecturer, in his opening remarks, pointed out to what a great extent the journalism of the present day owed a debt to the art of photography. Such papers as the *Graphic* and *Illustrated London News* are almost wholly illustrated by pictures produced by photography. The application of photography has, of course, tended to almost extinguish the wood-engraver, but such an extinction must always be expected when manual labour is replaced by machinery. As an instance, he referred to the substitution of reaping machines, which have thrown manual labour into the corner. Photography has ousted, to a large extent, the wood-engraver, just as photogravure is ousting the steel-engraver. It is to be deplored, and we sympathise with those who are thus thrown out of employment; but, on the other hand, we must congratulate ourselves on the steady advance photography is making year by year.

The existence of such papers as the *Cuts*, of which there are many would be practically impossible were it not for the art of photography. Mr. Hepworth then showed a copy of one of the earliest papers, published in 1679, entitled *Domestic Intelligence; or, News from City and Country*. The original had two columns on either side, and consisted of one small sheet eight and a half inches by six inches; only three advertisements appeared in the paper, and he contrasted these with the big triumphs of printing in the present day—*e.g.*, the *Telegraph*, *Standard*, and *Daily News*, which contain from fifty to sixty columns of closely printed matter, and are crowded with advertisements.

The want of illustration was felt at a very early date, and rough woodcuts very soon appeared; a specimen—*St. Christopher*—was shown on the screen. The original is supposed to be in the possession of Earl Spencer. The picture showed that the woodcut contained some really good work in it, rough as it was. This kind of illustration first appeared in the seventeenth century. A ludicrous specimen, representing a flood in Nottingham, caused great amusement. We must remember that there were few artists in those days, and people had to be content with such drawings. Still greater difficulty was experienced in getting some one who could cut the blocks for the press.

A portrait of Charles I. and his Queen, and another of Isaac Pennington which appeared in the *Mercurius Civicus* in the seventeenth century created some amusement when Mr. Hepworth informed the members that these portraits represented different people at different dates on account of the costliness of the blocks. This custom is still in vogue, as will be seen when our thoughts are directed towards the annual "penny panorama of the Lord Mayor's Show." He referred to a paper of some years ago entitled, *The Illustrated Times*, in which it was the custom to insert old blocks from which the heads of the people had been excised and new ones substituted. A picture of the marriage of the Princess Royal and the Prince Frederick (afterwards the Emperor) was represented in this way. The same block was in an old block representing the wedding of another couple years previously. For many reasons the *Observer* may be called the first illustrated newspaper. An example from that paper in 1827 was shown, illustrating the dire effect of using steam for locomotion, and it caused much laughter.

The copper-plate process was sometimes used. It differs from the woodcut in this respect: in the former the lines are cut in, and in the wood block the lines are raised. In the copper plates the lines are sunk, rolled with ink, the surface cleaned, the ink remaining in the lines of the picture. It was the practice to first print the newspaper in the ordinary way and then pass it through the copper-plate press in order to obtain the engravings. Specimen copper-plate engravings from the *Observer*, representing Nelson's funeral car, were shown on the screen.

Another class of picture known as the broadside then appeared in the papers. Sheets were issued having a rough picture at the top and perhaps underneath some lines or history of a murder. Some of these old broadsides may now be purchased in our back slums. A specimen was shown, Britannia bringing Nelson home from his last victory. In March, 1820, a picture appeared in the *Observer* representing the house in Cato-street where the conspiracy was first hatched. A broadside representing the execution of Mary Perry in 1834 was also placed upon the screen.

Comparing these broadsides with those in the *Daily Graphic*, it will be seen how we have advanced in the art of pictorial illustration. An amusing picture, representing "the first banns," was also exhibited.

Having treated of the historical portion of his lecture, Mr. Hepworth traced the history of the *Daily Graphic* woodcuts from their first conception to their appearance in the paper. The back of a wood block was shown, and it was explained that, owing to the difficulty in getting box-wood more than three inches in diameter, the block had to be composed of several small pieces bolted together. These pieces were distributed between several engravers, and, after the drawing had been engraved, the pieces were rebolted together, an impression taken in wax, a stereotype produced and bolted to a wooden block, which was then ready for press.

The method of engraving was described, and an illustration of the engravers' studio placed upon the screen. Mr. Hepworth stated that in the pre-photographic days the engravers very frequently spoiled the work of the artist, much to the annoyance of the latter. Examples of original drawings and of photographic reproductions were placed upon the screen, and it was difficult to distinguish one from the other. The lecturer then explained very fully the method of printing the *Daily Graphic*. He

stated that this paper was produced at the rate of 50,000 copies an hour, five machines being used. The paper, he said, passed through each of the machines at the rates of three and a half miles in fourteen minutes.

Type-composing, the formation of paper moulds, cylindrical casting, and the general working of a machine were fully explained from the illustrations. The method of drawing and photographing the pictures was very lucidly explained. Balloon sketches, telegraphic instruments, &c., were each in their turn dealt with, and Mr. Hepworth concluded his lecture with a photograph of a group of artists, amongst whom were noticed Professor Herkomer and Mr. Frank Holt. A vote of thanks was unanimously accorded to Mr. Hepworth for his lecture. Later in the evening the Club resolved to affiliate with the Photographic Society of Great Britain.

FORFARSHIRE INTERNATIONAL EXHIBITION.

The Forfarshire Exhibition was held last week in the Reid Hall, Forfar, the task of organization devolving upon Mr. R. Whyte, Forfar, and Mr. W. J. Anckorn, Arbroath, assisted by a local committee. Exhibits were on view from New York, Chicago, Italy, Vienna, and Germany; and, but for a hitch as to time, pictures from Russia, India, and Africa would also have been entered for competition. The Exhibition was well supported by the principal exhibitors throughout the country. For Judges, the Committee engaged Mr. Walter D. Welford, London; Mr. Marshall Wane, Edinburgh; and Mr. Adam Diston, Leven.

The following were their awards:—Class I., confined to Forfarshire amateurs: Silver medal, Peter Feathers, Dundee; bronze medal, G. Mackie, Brechin. Class II., open amateur landscape: Silver medal, T. M. Brownrigg, Guildford; bronze medal, A. H. Bishop, Helensburgh. Class III., amateur *genre* and portraiture: Silver medal, withheld; bronze medal, John E. Dumont, New York. Class IV., professional portraiture: Silver medal, W. J. Byrne, Richmond, "Winnie;" bronze medal, J. H. Hogg, Kendal. Class V., professional *genre*: Silver medal, Robert Terras, Markinch; bronze medal, W. J. Anckorn, Arbroath. Class VI., open class enlargements: Silver medal, Alexander Bros., Glasgow; bronze medal, W. J. Anckorn, Arbroath. Class VII., professional landscape: Silver medal, Robert Terras, Markinch; bronze medal, J. H. Hogg, Kendal. Class VIII., ladies only: Silver medal, Mrs. Bennetto, Italy; bronze medal, Mrs. Amy Warneuke; hon. mention, Margaret Watson. Class IX., lantern slides: Silver medal, T. M. Brownrigg, Guildford; bronze medal, Edgar G. Lee, Newcastle; hon. mention, W. Taverner and W. C. Beetham. Class X., champion class: Gold medal, W. M. Warneuke, Glasgow; silver medal, J. A. Dumont, New York; bronze medal, Robert Terras, Markinch. Special awards: Gold medal, withheld; silver medal, W. J. Byrne, London; bronze medal, Miss Hall, Brechin. Apparatus section: Bronze medal, A. H. Baird, for Todd-Forret flash lamp.

Our Editorial Table.

The Official Catalogue of the British Section of the Chicago Exhibition.

A consideration of the fact that this catalogue of the British Section fills 536 pages, together with 110 pages of advertisements, almost appals one at the probable immensity of a complete catalogue embracing all nationalities. That portion relegated to photography is prefaced by a brief summary by Captain Abney, from which we learn that, as regards the application of photography to scientific purposes, it is believed Great Britain is very much on the same level as other countries. Its uses in medicine, chemistry, astronomy, physics, mineralogy, gunnery, and other branches of pure and applied science, has been very fully demonstrated at the various learned societies, where a very large proportion of contributions are illustrated more or less by photographs. He gives credit to the Eastman Company for having given impetus to flexible film photography, and the form of roller slide in which to use it. We are pleased to see that a large number of pictures are contributed by the photographers of the United Kingdom.

Metol-Hauff.

London: Fuerst Bros., 17, Philpot-lane, E.C.

Messrs. Fuerst have sent us samples of the metol manufactured by Herr Hauff, and which, as we learn from their circular, has been patented in all countries. These samples are put up in small pill-box like tins, each containing thirty-five grains of metol, which, we may say, is in the form of a dry, white, sparkling powder.

Adhering to the instructions for use by which they were accompanied, the contents of one case (thirty-five grains) were dissolved in eight ounces of water—that of the New River Company in this case—and when dissolved, three-quarters of an ounce of sulphite of soda were then added. This, so far as we can perceive, is likely to remain good for an indefinite period; it therefore forms a useful stock solution, and may be labelled A. Solution B contains the same quantity of water—eight ounces—and three-quarters of an ounce of carbonate of potash. Now, in accordance with the proportions in which these are mixed, so does the character of the negative depend. For example, and in the case of studio portraits, the addition of one part of B to three of A, will give an ordinary average negative; while, if a soft negative be desired, one-half part of B will suffice for the same quantity of A; equal parts of A and B, with a third of its bulk of water, gives a hard negative. It will thus be seen that this developer lends itself to the production of any class of negative desired. We may add that, for the development of landscape negatives, a large admixture of water, even up to an equal bulk, is recommended.

But soda can be used equally as well as potash. The proportions recommended are:—

A.	
Water	1 pint.
Metol	130 grains.
Sulphite of soda	3 ounces.
B.	
Water	1 pint.
Soda crystals	2½ ounces.

We have only to add that the Metol-Hauff acts very admirably as a developer, and keeps well in solution.

Since writing the foregoing we have received from Messrs. Arthur Schwarz & Co. samples of Dr. M. Andresen's metol, between which and that above noticed we have not been able to discover any noticeable difference. The formula for development issued with this latter is as follows:—

Water	1 quart.
Metol	¾ ounce.
Sulphite of soda	7 ounces.
Carbonate of potash	3½ „
Bromide of potassium	⅒ ounce.

To photographers who prefer to work with separate solutions the following is recommended:—

A.	
Water	1 quart.
Metol	¾ ounce.
Sulphite of soda	7 ounces
B.	
Water	3 quarts.
Carbonate of soda	7 ounces.

Of these one part of A is mixed with three parts of water for use, bromide of potassium being added as required for the prevention of fogging. The preparations of Dr. Andresen reach us both in pill-box and cartridge form.

La Biblioteca de Fotografo.

Paris: 4, Rue Antoine Dubois. Milan: Lepage et Cie, 11, Via Santa Radigonda.

This little volume has for object the provision of a sectionised list of all published works, so far as can be ascertained, that relate to photography. It should be useful for reference, as the subjects are given in French, German, Italian, and English.

Willis's Photographic Mounts.

Messrs. Willis & Co, Limited, Long-acre, have submitted to us samples of various styles and sizes of mounts enamelled, plate sunk with paste down tint, plain-toned, dark enamelled in various colours, ivory surface, plain and gold blocked, embossed, gold bevel, &c. The mounts are not only all in excellent taste, but are beautifully finished, and appear to be very cheap. A specially pure, plain mount contains seventy-five per cent. of paper, which Messrs. Willis say is not usually found to that extent in photographic mounts. As showing the magnitude of Messrs. Willis's business, it may be mentioned that over 100 hands are employed in the production of the mounts. They supply samples free.

"To Every Photographer."

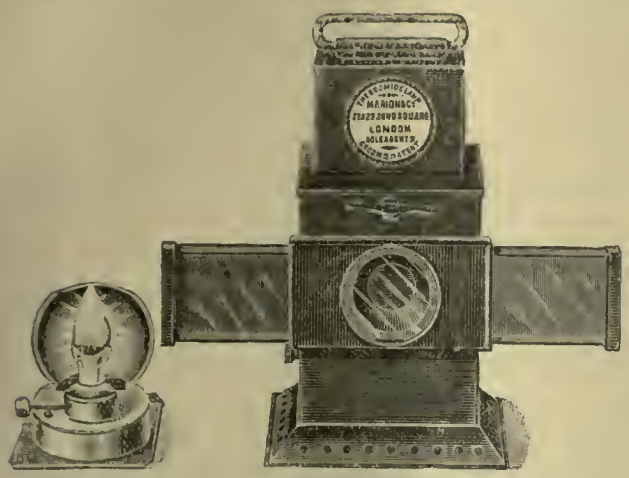
This is the title of a *brochure* issued by the firm of Taylor, Taylor, & Hobson, Leicester, relating to the standard lens flanges and adapters made on the principles recommended by the Photographic Society of Great Britain, and for accuracy in the construction of which this firm has acquired a great and well-deserved reputation. Having had

occasion to avail ourselves of their services in the adoption of several lenses to the one system, in view of the comfort that has, in consequence, been experienced, we can strongly advise those who have a variety of lenses to have them all brought under the standard, feeling assured this will conduce to their comfort as much as it has done to ours. The pamphlet contains a list of prices.

The Bromide Lamp.

Marion & Co., Soho-square, W.

This lamp, which is constructed under Groom's patent, is primarily intended for contact bromide printing, for which it seems admirably adapted, but it can make a useful lamp for all-round purposes. The lamp proper, which is shown in the cut isolated from its framework,



has its wick operated on by a pinion, and its flame is backed by a well-designed reflector. When inserted in its casing, no light is emitted save through the aperture in front, and this governed by slides fitted respectively with either colourless glass or ruby and yellow, the last two of which can be combined if desired. The lamp is so constructed as to consume kerosine without the necessity for employing a chimney. Total darkness is obtained by a shut-off actuated by a lever in front. The burner is regulated from the outside.

Photographic Accessories.

Mr. F. Beresford, 14, Bridge-street West, Battersea, S.W., has introduced several accessories calculated to prove of use to the photographer. The "Eclipse Focussing Cloth" can be instantaneously adjusted over the camera, excluding all light, and leaving the hands free. Several buttons and elastics ensure perfect fitting to the camera. The "Paragon Changing Bag" is designed for those who object to changing plates by touch. It is provided with sleeves for the admission of both hands, there is a ruby window in front, an elastic strap to pass over the head, and a pair of eye-holes protected by ruby glass, through which the operation of changing plates in the field may be watched. Accompanying this is the "Eclipse Light-tight Case" for use with it. This is strongly made of black and ruby fabric, and holds six plates. Mr. Beresford has timed the introduction of these useful accessories with prudence.

The A B C Guide to the Making of Autotype Prints.

By J. R. Sawyer. London: The Autotype Company.

The increasing interest now being taken in carbon printing renders the present a fitting time for issuing a reprint of the admirable manual written a few years since by the late J. R. Sawyer, director of the Autotype Works, and which in this edition has been brought up to date. When, six years since, we reviewed this *Guide*, we characterised it as a practical quintessence of all that had been previously written on carbon printing, and expressed ourselves sorry for the intellect of the man who, with such a *Guide* in his hands, could fail to produce excellent work. This, in effect, is all that we can say of this reissue, which is replete with all that is good and practical, and embodies the experience of this most experienced firm up to the present time. It should by all means be perused by every one who aspires to be a pigment printer of any eminence.

It is embellished by a full page illustration, *Sleepy Hollow*, by Colonel J. Gale.

La Fotografia: Secondo i Processi Moderni. Compendio Teorico-Pratico Del Doctor Luigi Gioppi. Second edition, Revised and Enlarged, with 472 woodcuts and 10 plates.

Milan: Ulrico Hoepli.

Dr. Gioppi's work extends to nearly 750 pages, and in that space he compresses a compendium of the theory and practice of modern photography, which, if not quite complete—as, for example, in the case of photo-mechanical printing—is at least full enough in other respects. The book is a compilation from recognised sources of information, which are acknowledged, the illustrations of apparatus, &c., being of an international character. It opens with an examination of natural and artificial light in their relation to sensitive surfaces, while successive chapters treat fully of the camera and accessories; the lens in its various forms; exposure; shutters, &c. Other divisions of the book are devoted to the negative; its development; after-treatment; retouching; printing processes; and many other departments of what may be termed pure photography. The book, which is dedicated to the Prince of Naples, Honorary President of the Milan Photographic Society, is a monument of industrious compilation, and should prove a useful work of reference for Italian photographers.

PATENTS COMPLETED.

A New or Improved Photographic Accessory for Portrait Photography.

No. 9721. Edmond Stanley Lauder and James Stack Lauder, 30, Westmoreland-street, Dublin, Ireland.—*April* 1, 1893.

This invention relates to a new or improved accessory for use in connexion with portrait photography, whereby such work may be carried on more economically and with greater convenience, and more artistic effect than hitherto.

The invention consists in the use of a sheet of clear glass, tinted or otherwise, arranged between the sitter, or object to be photographed, and the camera This sheet of glass is utilised as a medium to carry decorative designs, floral or otherwise.

The advantages of this arrangement are as follows:—

1. The interposition of the sheet of glass tends materially to soften the lights and shades in the pictures produced.

2. The operator is enabled to use designs of such a nature in front of the sitter as would be quite impossible by any other means.

3. It is rendered possible to photograph a variety of objects apparently occupying different planes, while they are actually in one plane, thereby ensuring perfect sharpness and definition for all distances.

4. When the designs upon the glass represent flowers, they photograph in front and around the figures in all naturalness of real flowers, but being upon the one plane they are much sharper and better defined than real flowers could possibly be under the circumstances.

5. Economy, inasmuch as the power is available at all times of the year of adding to portraits all the effects to be obtained from the choicest and rarest plants.

Improvements in Photographic Cameras and in Films for use therein.

No. 13,926. John Featherstonehaugh Parsons, Siddington House, Kingsdown-parade, Bristol.—*April* 1, 1893.

This invention relates to photographic cameras and to films for use therein.

According to this invention the films are arranged in a pack after the manner of a pack of cards, and are placed in a carrier inside the camera box and acted upon by a spring tending constantly to draw the carrier towards the lens. Each film is separate from the others, and each is provided with a tongue or strap, which is extended forward to the front of the camera, and made to project beyond a recess formed at the front for the reception of the straps or tongues. The latter may either be made in one piece with the films, or be separately made and attached to the films.

After exposure of the foremost film, it is drawn up from the pack through the medium of the strap or tongue aforesaid, and is pulled over the edge of a ledge, on which, after having been drawn, the film lies face downwards. The spring before mentioned as tending to draw the carriers towards the lens advances the pack of films so that each film is brought into focus in turn, and is drawn up after exposure as above described. Restraining strips or stops are provided for the films, so that they cannot be advanced beyond the proper focus.

The films as they are drawn out of the pack are piled one over the other on the ledge aforesaid, and can be removed at will. The chamber into which they are drawn is light-tight.

The operator is enabled to ascertain, by observing the outer ends of the straps or tongues, the number of films which have been exposed, and as each film is drawn up the operator may sever the tongue at the recess through which it projects.

Improvements in Photographic Cameras.

No. 9819. Conrad Beck, 68, Cornhill, London, E.C., and Joseph Thacher Clarke, Boston, Massachusetts, at present residing at 3, College-road, Harrow, Middlesex.—*April* 8, 1893.

Our invention relates to photographic cameras intended for the separation and manipulation of a pack of sensitised films or cards, such as that described in Clarke's Specification, No. 11,891, of 1890. In apparatus of this description a frame or holder, turning upon an axis, contains a pack or series of films or cards, which are separated and deposited by simultaneously acting selecting devices working upon the front of the holder. When released from the said holder and deposited in another pack or series, the films or cards have hitherto been held in position by a retaining device or presser foot, which was raised when a sheet or film was to be deposited from the holder, and was afterwards returned to bear upon and retain the deposited films or cards.

Our present improvement has for its purpose to replace the beforementioned retaining device or presser foot by a flexible and movable dividing band or septum, which, when the holder is in position for an exposure, intervenes between this and the pack of deposited films, and which is capable of being turned out of the way by the rotation of the holder when this is moved for the purpose of releasing and depositing the exposed films or cards. Such a septum may be formed of a strip of cloth or leather, a band of exceedingly flexible metal (as, for instance, sheet steel or phosphor bronze, about three or five-thousandths of an inch thick), or of any similar suitable material.

When it is introduced into a photographic camera having a chamber for the reception of the deposited films or cards situated at the bottom of the case, at right angles to the holder, it has been found advantageous to hinge or otherwise attach the lower edge of the septum to a low transverse partition strip, so constructed upon the bottom of the camera body as not to exclude the light of the lens from the holder. The upper end of the septum may be similarly attached to the cross-bar or flap, which forms the back of the holder and provides the abutment for the spring tending to press the pack of unexposed films forward against the separating devices upon the front of the holder. The width of the septum may be made nearly equal to the clear interior width of the camera itself, while the length may be somewhat greater than the distance between the partition to which its lower end is attached and the bar or flap upon the back of the holder to which its upper end is attached.

If the chamber for the reception of the exposed and deposited films be situated behind and parallel to the holder, the flexible septum may be attached by its lower end to the bottom of the case at some point between the receiving chamber and the holder, and by its upper end to the top of the holder itself.

In both cases it is requisite to reverse the direction in which the holder has hitherto been rotated, in such wise that the top of the holder is moved away from, instead of towards, the lens. By this motion, after a revolution of 270° or thereabouts, the septum is lifted out of the way of the falling films or cards. When the holder is in its normal position ready for an exposure, the septum intervenes (as before said) between the pack of unexposed and the pack of exposed and deposited films, thus preventing the latter from falling into the body of the camera when this is placed upon its side. At the same time it shields the pack of exposed and deposited films from the light admitted through the lens during the act of exposure.

The notable advantages of our invention—as compared with the presser foot which it is designed to supplant—are economy in manufacture, and the assurance that by no irregularity or other failure of reciprocal action on the part of the presser foot can a sheet or film be dropped into the body of the camera between the lens and the holder.

Improvements in the Manufacture of Transparent Materials, and the Application of the same to Photographic and other Purposes.

No. 7567. Thomas Christy, 25, Lime-street, London, E.C.—*April* 8, 1893.

This invention relates to certain improvements or modifications in the manufacture of transparent tissue described in my Specifications, No. 12,230, 1890, and No. 13,917, 1888, and it has more particularly for its object the rendering of such or similar material suitable in photography for dark-room illumination, or its application to the manufacture of photographic apparatus and appliances, such as transparent changing bags, chambers, covers, window blinds, films, and the like, and for other purposes.

In carrying this invention into practice, I make a solution of gelatine or an equivalent substance, and I incorporate therewith a ruby colouring matter of a nature which does not allow the actinic rays of light to pass through, such as red and yellow aniline, or other dyes in these colours. I also most generally add certain chemical agents which will render the glutinous substance insoluble, such as a salt of chromium; or I subsequently subject the gelatinised substance to a fixing bath, such as chrome alum or other agent having the same effect. I also most generally combine glycerine with the glutinous matter for the purpose of imparting flexible properties to the same. I more generally prepare the glutinous solution substantially as described in my Specification, 12,230, 1890, and I employ the same as a film upon glass or otherwise, or I treat suitable paper silk tissues or other fabrics with the glutinous solution, substantially as described in the hereinbeforementioned Specification, 12,230, 1890, and I apply the products as covers for camera screens, to the manufacture of developing bags in the form of muffs, or otherwise for photographic and for other purposes.

But, instead of simply proceeding as above described, I more generally prefer for the purpose of this invention to produce a transparent tissue substantially as described in my Specification, 12,230, 1890, and as above referred to, and then to cover the surfaces of such material with a coat of siccative oil or a suitable varnish, and after drying the material is ready for the purposes herein intended.

The desired colour is embodied with the material as herein described, or as described in my Specification, 12,230, 1890, and sometimes, for the purpose of intensifying the colour, I also mix a suitable colouring matter with the oil or varnish with which the material is to be coated.

Instead of producing a gelatinised base material as above referred to, I may also prepare a suitable paper, or silk tissue, or other material, with a solution of glycerine. I more generally employ an unsized or partially sized long-fibred paper for the purposes herein intended, and I saturate the same with a solution of glycerine in water, more generally a proportion of three to four parts of water to one part of glycerine with which I incorporate any desirable dye, or I dye the paper first to the required colour. The material is then dried, and I then saturate it with a suitable siccative oil, or varnish, and I more generally employ a quick-drying flexible varnish. I then dry the material again, after which it is ready for the purposes herein intended. With the object of producing very intense colours, and also to cover any minute holes in the material, I may also combine some of the colouring matter with the oil or varnish with which the matterial is to be treated.

I wish it to be understood that I may also apply the improved material for some of the purposes named in my Specification 12,230, 1890, such as for surgical purposes, and in this case colouring matters are more generally omitted.

The patentee claims:—1. The manufacture and application of material, substantially as herein described, for purposes in photography requiring the exclusion of the active rays of light. 2. The application of the improved material for surgical and other purposes. 3. The improved material manufactured substantially as and for the purposes herein described.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

May 9,—Ordinary Meeting,—the President (Captain W. de W. Abney, C.B., F.R.S.) in the chair.

The Brixtou and Clapham Camera Club were admitted to affiliation of the Society.

Judges for the Society's Exhibition.

It was announced that the following gentlemen had been appointed Judges for the forthcoming Exhibition of the Society:—Dr. P. H. Emerson, Colonel J. Gale, Messrs. F. Hollyer, F. M. Sutcliffe, and J. B. B. Wellington, with, as scientific experts, Messrs. Chapman Jones and Andrew Pringle.

Tinfoil as a Support for Photo-lithographic Transfers.

Captain A. M. Mantell read a paper on this subject, describing a process of Mr. Husband, who is employed in the Lithographic School at Chatham, for the substitution of tinfoil for paper in the preparation of transfers, so as to prevent expansion and consequent distortion. Captain Mantell showed comparative examples illustrating the superior qualities of picture produced by the use of tinfoil. [We shall print the paper *in extenso* in a future number.]

Mr. Leon Warnerke, in the course of a discussion which followed, suggested the use of silver foil, which he had successfully employed in another photo-mechanical process. It was easily obtainable commercially.

In answer to an inquiry by Mr. Bolas, Captain Mantell said the foil could be used for retransfers from the stone, having the advantage that it gave no distortion, but he did not lay stress on that, as the foil transfers were awkward to keep.

The President said that some twelve years ago tinfoil was employed at Chatham for the purpose, and he was enamoured with the results obtained, but

their great difficulty which Captain Mantell had surmounted, was that of obtaining suitable foil. He did not agree with Captain Mantell that process blocks were not required for military work; he held that they were of the greatest use.

A vote of thanks was passed to Captain Mantell for his paper.

The PRESIDENT then read a paper on *The Use of Rapidly moving Sensitive Surfaces*, with reference to their applicability to ascertaining the speed efficiency of shutters, the duration of flashlights, the comparison of the photographic effects produced by direct sunlight with the amyl. acetate lamp, &c. He also said it was possible by such means to measure the duration of the electric spark by employing a rotating reflector with the instrument.

Mr. G. L. ADDENBROOKE explained a similar instrument for measuring the speed of shutters, which he had described before the Society some years ago.

In reply, the PRESIDENT pointed out that the instrument referred to only demonstrated the speed and not the efficiency of the shutter, and was inapplicable to such work as the comparison of sunlight and candlelight. He also objected to the fact that its results were given in the form of ares, which were not so readily measured.

A vote of thanks was passed to the President for his paper.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

MAY 4, 1893,—Mr. Alexander Cowan in the chair.

Mr. Ashley Cowan was elected a member of the Association.

Circulars relating to the new Central Photographic Club were distributed among the members.

RESIGNATION OF MR. R. P. DRAGE, HON. SECRETARY.

The resignation of Mr. Drage, Hon. Secretary, having been announced, in consequence of the action of a previous meeting in requesting the chairman of that meeting to enter on the minutes a resolution moved by Mr. Beckett, referring to the remarks made in the spiritualistic press as to the attitude of the Association over spirit photography,

The CHAIRMAN said it was an unfortunate thing that Mr. Drage had taken a personal view of a matter which was strictly to do with the Society. He was sure the members would receive the resignation with great regret.

Mr. A. HADDON endorsed the chairman's expression of regret. The Society had been in a better state under Mr. Drage than under his predecessors, and it was to be regretted that he had taken the view of the matter that he had, and should have considered it such a personal insult as to throw them over. He (Mr. Haddon) hoped that Mr. Drage would continue with them as an ordinary member. Mr. Drage had always had a pleasant welcome for both members and visitors, and his resignation must cause them all great regret.

Mr. R. BECKETT echoed all that had been said by the previous speakers, and said that, in moving the resolution in question, nothing personal was intended for Mr. Drage.

Mr. W. E. DEBENHAM said that Mr. Drage's services had been extremely valuable to the Society; and, indeed, no Society could possibly have a better secretary than he had been, but Mr. Drage had, in his opinion, certainly committed a mistake in refusing to enter the resolution on the minutes.

A formal resolution having been put to the meeting, Mr. Drage briefly acknowledged it.

Mr. T. E. FRESHWATER acted as hon. secretary *pro tem.* during the meeting.

THE ASSOCIATION'S TECHNICAL LECTURES.—III. "DEVELOPERS."

Mr. E. J. WALL delivered the third of the series of the Association's Technical Lectures, his subject being *Developers*. Mr. Wall said he would not touch on theory, but he would controvert Messrs. Hurter & Driffield's statement, that a photographer had no control over his results, by saying that a photographer could so control them as to get what he wanted, either by the stain of the developer, fog, or different colours of the deposit, which so affect the printing qualities of the negative as to give him enormous power over those results. Mr. Wall then proceeded to discuss the practical advantages of the principal developers, first of all pointing out that a developer consisted of the developing agent, the restrainer, and the accelerator, and indicating the action of each. Having dealt with ferrous oxalate (formulæ for which, as well as for the other developers, will be appended to the paper when it is published), he passed to pyro, both with ammonia and the alkaline carbonates. In regard to the sulphites he said he thought they had some action on the developed image, as it seemed to him they altered the character of the print by keeping the shadows clear and had a tendency to prolong the unprintable numbers given by a Warnerke sensitometer. For a standard pyro developer for scientific purposes he recommended the formula recently published by Mr. Cowan, and by means of diagrams pointed out that prolongation of the time of development altered the ratios between the high lights (which he supposed to have been developed through) and the half-tones and shadows, especially with thinly-coated plates. Hydroquinone gave more unprintable numbers than any other developer. As a restrainer with it he preferred acetic acid to bromide. Eikonogen gave such softness that it was difficult to avoid want of contrast with it. It should be employed at a temperature of not less than 65°. Rodinal was a very convenient one-solution developer, and lent itself easily to modifications. In cases of under-exposure he employed it 1:60, for over-exposure 1:20, with 10 to 15 grains of bromide to the ounce, and for ordinary work 1:30. Mr. Wall concluded his paper by touching on amidol, which he recommended to be used freshly mixed, with a stock solution of sodium sulphite. He did not see the necessity for using alkalies. Finally, he promised at a future date to treat of metol and glycin, and said developers in use might be divided into two classes, the slow and gradually working developers, which lend themselves to modification, and rapid developers, with which the whole of the image appeared nearly simultaneously.

The CHAIRMAN said Messrs. Hurter & Driffield defined a perfect negative as the true inversion of the original. Mr. Wall said he obtained what he wanted by the aid of fog, but whether that was the way to get a perfect negative was another thing.

Mr. R. CHILD BAYLEY doubted whether pyro was the only developer which stained the gelatine of a plate.

Mr. W. E. DEBENHAM said Mr. Wall had quoted Mr. Bothamley's standard pyro formula, which contained two and a quarter grains of bromide to the ounce; he (Mr. Debenham) thought that too much, and about one grain sufficient to give density for portraiture. A standard time of development did not seem to him a practical thing, as some plates required much longer than others. It had been claimed for amidol that it allowed of a picture being taken with a quicker exposure than with other developers, but he could not find that he got out more exposure with amidol than with pyro.

Mr. J. S. TEAPE confirmed, from practical experiment, the statement as to different plates requiring different lengths of time for development.

Mr. A. MACKIE asked Mr. Wall which gave the denser image, potash or soda, and also what was the action of potassium ferrocyanide in the developer?

Mr. S. HERBERT FRY thought that tentative development implied more than the reduction of the pyro and bromide; he would begin with a weak solution all round. He asked whether bromide was of any effect in retarding over-exposure. Mr. Wall had said quinol made a large part of the image unprintable, but was not that largely a question of temperature? He could not get sufficient density with amidol unless he employed it at a strength of ten grains to the ounce.

Mr. E. H. BAYSTON had exposed two plates of the same speed, developing one with pyro and ammonia, while Messrs. Fuerst developed the other with amidol. He found that pyro and ammonia brought out more detail than amidol, although the latter gave a much quicker printing negative.

Mr. MACKIE had tried amidol, and found nothing in favour of it over pyro and soda. He did not think it was a really quick developer, for, although the image appeared quickly, if one wanted density the developer had to be kept on the plate a long time.

Mr. W. COBB was very favourably impressed with amidol, which seemed to him the developing agent of the future. The question of temperature was of great importance with it. It had a greater power over under-exposure, and gave a softer image than pyro.

After other discussion Mr. WALL replied: As to the staining action of pyro alone, he had referred to the other developers as they were generally used. He had not found that amidol enabled one to shorten the exposure, and he had tested it by means of the sensitometer and a standard light. As to standard time for development experience alone could teach that. He did not agree with a remark of Mr. Mackie that pyro and bromide were interchangeable. Mr. Mackie had doubted whether he could develop an image right through to the back of the plate, but he had done it. As to the action of bromide, Mr. Bothamley said it only had the effect of extending the time of development. Mr. Wall said he found that potassium ferrocyanide in the developer gave black and brilliant images. He could not say whether potash or soda gave the denser image.

A vote of thanks to Mr. Wall concluded the proceedings.

North London Photographic Society.—May 2, Mr. E. W. Parfitt in the chair.—A circular letter from the Photographic Society of Great Britain was read, asking the Society to furnish a set of lantern slides for circulation among the affiliated Societies. It was resolved that a collection of slides should be contributed by the members to form a set for circulation. A demonstration on *Carbon Printing* was then given by representatives of the Autotype Company. Mr. BRAHAM, one of the representatives, said that the process when first brought out was difficult and uncertain, but with the new and improved methods it was now one of the easiest to work. He gave a short history of the process, referring to the introductions and improvements of Messrs. Swan, Johnson, Sawyer, and Lambert. As to the advantages, carbon prints were undoubtedly permanent, and copies of drawings could be reproduced in facsimile, not only as regards colour, but on the same kind of material that the artist had used. The prints can be finished with the highest gloss or the roughest surface, and, as the tissue was brought into perfect contact with an uneven surface, the want of sharpness, which was apparent in other processes finished on a rough surface, was overcome. The transparencies produced by the carbon process are splendid. After commenting on the manner of printing from the negative, and the use of the actinometer, Mr. Braham developed several prints, and showed the single and double-transfer processes, and the production of transparencies. The demonstration proved the ease with which the process could be worked and the simplicity of the operations.

Harringay Photographic Society.—May 4, Mr. Towers in the chair.—A demonstration of development was given by the Vice-President, Mr. Bennett. In opening, the demonstrator said he preferred and recommended the fixed alkalies, as they were less liable to produce fog, and then proceeded to experiment on an unexposed plate, showing how, with the aid of ammonia, fog can quickly be obtained.

Hackney Photographic Society.—The Annual Meeting was held on Tuesday. A very successful season had to be recorded, the membership (although several removals had taken place) keeping up to 115. The Treasurer reported a fair balance in hand, and stated the weekly meetings had done much to improve attendances. The election of officers resulted:—*President:* Mr. F. Houghton.—*Council:* Messrs. W. F. Barker, G. J. Avent, F. W. Gosling, G. Hawkins, R. Beckett, W. A. Hensler, Dr. Roland Smith, and E. Puttock.—*Hon. Treasurer:* Mr. J. O. Grant.—*Hon. Secretary:* Mr. W. F. Fenton-Jones, 12, King Edward-road. *Hon. Assistant Secretary:* Mr. A. Dean. The Society meets weekly on Tuesdays at 206, Mare-street, Hackney. At the close of the business the prize slides of the *Amateur Photographer* were shown, augmented by slides of Messrs. T. H. Blake and S. J. Beckett.

Putney Photographic Society.—Dr. Sheppard in the chair.—Mr. CHARLES GAMBLE read a paper on *Lighting of Objects to be Photographed*, in which he clearly pointed out the importance of studying the effects produced under varying conditions of light. About 100 slides, prepared by himself to illustrate the lecture, were shown. Mr. Gamble explained the qualities or defects of each, and the members were thus able to see what effects they should en-

deavour to secure and what faults they should avoid. A vote of thanks to Mr. Gamble for his paper and for the thoroughly practical way in which he had placed the subject before the meeting concluded the proceedings. This was the last ordinary meeting of the winter session. The Annual General Meeting of the Society for the election of Council and other business was held on May 4, Dr. Sheppard in the chair. All the members of the retiring Council were re-elected; the accounts, which showed a balance in hand, were passed, and some slight alterations were made to the rules. As in previous years, a series of outings will be held on Saturdays during the summer months, a feature being that on each occasion one or more members will act as leaders, having previously gone over the ground and made the necessary arrangements. In addition to the opportunity of photographing picturesque scenery, it is intended to give instruction in field work to the novices and to arrange a series of experiments with, and comparative tests of, apparatus and materials. The first outing will take place on Saturday, May 13, when the Joint Hon. Secretaries, Mr. Gorin and Mr. Zachariasen, will take the members along parts of the Basingstoke Canal and the Wey Navigation, starting from Byfleet.

Brixton and Clapham Camera Club.—May 2.—One new member was elected, and three other gentlemen proposed for membership. The next meeting of the Club will be held on May 16, on which occasion Mr. W. Thomas will read a paper on *A Photographic Picture and its Production.* As the subject is one which every photographer should thoroughly understand, the attendance of every member and also of any gentlemen interested in photography is specially requested. Mr. Thomas's paper will be fully illustrated.

South London Photographic Society.—May 1, the President (Mr. F. W. Edwards) in the chair.—Mr. S. Herbert Fry delivered an address on *Multiple-coated Plates,* during the course of which he gave a minute description of the peculiarities of the Sandell plate, and the treatment of it. For development he recommended Messrs. Thomas & Co.'s "cyclol" developer, composed as follows:—Hydroquinone, 30 grains; eikonogen, 100 grains; rodinal, 9 drachms; sulphite of soda, 2½ ounces; carbonate of potash, 2½ ounces; water, 20 ounces. Use 1 part to 7 parts of water in the summer, and in the winter time 1 part to 3 parts of water. The fixing bath should be as strong as 8 ounces of hypo to a pint of water. A longer time should be allowed for the fixing and washing of the plates, owing to the thickness of the coating. Mr. Fry, in conclusion, claimed the following advantages for the Sandell plate:—(1) Special merit for hand-camera work; (2) peculiar fitness for interior work; (3) a practical cure for halation; (4) a better atmospheric effect and a longer range of gradation; (5) exposure is practically unimportant. Examples of work were passed round and examined. A question was asked: "What is the best background for photographing flowers for lantern slides?" It was answered, "A black velvet, brown paper, or a dark-coloured plain background. Two new members were elected, and five nominations were read. Attendance, fifty-two.

Croydon Microscopical and Natural History Club (Photographic Section).—May 5.—Mr. J. R. Gotz exhibited several photographic novelties, and explained their working. The chief one was a pair of lenses with a shutter attached—part of a new camera he was about to introduce—which could be used at will as a stereoscopic camera, or as a hand camera with full-sized finder, or as a double quarter-plate. The shutter had a considerable range of speed, and although working simultaneously on each lens could, when necessary, expose them independently. A changing box for large films was also shown, the films being carried in thin steel sheaths, and exposed in a single dark slide. Mr. Gotz then demonstrated the new Obernetter positive films, the various methods of toning Obernetter gelatine, and celloido-chloride papers, and their development when partially printed; the great variety of tones obtainable were shown in a number of prints that were handed round.

Birmingham Photographic Society.—May 2, Mr. W. Jones in the chair.—About forty-five members present. Mr. FRY gave a lecture on *The Uses and Advantages of the Sandell Plate.* Mr. Fry described the advantages claimed for multiple films. They are, briefly: (1) Freedom from halation even with the most trying subjects. (2) Possibility of giving enormously more than a normal exposure, which, with careful tentative development, would give all detail and density possibly required, and would dispose of the correct exposure question. (3) Increased detail and transparency in the shadows of instantaneously exposed plates. This was well exemplified by an extremely fine series of pictures produced by Mr. Sandell, the inventor of the plate. As to manipulation, briefly, one may say, give a long exposure and develop tentatively, hydroquinone and eikonogen used together being one of the most suitable developers. The CHAIRMAN said he had used and liked the plates very much; the one thing he did not like was the price. Mr. SIMKINS said he thought all that had been done by these plates could be done with any ordinary good plate properly backed. Mr. Simkins' method of working is to largely over-expose, development being tentative and stopped by citrate of ammonium when detail is out, and then redeveloped to full density as recently described. Mr. MIDDLETON said he thought the Sandell plates did not always prevent halation, and challenged M. Fry to expose a plate on the interior of St. Martin's Church, Birmingham, a very difficult subject. Mr. JAQUES said he considered the results shown very beautiful; so soft, and such transparency in the shadows.

Leeds Photographic Society.—May 4, Mr. J. H. Walker (President) in the chair.—Dr. Jacob gave a lecture, with practical demonstrations, on *Tone and Colour in Lantern Slides.* He showed that, with various exposures and suitable developers, a great variety of tones could be produced at the will of the operator. He also showed good results on the Alpha plate, toned in the combined bath.

Lewes Photographic Society.—May 2.—A demonstration of *The Cold-bath Platinotype* was given by Mr. G. I. Wightman, who developed a number of prints, and showed how glycerine could be used in controlling development and in saving over-exposed prints. The results were very satisfactory, and the demonstration was much appreciated. A number of sample packets of plates, kindly sent for trial by the Imperial Dry Plate Company, were distributed among the members.

Sheffield Photographic Society.—May 2, Mr. Bradley Nowill in the chair.—Mr. T. G. Hibbert showed four photographs taken in America by the Daguerreolype process, which are still in a good state of preservation.

Exchange Column.

**** No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance. The full name of the advertiser must in all cases be given for publication, otherwise the Exchanges will not be inserted.*

Optimus rapid rectilinear eighteen-inch iris diaphragm, want concentric seven-inch or over; difference, if any, adjusted.—Address, WRIGHT, Studio, Hanwell.

Will exchange Lancaster's half-plate camera, two double slides, landscape lens, and tripod for magic lantern or first-class rectilinear lens of four and a half inches focus by good maker.—Address, G. MOORE, Buckfastleigh.

Will exchange THE BRITISH JOURNAL OF PHOTOGRAPHY 1888, 1889, 1890, 1891, 1892 (about six missing), also 140 numbers *Photographic News* between 1880 and 1887, for a good hand camera or field glass (Lemaire).—Address, MURRAY LUNDIE, 11, Bridge-street, Rothesay.

Correspondence.

☞ *Correspondents should never write on both sides of the paper. No notice is taken of communications unless the names and addresses of the writers are given.*

THE CONCENTRIC LENS.

To the EDITOR.

SIR,—I have looked in vain for some authority in the photographic world to challenge Mr. Stillman's letter on this lens, as set out in the JOURNAL of April 21.

This is the second letter I have read from this gentleman, in which he contends that the Concentric lens defines as sharply with *f*-16 as it does with *f*-64, and I note he sends you prints with a view, no doubt, to an editorial foot-note confirming his conclusion. Messrs. Ross may well pray to be delivered from their friends; anything more misleading to the public or unfair to the lens cannot be imagined. Mr. Stillman makes 10×8 negatives with an eight-inch lens, attached to a camera with a cracked front, cuts out the centre of his prints, and rushes to the JOURNAL with a positive assertion, which he defies any one to contradict, "that an eight-inch Concentric defines as perfectly on whole-plate with *f*-16 as it does with *f*-64."

This statement is so opposed to my experience with the lens, that I can only conclude that Mr. Stillman obtained his two prints, which are so equal in definition, on the "pinhole" principle, through the crack in his camera front, and that he omitted to remove the lens cap in both cases when making the exposures.

When the Concentric was offered to the public, I obtained one of twelve-inches focus, with which I have made some hundreds of negatives. My lens is fitted with rotating stops which run from *f*-16 to *f*-32 only. I am therefore unable to say what it would do at *f*-64, but the difference in definition between *f*-16 and *f*-22 is so remarkable, that I venture to give my brother amateurs a direct repudiation of Mr. Stillman's contentions; and, further than this, to warn them to be careful how they use the lens at *f*-16. I spoiled plate after plate with this stop until I tried focussing with *f*-22, even when intending to make the exposure with *f*-16, but even then *f*-16 is not a stop for general use with this lens, and I now rarely or ever use it.

The strong points of the Concentric are its equality of illumination and the freedom with which you can raise or lower your camera front in difficult places; you can obtain sharp definition with the very edge of the lens, where an ordinary rectilinear would give you nothing but astigmatism, only let *f*-16 severely alone, and stick to the *f*-22 to *f*-32.

I am an utterly unknown amateur, who can remember the wet-plate days, but make no claim to the title of an expert. I do not wish to be discourteous to Mr. Stillman, but there are pitfalls enough for the unwary, and many are unable to discriminate between the sound and the unsound. I recommend your article on "Focal Peculiarities of Wide-angle Lenses," in this week's number, to Mr. Stillman's careful consideration.—I am, yours &c.,

F. H. BURTON.

Roundhay, near Leeds, May 6, 1893.

SULPHURIC ETHER.

To the EDITOR.

SIR,—I find by a clerical error I put down ·770 as the specific gravity of best sulphuric ether instead of ·717, in my "Lantern Mems." of to-day's "Lantern Record," and, as my correction did not reach you before going to press, I shall be obliged by your inserting this in the next JOURNAL. It should also have read: "·720 to ·750 specific gravity will do." As, however, the latter is stronger smelling, ·720 specific gravity is about the densest that should be used for the oxy-ether light.—I am, yours, &c.,

May 5, 1893. G. R. BAKER.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

To the EDITOR.

SIR,—My duties as Hon. Secretary and Treasurer having terminated, will you kindly allow me to inform your readers that all communications intended for the London and Provincial Photographic Association must be forwarded to Mr. T. E. Freshwater, 3, Fleet-street, E.C., who is acting as Hon. Secretary *pro tem.*—I am, yours, &c., R. POULTER DRAGE.

95, *Blenheim-crescent, W.*

GELATINO-CHLORIDE *VERSUS* ALBUMEN.

To the EDITOR.

SIR,—I think "B. B.'s" difficulty with gelatino-chloride is due to want of scrupulous cleanliness, without which it is impossible to work the paper satisfactorily.

I judge from "B. B.'s" letter that he finds his prints dirty after burnishing—dust is burnished into them. The remedy is obvious: as the prints are mounted, they should be placed on frames covered with muslin, and with short feet attached, so that when piled one on top of another an air space intervenes; the burnisher must be in good condition and well dusted; the prints carefully dusted and lubricated with Castile soap in methylated spirit before passing through (except a roller burnisher is used, which, I need hardly say, is by far the better instrument). To avoid abrading the surface, the prints must be *thoroughly dry;* had "B. B.'s" been so, they would not have been "scraped." They must not be baked to make them dry, for, if all moisture is taken out of *the mount*, no gloss can be obtained. With care, which ought to be exercised in every branch of photography, no prints need be spoiled in the burnishing, at least not more than if they were albumen, for even these, I gather, are sometimes spoiled in "B. B.'s" hands by "ordinary scratches." Pyro and amidol should not be weighed out in the printing room; this is sometimes done, and printers are puzzled to account for black spots on the prints.

I have never found prints on ready-sensitised paper to spoil sooner than those on the home-prepared article, and I think I am right in saying that, if prints on any paper "mottle," the fault will, in all probability, be found elsewhere than in the paper.

As to gelatino-chloride *versus* albumen, looking at the matter from a purely professional point of view, I consider the odds are greatly in favour of the former, for the following reasons:—It is uniform, the sheets cut more economically into photographic sizes, it is perfectly good to the edges, no water marks, it is beautifully clean *back and front*, and is almost invariably free from the slightest blemish, and for these reasons it is *cheaper*.

It is more permanent, as may be tested practically by putting gelatino-chloride and albumen prints, prepared with equal care, side by side in a well-exposed show-case; it gives more brilliant prints, washes quicker, prints faster (and "time is money"), both innately, and because thinner negatives can be used.

Albumen, on the other hand, is rarely uniform; in many photographic establishments, where carelessness reigns paramount, the bath is permitted to vary (I have known it to be used for months, and never once filtered), the albumenising formula is an unknown factor, or is permitted to be so, and the paper sensitised without regard to it. The ready-sensitised paper often comes, even from makers of repute, dirty, stained, and wasteful.

In many instances, where years have been spent in acquiring proficiency with albumen, gelatino-chloride is expected to be known in a moment. If those to whom gelatino-chloride is new find it at first a bit intractable, they should remember the *blisters and measles* of its rival.

Albumen (except for breakfast) is out of date; it wants careful labelling and placing on the shelf with the wet plate.—I am, yours, &c.,

May 6, 1893. T. FITZGIBBON FORDE.

To the EDITOR.

SIR,—I notice your correspondent, "B. B.," has got into some difficulties in working gelatino-chloride paper, and I want, in all brotherly love, to help him out.

I have abandoned albumen paper entirely for more than six months now. I use P.O.P. and work as under. For enamelling it is the best thing I have ever struck, but collodionise your plates first if you don't want opalines. For ordinary work, when the prints are mounted, rub them over with a damp, clean sponge to take off any dirt, and to remove the fluff which will adhere to them from the blotting-paper that is used to press them in contact with the mount. Then, mark this "B. B.," stand them up on end face to the wall till dry, this will prevent dust settling on the tacky surface.

Now the burnishing. When I began to burnish P.O.P. on a bar burnisher, I spoilt dozens. I used to heat the bar hotter than Gehenna, as in old albumen days, and, of course, it frizzled all the gelatine off the paper. Now I find it only necessary to make the bar about as hot as the hand will just bear for a second, say, about 300° Fahr. Previous to burnishing, I give the print a dose of my old silver print lubricator, but when dry rub it all off, or the prints may be streaky. The prints should now go through the machine like oil, and have a nice gloss. *En passant*, I may say I have never met with the marks referred to by "B. B." Probably these originate in the fixing bath; but the one thing that delights me in gelatino-chloride papers is the entire absence of measles, a malady to which our old friend albumen was very subject.—I am, yours, &c., "OTHELLO."

May 3, 1893.

REGULATORS.

To the EDITOR.

SIR,—I must certainly say, when Mr. Birrell asked for information respecting a regulator for oxygen and hydrogen gases, I was under the impression that it was a regulator for condensed gas at high pressure of not less than 600 pounds per square inch.

But by his latter remarks, and also judging from a print sent me by him of his apparatus, he evidently means a low-pressure regulator such as would be used upon the ordinary house gas mains of, say, from seven-tenths to four inches water pressure. Mr. Highley speaks of these for use with oxyhydrogen jets made by Mr. Parkinson as far back as 1870, but I don't profess to know the date of their origin. I only know there are more than I should like to enumerate.

Again, Mr. Birrell speaks of his anti-friction cock. Does he suggest a lubricant of any fatty matter? If so, he will find his anti-friction cock meet with little success. Gas compressors strongly discourage the use of grease of any kind whatever. Before Mr. Birrell proceeds further with his regulator he should get a cylinder of gas from the Scotch and Irish Oxygen Company to test it with.—I am, yours, &c., R. R. BEARD.

62, *Alscot-road, Bermondsey, S.E., May* 2, 1893.

"ART *VERSES* PHOTOGRAPHY."

To the EDITOR.

SIR,—At the present juncture of the endless argument on Art *versus* Photography (let them both have capitals) it was interesting to read in the *Saturday Review* of last week the following in their criticism of Mr. W. B. Davis's picture:—

". . . . Notwithstanding his wonderful sincerity and the almost perfect photography of his eye . . ."

Should we take this as a compliment to Mr. Davis or as a compliment to photography?—I am, yours, &c., FREDERICK H. EVANS.

158, *Osbaldeston-road, N., May* 9, 1893.

Answers to Correspondents.

*** *All matters intended for the text portion of this* JOURNAL, *including queries and Exchanges, must be addressed to* "THE EDITOR, THE BRITISH JOURNAL OF PHOTOGRAPHY," 2, *York-street, Covent Garden, London. Inattention to this ensures delay.*

*** *Correspondents are informed that we cannot undertake to answer communications through the post.*

*** *Communications relating to Advertisements and general business affairs should be addressed to Messrs.* HENRY GREENWOOD & CO., 2 *York-street, Covent Garden, London.*

PHOTOGRAPHS REGISTERED:—

Walter Azembey Smith, Southampton.—*Portrait of Dr. Perrin, Bishop of Columbia.*

John Stephen Brown, Bridgwater.—*Photograph of crayon drawing of Samuel Taylor Coleridge.*

Everitt Edward Hibling, Maidstone.—*Portrait of John Cuckow.*

George Henry Lawrence, Cardiff.—*One photograph of a Welsh Sunday "Field" Club.*

D. ROSS.—We know nothing whatever of the Company.

GIL BLAS.—The address of Messrs. Penrose & Co. is 5, Amwell-street, E.C.

WILLIAM BIRRELL.—See the JOURNAL for December 16, 1892, where you will find the specification.

ALPHA has not, in compliance with our rules, given his name and address. Hence his query remains unanswered.

C. H. E.—When the combined toning and fixing bath is used the double action is scarcely simultaneous. Fixing takes place first.

LANTRO.—To utilise a *carte-de-visite* as a lantern slide, copy it in the camera, and, from the negative thus obtained, print a lantern slide in the usual way.

CLEARER.—For all practical purposes you will find a solution of alum acidified with hydrochloric acid an efficient agent in removing the hypo from the film after washing.

P. JOHNSON.—For obtaining cloud effects, we do not think there is any advantage to be gained in the use of a yellow screen with ordinary plates. It simply lengthens the exposure.

DICK.—The Crysteleum process has never been much pushed by professional photographers. It may be considered as reasonably permanent, if the printing has been properly carried out.

J. BAXTER.—It is a very common occurrence. As we have no particulars as to the preparation of the paper, or know anything of the after-manipulations, we can offer no opinion as to the cause.

R. C. TODD.—So far as we are aware there are no patents in force at the present time with regard to ceramic photography. Several patents have been taken in connexion with the subject, but they have, we believe, long since elapsed.

CONEY ISLAND.—If we knew the use to which you were to put the lens, we could better advise you; but we think that there would be no difficulty in having a lens of, say, sixty to seventy inches focus made. The price will be greatly influenced by the diameter.

BRIXHAM.—It is of no use making an enlarging lantern with eight-inch condensers to enlarge from half-plate negatives if it only be fitted with a quarter-plate lens. The objective must be such as would be capable of taking a negative of the size of the one to be enlarged.

TORQUAY.—It is a fraud to supply bromide prints for platinotypes, as it is a false trade description. The fraud is easily detected. If a bromide print is immersed in a solution of bichloride of mercury, the image will, in a short time disappear, whereas a platinotype will be unaffected.

E. R. W.—There is no necessity to go to the trouble of making transfer ink for photography now. It may be purchased from any of the large firms supplying printer's material, and of a far more satisfactory kind than can be made on a small scale. Your difficulty, you see, is now overcome.

T. R. HEWDY.—When anything is directed to be boiled in a Florence flask, a glass flask, such as may be obtained from any dealer in chemical wares, is understood. It would not do to dissolve silver in nitric acid to make nitrate of silver, in an enamelled iron saucepan. The enamel is not perfect enough.

S. A.—If the exhibitor takes portraits for which he makes a regular charge' although he may carry on a totally different business, he is not an amateur, and is sailing under false colours. If this had been brought to the notice of the Society at the time, he ought to have been, and, no doubt, would have been, disqualified.

W. R.—It does not follow that because a gelatine is transparent and colourless that it is purer, or better suited for some photographic purposes, than others that have colour, and are more or less opaque. The majority of the colourless foreign gelatines are acid, some of them strongly so, and often contain other impurities. As gelatine, though not perhaps so slightly in appearance, probably the purest kinds are probably those of the best brands of English manufacture.

F. J. CLARK.—If you desire to make enlargements in carbon it will be necessary to make enlarged negatives. It is not essential that they be collodion ones so long as they are of the right character to yield good carbon prints. Extra sensitive carbon tissue is not equal to producing enlargements direct after the manner of bromide paper, unless the solar camera be employed, and then the exposure is very long. That instrument can only be employed in sunlight.

A. O. Z.—If the indentures are not drawn up in the proper form and duly stamped, they are not binding either on the master or the apprentice; therefore you cannot compel your master to teach you any more than he chooses. On the other hand, you can leave him at any time by giving a week's notice like any other weekly servant, and that is what you legally are, and take another engagement at higher wages. Considering the four years' experience you have had, and the merely nominal wage you are receiving, it may be advisable to take this course.

A. J. finds that while he gets good black and white enlargements on slow bromide paper, he fails to get equally brilliant blacks on rapid paper. He has varied the exposure without gaining any advantage, and asks if there is any modification of the developer possible, or any other means by which he can obtain good blacks on rapid paper.—We would like if some experienced reader would impart the required information; meantime, let him, after washing and before fixing, try the effect of immersing in a combined toning and fixing bath.

LOUIS TAINDON says: "I had, in the course of business, to copy a ferrotype picture, and, owing to part of picture being covered by a brass mask, had to remove it from the frame, and, as there were several particles of dust on the plate, I sought to remove same by brushing it lightly with my hand, when, to my horror, I discovered that wherever my hand had touched it the picture had vanished, leaving only a faint image, which can only be discovered by holding it sideways (Daguerreotype fashion). Can you tell me the cause of this, and also if there is any remedy?"—The cause is simply this: the picture not being varnished, and most ferrotypes are not, a portion of the image has been rubbed off. There is no remedy.

T. WARRENER says: "It is generally understood that when water is added to methylated spirit, it will still be quite clear; but, if it becomes milky, it contains gums—in fact, is what is known as 'finish,' which can be sold without a licence. I recently bought half a gallon of methylated spirit, and found, on adding water to it, that it became turbid. On taking it back to the oilman, he asserted it was not finish, but genuine methylated spirit, and refused to change it. Is this possible?"—Yes. Under the new excise regulation, a small proportion of mineral naptha has to be added to the spirit, the effect of which is that, on the addition of water, it becomes turbid. Now, without a special permit, the old kind of methylated spirit is not to be obtained.

W. P. N. asks: "1. Is it necessary after an addition of nitrate of silver to a silver bath to add iodide of potassium? I have been given to understand that there will be enough in an old bath by what it has extracted from the collodionised plates that have been excited therein. 2. In the case of the iodide getting in excess, what is the result and remedy? 3. Also of insufficiency?"—1. There will be quite enough iodide in solution to warrant the addition of more nitrate solution without any further addition. 2. Add distilled water, by which much of the iodide will be precipitated, then filter, and lastly, add crystals of nitrate of silver to bring up to the strength required. 3. Coat a plate with collodion, and allow it to remain immersed in the silver bath for one hour.

J. T. KENNISH writes: "I forward you a mounted print, which is much spotted, as you will see, and will thank you if you will give me your opinion as to the cause. The paper used was 'double albumenised;' fixed twenty minutes (in hypo, four ounces; water, one pint); hypo neutral to litmus paper; hypo used fresh; mounted with Glenfield starch, made fresh, and used as soon as cold; sponged while damp with clean water. *Cartes-de-visite*, whole-plates, and 12×10, produced at the same time, under exactly same conditions, are perfectly free from spots; washed all night in syphon trough. Cabinets only show these spots.."—Seeing that the spots only make their appearance on the cabinet prints, and assuming that in their after-treatment there is no difference made, the only suggestion we can make is, that our correspondent test the mounts. It is possible the trouble has its origin in them.

DURING the summer the steamship *City of Richmond* will make several pleasure trips to the fjords and mountains of Norway. The first trip is from Liverpool on May 20. Messrs. Staveley & Co., of 102, Shaftesbury-avenue, W., are the London agents, and will supply all particulars.

MESSRS. ADNITT & NAUNTON, of Shrewsbury, have sent us a short *résumé* of objects of interest to photographers visiting Shrewsbury. It is embellished with several picturesque views. Should the Convention carry out a half-formed intention of holding their meeting in Shrewsbury on an early occasion, such a list as this will prove very useful.

MR. E. H. FITCH, of 34, Angell-road, Brixton, will shortly introduce a celluloid film for photo-mechanical purposes; also a very light double slide-film carrier, and other novelties.

WEST LONDON PHOTOGRAPHIC SOCIETY'S DINNER.—The annual dinner of this Society took place on Tuesday last, May 9, at the Frascati Restaurant, Oxford-street, the President (Mr. J. A. Hodges) in the chair. The challenge cup won by the Society at the recent Crystal Palace Exhibition was on view. The President, in proposing the toast of "The Society," took occasion to comment on the fact that, although the Society had been adjudged winners of the Champion Cup at the Crystal Palace, no awards had been made to individual members, and thought some explanation of the circumstance was due. Mr. W. Eugland responded for "Kindred Societies," Mr. Thomas Bedding (THE BRITISH JOURNAL OF PHOTOGRAPHY) and Mr. E. J. Wall (*Amateur Photographer*) for "The Press," and Mr. T. R. Dallmeyer for "The Visitors."

THE BRITISH
JOURNAL OF PHOTOGRAPHY.

No. 1724. Vol. XL.—MAY 19, 1893.

NOTICE—PICTORIAL SUPPLEMENTS TO "THE BRITISH JOURNAL OF PHOTOGRAPHY."

It is our intention from time to time to issue with The British Journal of Photography pictorial supplements illustrating subjects of popular interest, and reproduced in the highest style of photo-mechanical work.

We have no doubt this feature will prove very popular with our readers. The first illustration will be given with the Journal of Friday, June 2, and, as the publishers anticipate a largely increased sale for that issue, orders for advertisements and extra copies should be given as early as possible.

INVERSION AND REVERSION OF IMAGES ON THE BINOCULAR FOCUSSING SCREEN.

When a stereoscopic image is focussed on the ground glass of a binocular camera, the image presented to the eye is seen to have undergone a total reversion, not merely in respect of its being inverted, for that is the case with every camera image, but also in regard to the relative displacement of the near and distant objects on the screen when viewed stereoscopically, could such be done by the neophite.

The stereoscopic photographer cannot, with his unaided vision, ascertain the effect of relief by the inspection of the camera image in the same way as he can when examining the finished print in the stereoscope; and this to some extent interposes a difficulty in the selection of the best point of view in order to secure the degree of relief which an artist of taste invariably likes to characterise his binocular pictures, neither, on the one hand, such protrusion of foreground objects as to cause the scene to look like a model, nor, on the other, such a lack of it as to impart a feeling of flatness to the united photographs.

Some who have not bestowed sufficient attention to the subject have imagined that, by employing a stereoscope to examine the image projected on the camera focussing screen, the desired end ought to be attained; but the futility of this is established by a single trial, for it will be found that the effect obtained is pseudoscopic, that is, the near objects appear distant, while the most distant ones are brought near. We shall apply the "similia similibus curantur" principle to this presently, and show in what manner, by looking on the ground glass through a pseudoscope, the desired relief can be seen.

A pseudoscope, we here pause to say, is nothing but a pair of small rectangular glass prisms, mounted the distance of the eyes apart, with the hypothenuses to the inside, so that each eye is directed to a surface inclined to its axis. In ours there is provision for an adjustment, by which the reflecting surfaces can be slightly inclined towards each other, so as to direct the eyes without any straining to any object situated from within a few inches to infinity. When a scene is viewed through this, it is neither magnified nor reduced, nor is its brilliance apparently diminished, but the singular effect is obtained that the distant objects are brought close at hand, while the nearest objects—such as a vase of flowers on a table in the window of the room from which the observation is made—is projected into the far distance, the near and distant flowers in the vase obeying the same law, that of visible direction. In virtue of this the nearness or distance of any object is ascertained by the greater or less convergence of the optic axes.

Were the mere inversion of a camera image desired, this could be secured by the time-honoured expedient of placing a mirror at an angle with the ground glass of the camera, and by looking down into this mirror, viewing in it the image on the focussing screen, not upside down as formerly, but erect, a reversion from right to left being still left uncorrected. This, however, affords no clue as to the amount of the relief or stereoscopeity of the scene focussed unless by crossing the axes of the eyes, the right side being viewed by the left eye and *vice versâ*. An examination by a pseudoscope would effect the same end.

The best way to employ this instrument is to view with it the direct image on the ground glass without caring that the image is seen inverted. Throw a large focussing cloth over the camera, and then use the pseudoscope as would be done in the case of an eyepiece held a short distance from the ground glass, and adjust the prisms till only one image formed of the coalescence of the two is seen.

But by far the readiest and most convenient method of judging stereoscopic effect in the camera is by the unaided eyes after they have been subjected to a very slight degree of training. Hold the head from twelve to sixteen inches from the ground glass, and cover the inter-space with an opaque cloth. Now direct the axes to a point midway between the eyes and the camera screen. This may at first be done by interposing a pencil or the finger at the midway point. It will now be found that the crossing of the axes at this point will have had the effect of causing the right eye to see the image on the left, the same being the case with the left eye. This may prove troublesome just at the first attempt, but after a few trials it will be found to be singularly easy. The combined image thus seen is the stereoscopic one, precisely as it will appear when printed on paper and viewed through a stereoscope, with this exception, that the camera image will be upside

down, a matter of but small consequence to an experienced photographer, who can in most cases better judge the effect of the ultimate picture when the image is inverted than when it is non-inverted, the consequence, doubtless, of practice.

EXPERIMENTS WITH MULTIPLE-COATED FILMS.

Resuming these experiments with a view of removing, if possible, certain apparent anomalies, a special collodion emulsion was prepared which, while moderately sensitive (for such an emulsion) was capable of giving *per se*, and with ordinary development, a perfectly clean image of good vigour and free from fog. The "pellicle" was washed with rather more than ordinary care, in order to ensure the entire absence of soluble salts.

In our earlier experiments it was mentioned last week that development was extremely slow in starting, as long as five minutes elapsing in some instances before any action was visible, while in other cases it began almost immediately. This we traced to mechanical causes connected with the collodion film, and it was one part of our new trials to remove as far as possible these uncertainties. In some instances, in the earlier experiments, the plates were exposed wet, *i.e.*, without drying the collodion film, in which case they were well washed with water before development, in order to remove the ether and alcohol and allow the developer to attack the films in a uniform manner. In other cases the collodion film was dried before exposure, under which circumstances it became necessary to flood the films with alcohol in order to reopen the pores of the collodion, and afterwards to wash well with water.

It was this treatment we found that caused the difference or uncertainty in behaviour, for the gelatine film became charged with varying proportions of water, which, assisted by the same protective action of the collodion film, prevented the free access of the developer. By working constantly under like conditions, it is true that comparative results would be obtained; but we were strongly of opinion that this preliminary absorption of water by the gelatine film exercised an important action in modifying the general character of the results—a view which we had subsequently reason to believe is the correct one.

One way out of the difficulty was to charge the collodion emulsion with a substance of the nature of a "preservative"—using the term in the sense in which it was employed by old dry-plate workers—which, being soluble in water, would render the compound film permeable to the aqueous developer; but, though this was tried, the introduction of the preservative did not seem a desirable complication, so it was relinquished in favour of the simpler plan eventually adopted. This consisted in coating the gelatine plate with collodion emulsion immediately before exposure, and postponing the development until nearly the whole of the solvents had volatilised without leaving the film absolutely dry. In this manner, and developing in a dish in the manner usual with gelatine plates, the "greasiness" caused by the small remaining traces of ether and alcohol was easily overcome, and the developer passed directly into the films both of collodion and gelatine.

Under these altered circumstances, the behaviour of the compound films becomes quite different, and more in accordance with what might have been anticipated. For instance, the high lights or sky of a landscape appeared almost instantly on the application of the developer, owing to the rapidity with which an impressed collodion film produces its image. Under the conditions in which these plates were exposed, the sky or strongest high lights were the only portion of the plate in which the exposure was long enough to impress the collodion alone; hence these portions only showed reduction as soon as the developer was applied, the remainder of the picture being formed by the slower action of the gelatine film.

In our article last week we specially mentioned the extraordinary behaviour of an unwashed collodion emulsion in producing an image practically without exposure, or under such circumstances that, if exposed alone, without the gelatine film, it would have been quite insensitive. We have repeated that experiment several times, with precisely the same result; but, although there is unmistakably an image formed upon the collodion film, we have arrived at the conclusion that much of the increase of density shown is the result of a general veil that seems inseparable from this method of developing the collodion emulsion. In fact, although, as we have said, the emulsion employed is capable of working by itself without any fog or veil, it will not bear the protracted application of the energetic developer necessary for the gelatine film.

It must be remembered that the development proper of any direct image upon the collodion film would be complete in a very short time—certainly under a minute, and probably before that on the gelatine had commenced—and consequently, while the gelatine image is progressing, that on the collodion is being subjected to all the influences of fog, which, under the circumstances, it is unable to altogether resist; and yet the gelatine film itself reacts upon the collodion in restraining the fog, as may be proved by scraping off a portion of the gelatine film before coating with collodion, when on development the portions of collodion unbacked by gelatine will be found as completely reduced as the sky. In all the experiments made we have therefore been careful to note as far as possible the effect produced by veil or fog as distinguished from a definite image.

Before describing the individual experiments we may briefly describe the general character of the results. The collodion emulsion employed is one, as we have said, of moderate rapidity, and requiring, under the circumstances of light, lens, and aperture, from twenty to thirty seconds' exposure, to give a perfect picture when used alone, when the exposures given to the compound films averaged about one second, the subject being an open view from the window in a good light. Under these conditions, it is obvious that the actual exposure received by the collodion portion of the compound films is quite insufficient to impress it except in the sky; but that is done easily, with the result that the sky always becomes visible within three or four seconds of the application of the developer. Yet in all instances, or nearly all, where the development of the compound film has been completed, a developed image has been visible upon the collodion film.

In order to prove this beyond doubt, we have gone to the trouble of stripping the collodion film from the gelatine when the precise nature of the deposit—image and veil—is palpable; but this trouble is not necessary, as, owing to the peculiarly metallic nature of the deposit on collodion, the image is perfectly visible as a positive, and that, taken in conjunction with the alteration in density produced where a portion of the collodion film is rubbed off, will show precisely how much work has been done by each film.

There is one point that may be noted in connexion with the rapid formation of the image upon the collodion film that has

some importance as bringing these experiments more into line with the Sandell plate than would otherwise seem to be the case. In the latter plate the first or outer film is the more sensitive, and therefore naturally develops first, the effect of that development passing on to the next film to modify it more or less. In the collodion-coated films, although the first or apparent film is by far the slower, it is the first acted upon by the developer, and in the same manner the action of this first development is transmitted to the underlying film, and produces most powerfully modifying effects, as we shall show.

Rather out of curiosity than as having a direct bearing on the rest of the experiments, a gelatine plate was exposed, and *subsequently* coated with collodion emulsion before development. According to the experiments of Captain Abney of sixteen or seventeen years ago, the collodion film should have shown an image; but, beyond a slight veil from over-development, no effect was produced upon the collodion whatever. A second plate, coated *before* exposure, and exposed for precisely the same time, gave an entirely different result; for, whereas in the first the sky was thinner in the coated portion than on a part of the plate that was left uncoated, owing to the resisting action of the collodion film, in the second plate the coated portion of the sky was very much the denser, though, on removing a strip of the collodion film, it became much thinner than the uncoated portion, proving that the greater part of the image was on the collodion.

With the normal exposure the general result was greater vigour, especially in the high lights; but, as the exposure was increased, the contrast became less increased, but general vigour, more especially in the half-tones, became the rule, that is, supposing the development to be carried out to its full extent; but, when the latter is stopped at an early stage, the results are very curious, for, if the collodion film be removed, the image of the high lights will be found to be completely in the collodion, the gelatine showing either completely clear glass or absolute reversal. That this is not due to over-exposure, or to any other cause but the bromine given off from the collodion emulsion film, can be proved by leaving a portion of the plate uncoated, when an entirely normal image will be formed. Moreover, if the development be stopped at the early stage on a portion of the plate, and completed on the rest, the first portion will show the reversal, the second a normal image.

Another plate was coated over a portion of each of its surfaces, back and front, with collodion emulsion, and exposed through the glass in order to show how much action the absorption of light by the collodion film had. The bare gelatine film exposed through the collodion, beyond its want of sharpness from diffusion, showed comparatively little difference from that where the collodion had not intervened. But the collodionised surface exhibited not the least action, for the denser gelatine film through which the light had to pass before it reached the collodion had altogether protected it from the light, and, except the usual slight veil from over-action of the developer, no image of any kind was seen.

The result of these experiments shows conclusively that each separate film exercises a very distinct action upon the others in development, and it seems probable that, the greater the difference in the sensitiveness, the greater will be the action set up. It seems also probable, but that remains for future proof, that, by so arranging the relative rapidities of the different films, a film absolutely proof against errors of exposure may be made, as claimed by Mr. Sandell.

GUMS AND GLUES.

It will be desirable in our purview of this subject not to omit some consideration of the so-called "British gum" or dextrine, a substance of most extensive employment for adhesive purposes. It can be purchased of many degrees of purity, but at its best is not available for photographic use on account of the uncertainty of its composition, and also the possibility of its containing deleterious substances introduced at the time of manufacture. Dextrine has been called torrified starch, and is, indeed, starch acted upon by heat, acids, or diastase, the amount of real dextrine, if any, actually contained in a sample of British gum being an undetermined quantity. Hence, looked at from all points of view, its use for any photographic work, at least where it would be brought into contact with silver compounds, should be deprecated; of course, for carbon or platinotype pictures, its introduction, either as glaze or mountant, would be productive of no ill effect, and for ordinary adhesive purposes it possesses advantages over both gum arabic and tragacanth. A little salicylic acid is recommended to be added to preserve it from mould. It may be interesting to give the formula for the use of dextrine as employed by the United States Government for coating postage stamps. It is made by mixing two parts (by weight) of dextrine, one of acetic acid (free of water), and one of alcohol.

When we come to discuss glues, the subject so expands that very many pages of this JOURNAL might easily be devoted to it; hence a few leading points most likely to be of use will be named. If we put the question, "What is glue?" a true answer would be very cumbrous, for it is not by any means a definite chemical compound, and its mechanical or physical aspects are as varied as possible. Briefly speaking, it is the dried jelly obtained by boiling certain animal substances in water for some time, and its colour varies from black when thick pieces are examined down to the patent straw. In the early days of the gelatine process, the use of glue or gelatine was hailed with acclamation as being a substance of so much more certain composition than pyroxyline; but, when it is considered that the jelly of which it is made is obtained from such widely different sources as we will specify in part, it would not be reasonable to expect constancy of chemical composition. Thus it is made from scraps of hides, tendons and intestines, tissues of bones, cartilages, horn, fishes swimming bladders, rabbit skins, parchment, old gloves, &c. When this jelly is required in the purest form, it is extracted from specially pure materials specially prepared; it is then dried, redissolved, and again chemically treated, and finally dried and put in form for the public. When it is required for dietetic or medical purposes the utmost care is taken, and the product is, when well selected, not at all likely to be injurious for any photographic purpose. At the time when there was more amateur gelatine plate-making than is now the case, most readers of the journals of the time had almost a surfeit of the properties of the various gelatines, British and foreign, and many brands grew to be well known. But at present the dry-plate makers may be presumed to know all about the matter, though there is no doubt of the advantage they gained from the discussions in the technical journals of the day. It was brought into prominence, for example, that the presence of a very minute quantity of grease had a very disturbing effect on the physical aspects of the film. It is not generally known that benzine and bisulphide of carbon are often employed in the preliminary treatment of bones before extracting the gelatine, so that all greasy matter is removed.

Most samples of gelatine of good quality are free from this

fault, and, as such articles as this are nothing if not practical, we may point out a few leading characteristics of a useful photographic glue. First, let us say that chemicals—bleaching agents and mineral acids—at one stage or another are so largely used in the manufacture of glues, that, though glues of most excellent purity are obtainable, a sample of so-called gelatine is far more likely to be pure and trustworthy for photographic use. One of the most important characteristics is the melting point. For sensitive tissue and many photo-mechanical purposes a gelatine with a high-melting point is to be preferred. As explanatory, we may remark that an ounce of glue, for example, may require a certain amount of water, at, say, a hundred degrees Fahrenheit, before it will be a firm jelly, while another sample, with the same weight of gelatine and water, will keep liquid until it is reduced to perhaps sixty or seventy degrees. How to ascertain the suitability of a glue for this purpose would involve considerable loss of time, though a glue expert could perhaps give a valuable opinion from personal knowledge. The photographer paying a good price for a pure gelatine, is able to obtain what he requires in this direction simply by asking for it, at the same time ensuring freedom from injurious chemicals and from incipient decomposition so likely to be ruinous to a silver photograph of whatever sort. In conclusion, let us say that, whatever price is given, or whatever brand is bought, a sample first brought into use should be, at any rate, tested with litmus paper to ensure its neutrality, too many of the examples of modern fading being undoubtedly due to the use of acid gums and glues.

Silver in Dry Plates.—Complaint is frequently made of the small amount of silver now put in dry plates. But it is consoling to know, according to a writer in the *Revue de Photographie*, that English manufacturers are quite as liberal with their silver as Continental makers. Out of about a score of brands tested, an English plate, the Sandell, stands first, and a Belgian and French the lowest. The former contained about three times the silver the latter did, other English brands being intermediate. We are, therefore, not so badly treated, after all, particularly when it is considered that, as a rule, foreign plates are dearer than English ones.

Discontent at the Chicago Exhibition.—Considerable dissatisfaction has been expressed as to the system upon which the awards are to be made, and it is stated, in a recent telegram, that the British, Belgian, French, German, Italian, and Russian commissioners have protested against it. Americans, it is said, would also prefer that the awards should be made by jurors, instead of, as proposed, upon the decision of a single expert, to be ratified upon report to a superior Board. In consequence of the adoption of the latter system, many exhibits will be withdrawn from competition. It is to be hoped that the judging of the photographs will not be relegated to a single individual. If it is, we may be certain of much discontent.

Chromo-photography.—*Apropos* of this subject. It is much to be wondered at that English photo-mechanical workers are giving so little, if any, attention to chromo-photography—that is, printing in colours from different matrices after the manner of chromo-lithography and the like. On the Continent excellent work in this direction is produced on a large scale, and it is proving highly remunerative; and, what is more, it meets with a ready sale here. Several systems are in vogue, including intaglio plates, the collotype process, and process blocks. For lack of enterprise much photo-mechanical work that might as well be done here goes abroad for execution. Just now there is an agitation about the Trade Marks Act, but we strongly suspect that "printed in Germany" will not deter English people from having the pictures if they are not to be had of equal merit of home production.

A Good Opinion of Himself.—A South African contemporary has the following interesting extract from the letter of a disappointed exhibitor:—"For cool, consummate assurance commend us to the letter in which ———, of Natal, declines the silver medal awarded him by the Executive of the Kimberley Exhibition. Here is the precious document: 'My reasons for so doing are, I do not acknowledge any superior in my profession in South Africa, and, after a careful and personal inspection at your Exhibition, I claim that my exhibits generally gave me *every right to first* position and honour, whether it was a gold or silver medal or diploma, my photographs being superior in *every* way to any others exhibited. The softness, delicacy of tone in detail, and high-class finish were altogether far above the work of any other exhibitor.' And the photographs are said not to have been such brilliant specimens, after all!"—which is what might naturally be expected.

Cheap Railway Tickets for Photographers.—Attempts have before now been made on the part of individual photographic societies to induce the railway companies to grant to parties of photographers or members of photographic societies a reduction on railway fares, just in the same way as a like kind of concession is given to anglers. Those attempts have, however, failed, possibly because the request for the rebates have not emanated from sufficiently representative sources. It has occurred to us that the Photographic Society of Great Britain, in conjunction with the fifty or so photographic societies now affiliated to it, might well approach the various railway companies on the matter, and we throw out the hint to the Affiliation Committee, of which there is at least one member who might put his railway experiences in the pursuit of the gentle art of angling at the service of photographers, in respect of obtaining them cheap fares on their outings.

Royal Society Soirée.—At the *soirée* last week, photography was well to the fore, it being utilised in somewhat novel directions. In the display there was a series of photographs of swede turnip plants grown in rotation, with mineral materials alone, and with mixed mineral and nitrogenous manures, to illustrate that it is a fallacy to suppose that root crops derive any great amount of their nitrogen from the atmosphere through their extended leaf surface. There was also a valuable contribution to the knowledge of the minute formation of rock structures by micro-organisms, in the form of a collection of photo-micrographs, by Mr. Wethered, of transparent slices of various rocks. Astronomical photography, was, of course, well represented in a collection of photographs of nebulæ and star clusters, taken by Mr. Roberts with a twenty-inch reflector; also by some photographs of stellar spectra, by Mr. Lockyer. Not only is photography largely used in science, but also in art, as witness some of the paintings to be seen in the multitudinous exhibitions now open.

More Photography in Colours.—This time it is, according to an evening contemporary, the Paris Photographic Club that "has apparently solved the mystery of coloured photography." According to this authority, "the members have just exhibited photographs giving all the colours of the original objects." Amongst these are enumerated a bouquet, with red, violet, green, blue, and other colours, in their various tints;" another, "a corner of a park, with a blue sky, gravelled avenues, and trampled soil." "Then there was a series of coloured placards in all their glaring hues, and next a photograph of a Japanese screen." In concluding the announcement of the great achievement, our contemporary adds: "As, however, with the early Daguerreotypes, each photograph is unique. How to obtain proofs on paper has yet to be discovered. Nearly half an hour's pose is also at present required, which would over-tax the

patience of any sitter." The continual prominence of colour photography given by the lay press naturally leads the non-technical public to infer that photography in natural colours is *un fait accompli:* hence so many applications to professional photographers for portraits by the new process in natural colours, and the scepticism of the would-be sitter when they are told the thing is quite impossible.

The Eclipse Photographs.—Highly successful as have been the two English expeditions, there now appears to have been a slight hitch in the photographic department of the one to the West Coast. Mr. A. Fowler says in a report that the English signal of the commencement of totality—the discharge of a pistol—was not given until ten seconds after the French one, which caused him "to lose three exposures during totality, and reduced the number of Sergeant Kearney's photographs from twelve to ten." In reply to this, Mr. T. E. Thorpe, in a letter to a daily contemporary a few days ago, says, although he did not hear the French signal himself, that another observer estimates it at two seconds only, and adds, "It is possible, therefore, that Mr. Fowler's estimate of ten seconds may not only have been erroneous, in consequence of the known difficulty of accurately estimating a time interval during the exciting conditions of an eclipse, but may also have arisen from the fact that the actual eclipse was shorter than the calculated one." It can readily be understood, with the months of preparation and anticipation, and the thousands of miles travelled to execute 243 seconds'—French calculation two seconds less—work, that there would be some little excitement, subdued though it might be, during that brief period. The thing can be better imagined than described.

EXHIBITION OF THE PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

The Exhibition of the Society for 1893 will be held in the Gallery of the Royal Society of Painters in Water Colours, 5A, Pall Mall East, London, S.W.

The Exhibition will be inaugurated by a *conversazione*, open to members and their friends and exhibitors, at eight p.m., on Saturday evening, September 23.

The Exhibition will remain open daily (Sundays excepted) from Monday, September 25, until Wednesday, November 15. Admission (from ten a.m. till five p.m.), one shilling. It will also be open on Monday, Wednesday, and Saturday evenings, when lantern slides will be shown; admission (from seven to ten p.m.), sixpence.

Members have free admission at any time. They may receive twenty day and ten evening tickets for their friends, and can purchase additional tickets at half-price. Members of affiliated Societies can purchase tickets at half-price of their respective Secretaries.

Medals will be placed at the disposal of the Judges for the artistic, scientific, and technical excellence of photographs, lantern slides, and transparencies, and for apparatus.

The undermentioned gentlemen have been elected by the members of the Society to act as Judges, and have consented to serve:—Mr. P. H. Emerson, B.A., M.B. (Cantab), Colonel J. Gale, Messrs. F. Hollyer, F. M. Sutcliffe, and J. B. B. Wellington. Scientific experts: Messrs. Chapman Jones, F.I.C., F.C.S., and Andrew Pringle, F.R.M.S. The Judges will select the exhibits before the Hanging Committee begin their duties.

Blank entry forms and any further information respecting the Exhibition, apparatus, and lantern slides, also nomination forms for membership, can be obtained from the Assistant Secretary, P. S. G. B., 50, Great Russell-street, London, W.C.

ARE GELATINO-CHLORIDE PRINTS PERMANENT?

When gelatine was first proposed as a substitute for albumen in the preparation of printing-out paper, we said that on theoretical grounds there was no reason why gelatine should not be made to supersede the other entirely. On what grounds it was at one time stated that it would be likely to set up a decomposition of the silver image we never could learn, beyond that it was a mere surmise.

We could better understand the good old conservative argument that, as albumen had stood the test of many years' experience, it was not well that an old friend should be discarded in favour of an interloper. Well, gelatine has now passed its novitiate, and has proved to be all that we anticipated for it. We possess the first, or among the first, photographs that have been produced on this substance, and can attest their excellence as regards their unfading properties.

As corroborative of this, we have just been shown the contents of a show-case which has been exposed outside a photographer's studio in Loughborough since May, 1892, and on which the light has been acting throughout the year, with such effect that the plush, originally of a maroon colour, which formed the background base on which the specimens were mounted, has entirely succumbed to the exposure except where covered by the prints—those known as "P.O.P." These prints show not the slightest indication of having been affected by sun or weather, notwithstanding their fairly long exposure to this crucial test.

INTENSIFICATION OF GELATINE PRINTS.

The *Photographisches Archiv* suggests the intensification of gelatine prints by means of physical development. It is unimportant whether the prints have been toned or not, but it is necessary that all traces of the fixing agent should have been removed. Briefly, the prints may be intensified in the same way as gelatine negatives.

A print on aristotype paper, fixed and dried, is placed in a solution containing hydroquinone, tartaric acid, and silver nitrate. The proportions of these substances can be varied without inconvenience, except that there should be a quantity of the acid sufficient to prevent any reaction between the hydroquinone and the silver. A few drops of ammonia are added to the solution to neutralise it. This will effect a slight deposition of silver on the image, which may be increased by the addition of more ammonia to the solution.

Instead of hydroquinone other developing agents may be employed. It is essential that the print before the solution is applied should have its gelatine surface flooded with water, otherwise the silver has a tendency to be deposited in the gelatine on a powdery form instead of acting as an intensifier of the image.

NOTES ON VARIOUS SUBJECTS.

Black Tones on Rapid Bromide Paper.

The difficulty mentioned by "A. J." in the last number, of getting as good blacks on rapid bromide paper as on slow, is one that I have experienced and surmounted, and therefore, perhaps, a few lines on the subject may not be out of place. Unlike Mr. Pike, who writes in your last issue, I have not made thousands of bromide prints and used hundreds of gallons of iron developer, but I have had a good deal of practical experience of bromide printing, and it confirms me in the opinion that for development on the slow paper ferrous oxalate still has a future before it.

"A. J." does not say the developer he employs with the rapid paper; but, assuming it to be ferrous oxalate, I find that by acidifying the potash and iron stock solutions with oxalic acid and sulphuric acid respectively, instead of, as many recommend, acetic acid, the mildly restraining powers of which I have observed have a marked effect on greying the shadows, a slight improvement in the tone results.

Again, I do not use an unnecessary quantity of solution, but, say, for a 12 × 10, about three ounces, as in my experience of both positive and negative work an excessive quantity of solution leads to loss of contrast.

A hint as to exposure. If "A. J." uses the same light for the rapid paper as for the slow, let him diminish the volume of light by a stop rather than simply shorten the exposure, or, for contact work, let him double the distance between flame and illuminant. For correct exposures I find the proportion of 3 : 1 answer perfectly. Some year or two back I experimented with ammonia-sulphate of iron as a substitute for the ferrous sulphate, and found that it assisted to produce tones of a deep velvety black without any tendency to greyness or rustiness. Of course, I am referring to a slow paper.

If "A. J." is using amidol, hydroquinone, or eikonogen, or a mixture of the two latter (which I have used with great success), I would

recommend him to be as sparing as possible in the use of sulphite, the effect of a large quantity of which seems to me to produce images having a combination of three undesirable qualities—flatness, greyness, and hardness. Of the fixed alkalies, carbonate of soda in my hands promotes softness and a good colour, and a sparing use of bromide will prevent the greening of the black, as the Irishman would say, which can so often be traced to its use.

Another plan of a remedial character for giving good blacks to bromide prints is that mentioned by you, namely, the immersion of the washed unfixed print in a combined toning and fixing bath. From practical experience I can endorse your recommendation to "A. J." to try this useful dodge. It is applicable to either slow or rapid bromide paper, and for those who like rich platinum-like pigment deposits (I am one of those myself) I would recommend that for this purpose the fixing bath be permanently enriched by the addition of a little alkaline gold solution (*q. s.*).

The Concentric Lens.

I was interested at reading Mr. F. H. Burton's comments on the letter of Mr. W. J. Stillmau, in which the latter gentleman states that, with the Concentric lens in his possession, he obtains as good definition with *f*-16 as with *f*-64. I, too, have one of the Concentric lenses, fitted with rotating stops from *f*-16 to *f*-32, so that I am unable to speak as to the quality of definition with the small aperture with which Mr. Stillman's lens has been fitted, but in other respects my experience tallies very closely with that of Mr. Burton. The single object with which I should use *f*-16 would be for obtaining landscapes in which the acme of definition was not required. At that aperture I find the lens give a degree of sharpness which, to slightly traverse Mr. Burton's statement, would only spoil such negatives as those of maps, or of subjects with very fine lines.

Mr. Burton appears to hint at having focussed with *f*-22 and exposed with *f*-16. This, in my experience, would give no better definition than by focussing with, and using, *f*-16 alone, if as good. Indeed, I tested the point by practical trial, and was surprised at the extent at which the focus was altered. Like Mr. Burton, I am an unknown amateur, but I appreciate a lens giving a flat field, even illumination, and fine definition. To obtain such with the Concentric I follow one simple rule, which I recommend to others who have the lens, and that is, to neglect *f*-16 for critically sharp work, and *focus with the stop you are going to expose by*. The principal point Mr. Burton touched upon, namely, that the flatness of field of the Concentric enables the camera front to be lifted or lowered without impairing definition at the edges, is an important one, which should be noted by architectural photographers.

A Suggested Backing Medium.

The application of such a backing medium as a caramel mixture to glass plates, and, indeed, backing generally, involves more trouble than the ordinary amateur cares to expend. There is a species of ever moist rubber solution, I think it is, which, when spread upon a cardboard support, I have used for attaching large films to when exposing such in the camera, and it has occurred to me that possibly the use of such cards, coated with the rubber medium in question, might answer for the purpose, especially if it proved to be readily detachable from the glass. I presume perfect optical contact could be obtained. The coated cards, of course, could be used again and again.

J. R. Hopwood, Ph.D.

IS THE PRESENT CONSTRUCTION OF PHOTOGRAPHIC STUDIOS WRONG IN PRINCIPLE?

[London and Provincial Photographic Association.]

In the construction of photographic studios, whenever possible, the chief light is obtained from the north, and the studio is principally glazed on the northern side: by this method direct sunlight is cut off from the sitter and steady illumination is obtained. Hence the light most used by photographers is that reflected by the particles floating in the air, for, if no particles were there to throw back the light of the sun, we should have the black sky sometimes witnessed in the Alps when the air is extremely dry, and then might almost as well use the light reflected by an unglazed blackboard. It is the same with the sea. Within a few miles of the shore we get different shades of green which grow clearer as the land is left behind; but farther out the sea appears of a dark indigo colour, because of the scarcity of floating particles to reflect light to the eye. If, then, Professor Tyndall's plan be tried of putting a particle of large size into the sea, by flinging a white dinner plate overboard, that particle reflects green light to the eye as it sinks, and would do the same were it broken into myriads of smaller pieces.

Before coming to the practical part of the subject, it is necessary to consider the nature of our reflecting screen in the northern sky. The floating particles in the air of towns consist of minute drops of water, innumerable spores of small seeds, greasy coal smoke, fragments of dried horse dung, influenza and other germs, and dirt of endless varieties, including dust from meteoric stones rendered incandescent by friction when entering our atmosphere at planetary velocities. These solid particles favour the precipitation of water, so also in a still greater degree does the sulphurous acid given off from our coal fires. These aggregated varieties of floating dirt are to some extent rendered visible when a beam of sunshine is reflected by them, so as to mark its track when the beam enters a dark cellar through a hole in a shutter; we also see them floating in the light coming from the projection lenses of the magic lantern, and we swallow them wholesale with every breath of air which we take into our lungs. These dirty particles, then, form our reflecting screen in the sky to the north of the studio.

Sometimes we get a better reflecting screen, consequently more light in the studio, when cumulus or other clouds in the north are illuminated by the sun. This improvement is but partial, because the clouds present also portions of their shadow sides, and do not cover the whole of the northern area in view.

The question I now wish to raise among those present who know so much more about glass studios than myself, who am not the happy possessor of one of them, is whether it would not be better to abolish the floating dirt reflector and diffuser—to abolish even the floating cloud, and to provide a cloud of our own which shall be always there, which shall present to the eye no shadow worth mentioning, and shall be of a pure white. I mean a whitewashed wall, for experience with the lantern has already demonstrated that, as a dead-white reflector and diffuser of light, nothing excels common whitewash.

Supposing these ideas to be correct, the result is that we shall have to build studios with a southern aspect, glazed high up on their southern sides. The accompanying diagram will show what is intended, for verbal descriptions of mechanically constructed objects are liable to confuse both listeners and readers, unless illustrated by drawings to show exactly what is meant. The suggested studios will be high in proportion to their breadth; for instance, let A B be the end of a little studio twelve feet wide, then the whitewashed wall, W B, say, of an adjoining building should perhaps be twenty-four feet high. The southern side of the studio is boarded up, except for special purposes, to a height, A K, of, say, ten to twelve feet all along the side, and the glazed portions are at K N W. Thus, the rays of the sun entering the studio in the direction indicated by the arrows fall upon our artificial cloud or whitewashed wall, W B, which wall under the circumstances then gives the chief light for the illumination of the sitter at H.

Into minor details it is not necessary to enter. Of course, the studio, as at present, will have to be boarded at the opposite ends, also along the roof, N W, and the side, N K, for a short distance from the ends. Blinds for regulating the major light should be of neutral or dark tint, and movable along the face of the wall, W B; blinds also at the glazed portion of the studio will be necessary. Incidentally, it may be pointed out that, if A be a garden wall with a street on the southern side at R, that wall can be raised to K, and a good studio built at A B without enabling boys in the street to make remarks for the calming of the minds of the sitters, for street boys not being ten or twelve feet high in these latitudes will be unable to see into the studio. It would be difficult to build upon the ground a good present-day studio if there were a brick wall and street to the south and a high house to the north. If the glazed roof had the pitch K W, the suggested studio of the future might do nearly as well, and would shoot off snow capitally. This kind of lighting might also be obtained

by building a studio of the usual Noah's ark shape, and taking the chief working light from the whitewashed side of a dwelling-house to the north; but, in the preferable lean-to studio pictured, a lower roof and a whitewashed house-wall outside and above it would not give as good lighting, because the light from the outside wall would fall upon the glass roof at such a grazing angle as to be largely reflected off outside without entering the studio at all. The boarded side, K A, might be made of large sliding partitions, to be pushed back into the two ends of the studio, and then expose a glazed surface so as to take direct light in from the south upon those winter days during which the photographer is glad of any light he can get.

Peradventure those portrait photographers, who have taken special notice of the extent to which exposures are shortened when the northern sky is filled with clouds illuminated by the sun, may be able to make some kind of guess as to the extent to which studios of the kind now suggested may expedite exposures, and lengthen the average photographic working day, remembering also that the whitewashed wall presents a more uniform white surface than do masses of cloud. In the remarkable weather we have had for the last six weeks of almost unbroken sunshine, I have noticed that there have been scarcely any bright clouds, at least within a circle of a mile or two of the Crystal Palace, for, being engaged in some new investigations in relation to gelatine emulsions, I have specially noticed the absence of clouds when I was frequently out of doors trying plates. Had portrait photographers had a white wall to the north, instead of the grey haze of an average cloudless London sky, they would have received even better light in the studio than during April last. Some comparative experiments on the light from a northern sky and the light from a northern whitewashed wall, made with the sensitometer of Mr. J. B. Spurge, of London, which is one of the most accurate standard instruments we possess in photography, would be exceedingly useful. They should extend over a considerable length of time, and be made under different conditions of weather and elevation of the sun.

Having raised the major question before you—who know so much more practically about glass studios than myself—whether photographic glass-houses should not be glazed on the south instead of the north, and have an artificial reflector and diffuser, it is not desirable to-night to go into minor details about studios. Many of those in existence are too short; there are reasons in portraiture as in landscape work why more pleasing results can be obtained by using lenses of longer focus than those usually employed; in fact, if a photographer had light enough, and a studio long enough, there is much to be said in favour of his using single combination lenses of long focus for portraiture. Supposing the studio to be built of glass and wood, there is much to be said in favour of making its walls and roof double with an air space between: it would be much warmer in winter and would economise fuel. Some studios are built in this way in St. Petersburg. There are considerable advantages in the use of iron instead of wooden frames for glazing. The developing room should not be a small death-trap, but, when possible, a good-sized room in the adjoining dwelling-house, and fitted up as a laboratory. When, however, it is built as part of the studio, it should be a large room at the opposite end to that occupied by the sitter, and the door should so open that the camera can be used from inside the developing room, when it is desirable to place it at an exceptionally long distance from the person to be photographed. All these, however, are matters which have been previously publicly considered; but the major problem mooted in this paper is new so far as I know, and I have recently made some search into the literature relating to glass studios. In photography it is dangerous to say that anything is new. Whether the problem before us is or is not new matters little so long as in the discussion it brings forth from your stores of knowledge some information which will be useful to the photographer.

W. H. Harrison.

PHOTOGRAPHY WITHOUT AN OBJECTIVE.

The great advance which has taken place in the manufacture of sensitised films, and the enormous increase in their sensibility to light energy has now brought photography without an objective within the sphere of practical work, and at this time it may prove interesting to note the real position of this method for obtaining photographic images.

It will be found that the present literature on the subject is very meagre, and that the accounts of the experiments are so conflicting as to be unreliable.

Experimenters have found that, with large apertures, some positions of the sensitised recipient surface in the camera are better than others, and formulæ have been published, and theories have been propounded, on account of this fact.

The best known formulæ are as follows:—Lord Rayleigh gives $f=(2r^2/\lambda)$ where f is the least distance of good definition, r the radius of the aperture, λ the wave length of G=0·000017 inch.

A Frenchman, Captain Colson, also derives a constant from a wave-length; the constant is 0·00081 on the metric scale, and his formula, $d^2=0{\cdot}00081$ F, where d is the diameter of the aperture and F the least distance of good definition. This formula means that nine-tenths of a millimetre aperture has the least distance of good definition at one metre distance.

Mr. Dallmeyer gives the formula $b=\frac{r^2}{\lambda}$ where b is the least distance in inches for good definition, and λ the wave-length G=0·000017 inch, and r the radius of the aperture.

Captain Abney gives $2\sqrt{\lambda b}$, or, in other terms, the square root of the distance from the hole, multiplied by the constant ·008, gives the diameter in inches of the aperture which will give the best definition.

The theory propounded by both Captain Colson and Captain Abney is the same; viz., that the wave-phase from the edge first meets the wave from the centre of the aperture in equal phase at the focus; the misfortune is, that the formulæ based on that theory by these two gentlemen are not in accord, as the latter gives the focus about one-half that of the former.

Another view held by some experimenters is, that if with larger apertures a shorter focus be taken than the one given by their formula, then each point of the object makes an image on the recipient surface, which has the same shape as the aperture. What I have found is as follows:—

1. All large apertures give soft pictures; small apertures, sharp pictures, regardless of the focus employed. An aperture of one-thirtieth of an inch will give just as good a picture at thirty-two inches, at sixteen inches, at eight inches, at four inches, at two inches focus, and where discs appear in the negative they have much more to do with the illumination of the object than they have to do with the short focus, as they appear like cone shadows. An aperture of one-three-hundredth of an inch will give a sharp image at any focus.

2. The photographic energy passing through an aperture is eight times greater than passes through a lens having a stop the same size as the aperture.

3. The exposure required for ordinary plates can be worked out from the datum, that where the focus is sixty-four times the diameter of the aperture the time is one second.

4. The experimental evidence is rather in favour of there being an infinite number of foci through an aperture; but, if the large apertures have distinct foci, it almost follows that the small apertures must have the same.

5. Apertures above three-sixteenths of an inch in diameter do not produce photographic images in a camera; an aperture of one-eighth of an inch appears to be in the border-land between holes which will produce images and those which will not do so.

6. The distance of the object from the aperture does not appear to have any influence on the definition or the focus.

The only theory which will embrace these experiments is the supposition that when the light energy from the object grazes the edge of a suitable aperture, then the whole vibrations undergo a change of direction, because the edge of the hole becomes a new source of vibration. In other words, the infinite number of molecules on the edge of the aperture take up the vibrations, and they form new centres, from which the vibrations of the light are transmitted on to the recipient surface in the camera.

It is not difficult to imagine the result which will follow this idea. The edge of the hole for all practical purposes becomes the object, as it is imagined to be the source from which all ethereal vibrations emanate to the sensitive plate. If the longest focus could be ascertained by direct experiment, it would follow as a consequence that another focus will be found at $\frac{1}{2}$, $\frac{1}{3}$, $\frac{1}{4}$, $\frac{1}{5}$, and so on of that distance. As the number of axes of vibration are considered to be infinite, on that account the number of foci may also be considered infinite. At long distances the foci are remote one from the other, but as the distance between the plate and the aperture is approached, the foci become nearer and nearer to each other, until the point is reached where the foci follow each other so closely as to escape observation. If there is any truth in this theory, it is evident the value of this method of photography must depend on the accuracy with which the edge of the hole is drilled and upon its perfect circular form. Heretofore little care has been bestowed on apertures, and the designs of most are faulty. For example, it would be almost impossible to get a perfect image through a cylindrical or conical hole, the liability of disturbances from other surfaces or edges is too great. As our appliances for drilling holes is improved, the time may be reached when a perfectly circular aperture of one-thousandth of an inch

may be made, and a hole that size would become the best optical contrivance for enlargements.

The skilful use of apertures will enable artists to select any description of texture for their subjects, and the skilful use of foci any system of illuminating the field of their pictures.

To give a practical illustration of the views expressed in this paper, the writer has put in the market a quarter-plate camera fitted with two accurately drilled holes, the one aperture to give a soft picture on ordinary plates in one second, the other a sharp picture in sixteen seconds; and yet the focus is only two inches for both apertures. The result of this contrivance is that now, instead of using a magazine camera or dark slides, all that has to be done is to pack six, twelve, eighteen, or twenty-four cameras into a satchel, and to use a separate camera for each picture. The cameras are so light that nine cameras only weigh two pounds, and twelve cameras pack into the ordinary satchel for a camera. There is no machinery to go wrong, and the plates are in no way disturbed until they are fit to be developed in the dark room.

The only requirement these cameras cannot yet fulfil is instantaneous pictures; the time, however, may arise when plates are so sensitive that even instantaneous images will be within the reach of cameras without an objective. ARCHD. C. PONTON.

PRACTICAL REMARKS ON PHOTOGRAPHING DIFFICULT INTERIORS.

I.

PERHAPS there is no class of subject that offers so many and widely different conditions in respect of photography as interiors, for between the well-lighted drawing-room or public hall, and dark vault where little, and indeed it frequently happens, not a ray of daylight penetrates, there is a very wide difference indeed.

The remarks which I am about to offer are the outcome of much close study and practical experience derived from an intimate association with the various classes of subjects I shall refer to, and embrace cases where it was only possible to use artificial light on account of the entire absence of light.

One of the most commonly met with kind of interiors, especially on the part of amateur workers, is that of an ordinary drawing-room or other similar apartment in a private house. With many workers the photography of such is looked upon as an undertaking entailing little or no difficulty; it is so easy to run the blinds to the top of the window, place the camera in the position that will enable the utmost amount of view to be embodied in the picture, expose long enough, and there you have it. In nearly nine cases out of ten these subjects are photographed without due regard being given to the best method of lighting the room.

An idea prevails to a very large extent that it is necessary to flood the room with the utmost amount of light possible. Therefore the blinds are run up to their utmost extent, and the time of day selected when the greatest amount of direct light enters the apartment, there being no thought given to the employment of what is really the *proper quality* of light to employ.

I do not wish it understood that I am in any way advocating the employment of a poor or deficient quantity of light; quite the reverse. The more light any one can command, the better, but it must be of the proper *quality*, and this, to a very large extent, is a bright diffused light.

A very interesting operation for any one desirous of experimenting in this class of photography is the following:—Arrange any well-lighted room, and expose a plate upon it with the blinds run up to the top, so that the utmost amount of light floods the apartment, develop, and print the result. Afterwards expose another plate, with this difference, that thin muslin blinds are hung over the entire window or windows, so that every ray of light entering the room passes through the muslin; expose, develop, print, and mark the difference in the results obtained. It certainly will be instructive to any one who has not previously studied or become aware of the difference in results obtained by diffused light.

In some cases it may be desirous to allow a short duration of direct light to enter the room during the exposure, so as to gain a certain amount of force in the high lights, but this is easily accomplished by capping and uncapping the lens, and removing the muslin from the window a short time previous to the conclusion of the exposure. The first essential, however, is the employment of the proper quality and quantity of light.

Another error frequently seen in this kind of work is the overcrowding of too many articles of furniture into the room. I often think were as much pains taken to see *how much could be done without* as is generally taken to cram into the room, better results would be obtained. In this there is a very wide field for the exercise of good if indeed not artistic, taste, and it is a part of the undertaking that always enlists the attention of the ladies of a household, for they invariably like to be consulted in such matters. As a rule, however, I think it will be found they nearly all fall into this same error of crowding too many ornaments and other articles of furniture into the room; this may not be so very noticeable to the eye at the time when photographing, but after the negative is printed it becomes more apparent in the picture, and then will be seen how much better it would have been had such and such an article not been here and there, and so forth, the result being, try again.

Next to taking a picture of one's drawing-room, the amateur worker will be found to have a weakness for securing a picture of the interior of his church, and to a very great extent the remarks I have made regarding the employment of the proper quality of light will apply to this class of subject also, only with this difference, that it is almost impossible to resort to any means of acquiring an artificial diffusion of light, and hence exposures are made very probably with the sun's rays streaming through some of the windows, the results being by no means as good as they might be. Let any one carefully note the great difference in appearance which the interior of such a building as a church presents under the following aspects, viz., when no sunlight enters, but the sky is full of white fleecy clouds, and then note the change that suddenly arises when the sun shines strongly in through the windows.

In the former case, with a bright, diffused sky lighting up the interior, every minute detail will be observed even in what is considered the dark corners of the edifice; the moment, however, the sunlight comes streaming in, all this suddenly changes, the dark corners appear ten times darker, and much that was noticeable to the eye before has now disappeared, and nothing but violent contrasts prevail.

This is a state of matters that any one can easily see without much trouble, and it stands to reason therefore that sunlight should be avoided, and such times chosen for doing the work when the sky is full of bright, fleecy clouds; and, should the sun come out during the exposure, the lens should be shut off by placing in the cap until it is obscured again with clouds. If we cannot in such cases assist matters by artificial diffusion, we can at least by the exercise of untiring patience bring to our aid Nature's own method of diffusing light.

In landscape and many other outdoor branches of photography sunlight is a *sine-quâ non*, but for interior work the photographers' sheet-anchor is undoubtedly a bright diffused light.

Passing from such subjects as well-lighted rooms, churches, and public edifices, we are often brought face to face with interiors of a totally different kind, such as badly or indifferently lighted workshops, engine-shops, ships' cabins, and such like, where the amount of light at command is very small and gives no end of trouble.

Quite recently I have taken a series of views of the interior of the magnificent new Atlantic greyhound, the *Campania*, and can speak from experience of the difficulty attending the getting of good results in confined and cramped positions, and in many instances where the subjects are lighted by means of port lights only. Nevertheless, by the exercise of thought and patience, much that at first sight appears an almost insurmountable difficulty will to a great extent be overcome.

In engine shops there is generally a need for some preliminary arrangements being made so as to secure the best results. These, most likely, will embrace the covering up of some unwelcome window, and in other cases the colouring of some parts of the machinery with a suitable tint, also the toning down of any very bright portions of the engine or machine that is being photographed. Although, in one sense, machinery does not come under the category of interior work, still in numerous cases operators are called upon to photograph engines, machines, and other heavy portions of work in the positions they occupy before being taken to pieces or removed.

In cases where such are placed in close proximity to a large window or sliding door, a very great difference will be experienced in the time of exposure necessary as against the time taken of an entire interior. I have known cases where the whole interior required a day's exposure, and a machine placed somewhat close to a large side window of the shop was well exposed in ten minutes. There is a very wide range for thought in this kind of work, and a practical experience of this class of photography is of great value, differing as it does in a great measure from ordinary studio work.

From badly lighted interiors to interiors where no daylight enters at all is the next step down the ladder, and in this class of work may be mentioned bonded stores, warehouses situated under railway arches, underground workings, &c. T. N. ARMSTRONG.

SELECTIONS.

[Holborn Camera Club.]

The title I have chosen for my paper seems to me to permit a little wandering about from subject to subject, without inferring an obligation to limit myself to any particular thing, or to bore you by harping on some process or other that would of necessity be more or less stale.

My first selection is to touch on the errors of omission and commission often indulged in by photographers, not from the lofty standpoint of assumed perfection, but rather from that of one who has muddled and messed about in the sloughs of photographic despair, sometimes getting out, but sometimes sticking fast until the friendly help of a brother photographer has landed him on solid ground. There s no disputing that most of us are, or fancy we are, artistically inclined, or we should not select photography for a hobby, an amusement in which genuine success *chiefly* depends on artistic ability. Whether we become successful photographers or not is determined by the amount of scrupulous attention we give to trifling details, *guided by artistic instinct*, or whether we look at the thing as only an interesting mechanico-chemical process, whose ultimate result is a so-called pretty-looking negative. There is a gulf between the two ultimates too wide to be bridged over.

Just recently an energetic controversialist has denied our right to the name of artist, and repudiates in big letters the very idea of photography being an art, fine or otherwise. For the sake of argument, we will assume that photography is an art, and that any of us who succeed in making good pictures, however artfully, are artists. This brings me to talk about the things we do, and those we leave undone in this connexion. Since I had the pleasure of last addressing you, I have had the opportunity of seeing much photography by those who take it up for amusement rather than profit, and must confess I am surprised at the small percentage of those who make the *best* of their negatives.

Judicious Doctoring of Negatives.

Many very clever manipulators are content to print their negatives *just as they come*, and it is not till one puts the finger on such-and-such effects, and asks, "Why this?" that they perceive there might be some improvement in the direction indicated. The two most striking delinquencies are under-exposure and blank spaces, where there ought to be clouds. The universal desire for rapidity in securing representations of moving objects induces under-exposure and all the evils that follow in its train. *An under-exposed negative will never make a perfect print*, although very often much better results might be secured by judicious doctoring than by printing the negative in its untouched condition. Of the various methods of doing so, some are as follows:—In the first place, make a rough print (which, by the bye, is a much better guide than the negative itself, which is apt to give wrong ideas of its printing capacity), and notice especially those parts in which increased or reduced density would be an improvement, or where masses of shade are broken up by small points of light that would be much better absent.

The method to be chosen for treatment depends entirely on the subject. The proof may show that the high lights *throughout* are a little too dense; this indicates treatment with a weak reducing agent in the bath form, or too weak, requiring additional density, or it may show only portions that would be better for reduction, made by local action chemically or mechanically by rubbing down with spirit. The objectionable points of light may be removed by a sharp-pointed knife. We now cover the back of the negative with tracing paper—"papier minéral" is the best—cutting away the paper over the too dense portions, and working on the darker parts with lead pencil, and strengthening the lights on them where it would be an advantage—sometimes merely rubbing a little black lead over front or back with the finger's end—will be found useful to generally reduce a shadow. I have now alluded to some of the different means in general use for improving a negative. An apparently good negative might not probably require all this doing to it, but one or other of the plans might effect an improvement *on nearly all the negatives that are made*. Sometimes a mere touch or two of pencil on the highest lights on the film side will make a considerable addition to the brilliancy and scale of tone in the picture, and sometimes covering up one part, whilst another continues printing, will work wonders.

A Word or Two about Papers.

Now a word or two about papers. I find negatives that are unexceptionally good for albumen-paper printing *much* too strong for the best results on the gelatino-chloride papers, that seem to be fast superseding our old acquaintance, albumen. Of what kind a negative should be as regards density is undoubtedly regulated by the surface upon which it is intended to print it. With the gelatino-chloride papers our old-fashioned ideas of a good negative seem to be somewhat upset, a very much flatter, thinner *cliché* being required. One that with ordinary silver printing on albumen paper would only produce a poor, insipid result seems to be most suitable. With gelatine dry plates there is, undoubtedly, a large percentage of flat, muddy-looking negatives made, quite useless for producing *good* results by the old processes, but with the new they make excellent pictures. The print I now pass round was from a flat, over-exposed-looking negative, and one I should certainly have discarded for albumen-paper printing, but which comes out very fair on the gelatine paper, so much so that the question is, Ought we to make our negatives to suit the new paper as a regular thing, and at once and for all give up the standard of "wet-plate negative" as the *ne plus ultra* of perfection? At any rate gelatine paper puts *pretty* negatives at a discount. If no particular faults develop in this kind of paper by keeping (and I see no reason why there should), we may congratulate ourselves on a very valuable addition to our material, as by its means we certainly secure a better exposition of the delicate detail of a negative than was possible with the best albumenised paper, unless it was enamelled with collodion and gelatine afterwards, and even there I think the new paper has an advantage. I have experienced some little difficulty in mounting the prints when a fairly *large* batch has to be dealt with. I, possibly, have not found the best way of setting about it, not having had much practice with this class of paper. With all the collodion-surfaced papers I have tried there is considerable trouble to manipulate; their curling propensities, when wetted, are simply abominable. They may, however, vary somewhat, according to their manufacture. Perhaps they do, but the samples I happen to have tried as soon as they are wetted turn from prints into cylinders, and keep so unless forcibly held open, so that toning or working with any degree of satisfaction is out of the question. A good collodio-chloride print should, I imagine, be most permanent, if we may hazard an opinion from the behaviour of other collodion surfaces, although from time to time doubts have been expressed to the contrary. Gelatine papers do not curl, but suffer all the treatment of toning, fixing, and washing with the greatest pliability. Whether an abnormally hot summer will introduce difficulties remains to be proved.

Spectacle Lenses.

The last time I had the pleasure of addressing you, the topic was, I believe, on spectacle lenses as used for photography. Since then I have constructed several other combinations of varying foci, and really, for all ordinary work not necessitating rapidity, nothing could be better. Depth of definition, rectilinearity of lines, and covering power seem, as far as I can judge, equal to any orthodox lens. In spectacle combinations intended for wide-angle work I fancy there is less apparent distortion than in the orthodox form. Why I cannot say. Take, for example, cylindrical objects; there seems to be less disposition to the oval form if situated at the margin of the plate; not that it is quite absent, but that there is less of it; also, objects in the near foreground and near to the lens are not rendered so large *in proportion* to the rest of the picture. These prints I pass round will illustrate my meaning. In the interiors the nearest objects shown were not more than five measured feet away from the lens, and in the church view the tomb in the foreground was about nine or ten feet away. Now, with an ordinary wide-angle lens in the same position, I fancy the perspective would appear much more violent, also the lines forming the upper angle of the tower would be more acute, for the camera was tilted, the lens pushed up high as it would go, and swing back used. Still, with all this, the picture has to me more the effect of being taken with a narrow-angle lens removed to a greater distance. This, I must confess, is not at all a scientific or convincing method of argument; but, as I had no other lens at hand to test the accuracy of my impressions, I give you them for what they are worth. The combination was five and a half inches focus on a whole plate, with a stop one-sixteenth of an inch in diameter, so you can draw your own conclusions.

The exposure was about ten or twelve seconds; but, in the matter of exposures, I am somewhat of an impressionist, that is, I trust to judgment rather than giving a definite number of seconds, for, with regard to outdoor work, with all its varying lights, I often do not quite decide about an exposure until it is actually taking place, and then may elect to slightly lengthen or curtail my previous judgment, according to circumstances. I have found a one-sixteenth of an inch stop the best working stop for *all* combinations of spectacle lenses, although, with the long-focus ones, a tenth of an inch is useful. Twelve inches focus and one-sixteenth stop makes the working aperture *f*-192. This seems as if it would necessitate *very* long exposure, but in reality ten seconds on an Ilford ordinary plate is ample time in a fair light. The two Thames-side views I pass round were taken under such conditions; in fact, less time would have done, as I found they did not require the full amount of

alkali to bring them up to printing strength, and they developed rapidly, indicating that with a normal developer they would have been over-exposed. The advantage of the small stop is getting beautiful definition all over the plate, and, when an exposure is required of more than one or two seconds, it matters, I think, very little if it is ten or twenty. In the old collodion days half a minute was considered an average exposure on an ordinary landscape, such as these are, and it was often very much longer, and even then not considered very protracted. I am aware that many think the use of an exceptionally small stop prejudicial to atmospheric effect, an opinion I cannot altogether endorse, as, with a *proportionate exposure*, I have in this respect found no falling off, and I quite believe atmosphere and definition may go hand in hand. Where it does not, I think the fault may be fairly attributed to under-exposure.

EDWARD DUNMORE.

(To be concluded.)

PHYSICAL DEVELOPMENT.

THE substitution of bromide of silver without free nitrate of silver, and the consequent development of the image from the haloid itself for iodide, or bromo-iodide of silver with free silver nitrate as the sensitive material, along with its accompaniment of development of the latent image, not from the haloid, but from the extraneous silver nitrate, was undoubtedly the especial point of change when about twenty-five years ago the wet-collodion process was gradually displaced by the dry-plate process.

In the wet-collodion process, as well as in Daguerreotype, the silver deposit which constituted the developed image was not the product of a chemical reaction, as is the case in modern photography by the use of alkaline developers, but originated by a peculiar physical property of the latent image, called photographic attraction. The developing agent—in the wet-collodion process the free silver, and in Daguerreotype the mercury vapour—formed a compound with the reduction product and not with the unaltered haloid, without altering the chemical constitution of the former.

But, even in one of the modern photographic processes, the development of faintly printed gelatino-chloride printing-out paper, this old method of physical or molecular development plays a part. In this process, as well as in the collodio-iodide process, the sensitive film itself contains the soluble silver salt, which in contact with the exposed silver haloid is reduced by the developer. It may, however, be equally well added to the developer, especially if the silver salt of the sensitive film has been exhausted, as, for instance, in the process of intensifying collodio-iodide plates with silver. If any other suitable sensitiser is added to the sensitive film, as in the case of the iodide of silver dry process, the silver nitrate needs to be employed only in the developer.

It is intended by the following lines to draw the attention of the readers to a number of interesting applications of physical development, which, after very careful and extensive experiments, have been described of late by Herr R. Ed. Liesegang, in the *Photographische Archiv*:—

1. *The Employment of Gallate of Silver in the Process of Developing Gelatino-chloride Printing-out Paper.*—In developing gelatino-chloride printing-out paper the excessive silver nitrate can be removed from the film by washing, when a mixture of the developer, which may eventually be acidified, with the former can be employed. Upon this observation the following method, described by Herr Liesegang, is based: If faintly exposed aristotype paper is freed from the excessive silver nitrate, and from other soluble compounds by washing in several changes of water, the image printed on it will develop in a concentrated aqueous solution of gallic acid to which a slight quantity of silver nitrate has been added, equally well as on paper of the same kind which is developed without washing in plain gallic acid. Whilst, however, in the case of the latter method the prints are reddish-brown before fixing, the washed prints will become intensely black by development in the gallate of silver solution. Over the older method, with plain gallic acid, this new one has the advantage, that the deposit formed in the developing solution is considerably slighter. Mixtures of slightly acidified hydroquinone, pyrogallic acid, and of other organic developers with silver nitrate will act in a like manner.

2. *Acid Developers for Gelatino-bromide.*—Though, in the gelatino-bromide dry process, the chemical developing method has been exclusively used hitherto, the exposed gelatino-bromide film may also be treated with a physical developer, if either a mixture of silver nitrate with a developer, which may eventually be acidified, is used, or if the plate is treated at first with silver nitrate, and then, without washing previously, with the developer. If a normally exposed gelatino-bromide plate is placed in a mixture of—

Hydroquinone (2 per cent. alcoholic solution) ..	5 c.c.
Formic acid	5 „
Water	50 „
Silver nitrate (5 per cent. solution)	5 „

a faint yellowish-brown image will be obtained after eighty minutes. The developing solution remains perfectly clear. To obtain negatives of sufficient density it will be necessary to expose the plates from three to four times longer than those to be treated with a chemical developer. If in the above formula the acid is omitted, a reduction of the silver salt of the liquid soon takes place.

As mentioned above, a similar result may be obtained if the plate is at first placed in the five per cent. silver nitrate solution, and then, without washing, in the developer. In the case of taking a one-half per cent. hydroquinone solution as the latter, a brownish-red image will appear after about half a minute, but afterwards a metallic powder is precipitated, which, however, does not in the least adhere to the film of the plate. If acetate of soda is added to the hydroquinone solution, red fog will be produced. Silver nitrate mixed with metol very soon gives an olive-brown image, whilst, if mixed with para-amidophenol, a yellowish-brown image is produced, development being, however, slower. Gallic acid with silver nitrate does not at all develop, and with amidol at once red staining of the film is produced, together with a considerable precipitate in the liquid.

3. *Developing the Plates after Fixing.*—If a gelatino-bromide film which has been exposed to light is fixed, the sub-bromide of silver is very likely decomposed to bromide and metallic silver; but, in a normally exposed gelatine film, the contents of metallic silver are so slight that, after fixing, not the least darkening at the exposed parts will be visible. With nascent silver the molecules may, however, be rendered considerably larger, and the image becomes then visible.

If a gelatino-bromide plate which has been normally exposed in the camera is placed in a solution of hyposulphite of soda and, after fixing and well washing, treated at first with a ten per cent. solution of silver nitrate, then, without washing, with a developer consisting of hydroquinone and sodium acetate, a blue to bluish-violet image of slight intensity will be developed in the latter solution. The process after fixing may be carried on at daylight. Para-amidophenol, metol, or pyrogallic acid, may be substituted for the hydroquinone developer, or silver nitrate and hydroquinone may be mixed to a single bath if the latter be slightly acidified.

4. *Intensifying Negatives by Acid Development.*—If a sensitive film which has been exposed in the camera is treated with nascent silver, the latter is precipitated not only on the exposed silver haloid but also on finely divided metallic silver in absence of halogen silver. For this reason it will be possible to intensify a gelatine negative with a physical developer by separate treatment with silver nitrate and gallic acid, or hydroquinone, &c. The separate employment of silver nitrate and developer has the advantage over a mixture of the two, that in the case of the former substances may be added by which the keeping qualities of the developer are improved, for instance, sodium sulphite, and also substances by which the process is accelerated, for instance, sodium acetate. The following method has been used by Herr Liesegang:—

The gelatine negative is very thoroughly washed and then placed in a five to ten per cent. silver nitrate solution. After a few minutes it is transferred, without washing previously, in a diluted mixture of hydroquinone with sodium acetate, known as "aristogen:"—

Hydroquinone (7 per cent. alcoholic solution)..	4 c.c.
Sodium acetate (15 per cent. solution)	8 „
Water	60 „

and allowed to remain until it has acquired the desired density. It it well to place it finally in a solution of hypo. Other organic developers, in plain solutions or mixed with sodium acetate, may be substituted for the above hydroquinone developer. The intensification which may be obtained by this method is said not to be as considerable as with bromide of copper and silver nitrate.

5. *Intensifying Fixed Prints.*—According to the same principle as described *sub* 4, also fixed prints on various printing-out papers may be intensified after fixing by physical development. It makes no difference whether they have been toned or not; but it is, of course, necessary to wash them previously very thoroughly, since the least trace of hypo in the film causes yellow fog. The following experiment has been made by Herr Liesegang:—

A finished print on aristotype paper was placed in an aqueous solution of hydroquinone, citric acid, and silver nitrate. The proportons of these substances are of no importance; however, a sufficient

quantity of acid should be present, to prevent the reaction between the hydroquinone and the silver salt. At first no intensification of the print took place, on account of the fact that no precipitate of silver was produced in the liquid; but, as soon as a few drops of ammonia were added, so as to render the bath just neutral, a slight precipitate of silver was formed, and, at the same time, intensification of the image took place. If the latter was not sufficient, a few drops more of ammonia were added. In this way the prints may be strengthened to any degree. For hydroquinone all the other silver intensifiers may be substituted. It is necessary that previously to the above treatment the prints, especially those on gelatine-emulsion papers, should be well soaked in water, in order to prevent the silver deposit adhering to the film. In adding the liquid ammonia, care should be taken that it does not drop directly on the print, because it would otherwise produce yellow spots.

6. *The Application of Physical Development to Various Other Surfaces.* — From the experiment described *sub* 5, it will be seen that not only the silver molecules have the property to attract the nascent silver of the developing liquid, for in the case of a toned and fixed print, which therefore contains no more silver haloid, the gold has the same function as the silver. In like manner, in a freshly prepared mixture of silver nitrate with a suitable developer a purely physical intensification will take place :—

(*a.*) Of finished chloride of silver positives in which gold, platinum, osmium, iridium, and other precious metals have been substituted for silver.

(*b.*) Of finished platinotype prints, carbon prints, Woodburytypes, of prints obtained by the powder process, and of similar prints, provided that no greasy substance has been employed in combination with the pigment, as in collotypes, letterpress prints, &c.

(*c.*) On glass, celluloid, ebonite, and on several other substances the silver is deposited, if they have previously been freed from the gas or water atmosphere condensed on them.

7. *Intensifying Finished Platinotypes.* — As mentioned above, *sub* 6 *b*, finished platinum prints may be successfully intensified by the application of physical development. The print, after being wetted with water, is placed in a mixture of—

Aristogen (see above, *sub* 4)	10	parts.
Citric acid (2 per cent. solution)	5	„
Water	150	„

to which, just before use, ten parts of a five per cent. nitrate solution have been added. After a few minutes finely divided metallic silver will be precipitated in the liquid, which, however, does not alter the qualities of the bath. The platinotype will very soon gain in density, and at the same time it turns intensely brownish-red, the whites remaining perfectly clear. The precipitate of the bath will adhere to the paper only in cases where the print has not previously been moistened with water. Afterwards the print is treated either with hypo or with any combined toning and fixing bath. In fixing, the brownish-red tone of the print is preserved, though it will be reduced to some degree. With the toning and fixing bath the colour of platinum is nearly obtained. Instead of aristogen, para-amidophenol, pyrogallic acid, metol, and other developers may be employed, if they are previously rather strongly acidified. With pyrogallic acid the black silver modification will be obtained in place of the brownish-red one.

8. *Silvering Glass.*—By aid of a quite freshly prepared, still perfectly clear mixture of slightly acidified pyrogallic acid, or of para-amidophenol, aristogen, &c., with silver nitrate the silvering of glass is a matter of great simplicity, provided that the surface has been previously freed from the adhering gas or water atmosphere by rubbing it vigorously with alcohol or ether. The glass surface will then be covered in a few minutes with a thin layer of tightly adhering silver. Should the thickness of layer be not sufficient, pyrogallic acid or para-amidophenol, aristogen, &c., respectively, and then silver nitrate solution should be added alternatively. The experiment will be still more successful if the glass surface is at first poured over with the concentrated alcoholic aristogen solution, as it is sold by the manufacturers, and then, after the excessive liquid has been allowed to drain, placed in a diluted aqueous solution of silver nitrate. For the aristogen strong alcoholic solutions of other developers may be employed. The silver deposit is produced within a few minutes.

The glass may be equally well silvered if it is at first moistened with an alcoholic solution of silver nitrate, and then placed in a diluted developer; for instance, in aristogen 1 part, water 12 parts. The operation, as a rule, must be repeated in order to obtain a sufficiently intensive deposit.

In conclusion, it may be mentioned that Herr R. Ed. Liesegang gives the following explanation with regard to the action of the physical developers :—Soon after the pyrogallic acid, or the para-amidophenol, metol, &c., has been mixed with the silver nitrate, the silver is suspended in the liquid in the finest state of division. The result is not a solution as it is generally understood, but a kind of emulsion. The portion of the liquid which encloses the single particles will, however, not be able to perfectly separate the silver molecules, the power of the latter for uniting themselves being greater than the adherence with the liquid atmosphere. Consequently, the silver particles unite to form larger particles. HERMANN SCHNAUSS.

A NEW TELE-PHOTO LENS.

Our attention has been specially drawn to a new lens of the "tele-photo" *genus* just received by Messrs. George Houghton & Sons, 99, High Holborn, W.C., and we have before us quite a number of views that have been taken by its agency. Having been afforded an opportunity of examining the lens in question, we are enabled to give the following description, aided by the drawing underneath.

In the first place, there is what seems to us a well-made "rapid rectilinear," eight inches in focus, fitted with iris diaphragm, and which, when unscrewed and used alone, fits the flange, A, of the tele-photo system screwed on the camera front. This lens covers a half-plate to the corners, judging from a specimen of its work sent us. When screwed into the outer flange, C, of the tube (which is four inches long), carrying at its nearer end that which is next the camera, the tele-photo system is now complete. The image on the focussing screen is seen magnified up to eight times; but, by operating a rack and pinion, the concave lens B, can be brought nearer to or farther from the rectilinear lens in front, and can thereby be made to increase or diminish the telescopic effect to the desired extent.

In the views submitted to show its various powers, there is, first, a print from a negative by the rapid rectilinear alone, and this, we may say, leaves nothing to be desired as regards definition. We have next four other photographs, taken from exactly the same standpoint, showing degrees of enlargement, respectively three, four, five, and six times that of the primary picture. These, as they ascend in magnifying power, show a corresponding increase of detail, ornamental ironwork which is merely suggested by the original lens now showing its pattern with very desirable distinctness; while distant trees, still more feebly suggested in the primary picture, are shown individualised in the tele-photo ones.

An engraved scale on the sliding tube which is actuated by the rack and pinion permits one to see at a glance to what extent the camera has to be extended in order to produce the degree of magnification that is to be adopted in any special case, and this, in our opinion, is a great convenience.

The lenses, of Parisian make, are by the house of Clement & Gilmer (late Laverne), whose reputation is good. The concave lens, which acts such an important part in tele-photo combinations, is of the same diameter as those forming the rapid rectilinear. It is a crossed double concave, the deepest curve being to the front, the surface to the back being concave in only a slight degree. They are all said to be formed of Jena glass, and the price (5*l.* 5*s.*), which includes the rapid rectilinear, will be considered strictly moderate.

To magnify three times, the camera requires racking out six and a half inches; six times necessitates sixteen inches, and so on, according to the indications on the scale.

Messrs. Houghton & Sons supply the trade and the public in this country.

BIRMINGHAM PHOTOGRAPHIC SOCIETY'S EXHIBITION.

THIS Society held its annual Exhibition last week, nearly 400 exhibits being shown.

In instantaneous work the silver medal fell to Mr. William Rooke for a Christiania street scene, and Mr. J. P. Heaton, Mr. H. W. Southall, and Mr. T. Taylor (Staffordshire) received honourable mention. Mr. J. Simkins was the medallist, and Mr. J. H. B. Manly is honourably mentioned for cloud photographs. For landscapes Mr. H. W. Southall carried off the chief award with a clever little bit of work—*Chadbury Mill*. Mr. W. Jones was the medallist for enlargements. For portraiture the silver cup went to Mr. Leeson. Mr. J. Simkins was the medallist for interior work, his exhibit being the tomb of Sir Fulke Greville, in Alcester Church, honourable mention falling to two productions of Mr. G. F. Lyndon and to one of Mr. W. T. Greatbach. Mr. Simkins was again the medallist for exterior architectural work with a view of the *Chapter House, Much Wenlock*. He was also honourably mentioned, as was Mr. C. J. Fowler, who also obtained the chief award in *genre* work, Mr. Southall being also mentioned. In hand-camera work there were only three exhibitors, consequently there was no award. In the seascape exhibits Mr. A. J. Leeson was the medallist. Mr. M. H. Chubb was the successful exhibitor both in the champion class and in that for three prints, any subjects, any size. Mr. T. Taylor took the bronze medal for the third award in the champion class, the second not being allotted, while Mr. H. C. Manton took the corresponding prize in the class for any three prints, Messrs. W. S. Aston and C. H. Barnsley being honourably mentioned. Mr. William Rooke took the silver medal in the section for photographs not included in the above classes, with a hoar-frost picture; Messrs. J. Simkins, P. T. Deakin, and W. Topham were mentioned. Mr. H. W. Southall was the medallist for bromide prints, with a view of the Avon at Cropthorne. Mr. E. C. Middleton was successful in the class in the survey section for three doorways in Warwickshire, and Mr. E. Underwood, who alone seems to have understood the object of the class, the medallist for a nonagenarian in *Warwickshire Peasantry*. The last-named gentleman was also successful in another open class in the survey section, while Mr. Middleton obtained a second medal for a view of Stretton-on-Fosse, in *Characteristic Village Scenes*. The medal for church windows was not awarded. Mr. J. H. Pickard received the medal and two (the only) honourable mentions in the class for architectural details. Mr. E. C. Middleton added one more to his successes by securing the medal for lantern slides.

THE summer season of the Polytechnic School of Photography will include a series of lectures by Mr. Horsley Hinton, Mr. Charles W. Gamble, Mr. E. Howard Farmer, and Mr. Gamble, particulars of which will be found in our advertisement columns. We are pleased to find the Polytechnic is so popular as an agency for diffusing a knowledge of photography.

Our Editorial Table.

THE MARTIAL ANNALS OF THE CITY OF YORK.

By the Rev. Cæsar Caine, F R.G.S. London: Chas. J. Clark, 4, Lincoln's-inn-fields.

As a former A. C. to H.M. troops, York Garrison, the author has had exceptional opportunities for qualifying himself for the task he has undertaken, and which has culminated in this work. The Eboracum of the Romans, York can boast of having been the residence of a Roman Emperor, Severus, in A.D. 208, having dwelt here while his troops were constructing the great wall of defence across the island. For a long period York was the capital of this country, and it, or its vicinity, was the scene of several battles. It is gratifying to find that a historian of Mr. Caine's abilities and powers of research has undertaken to give in a single volume the succinct and methodically arranged account of this ancient city, its martial annals, and incidentally its antiquities. It is to be regretted that the temples, palaces, theatres, and similar public buildings with which the Romans adorned their cities, have long ago disappeared, but one cannot take even a brief walk through this city without realising that he is still in the presence of antiquity. As a clever and discriminating photographer, Mr. Caine has most copiously illustrated his book with the archæological remains, for the possession of which the ancient city enjoys a proud pre-eminence over every other town and city in this country; and in one or other of the sixty illustrations which embellish the book we have the most of them. Many of the bars or gates through which the city was entered are imposing structures, and make good pictures. This is especially true of Micklegate Bar and Monk Bar, which present the appearance of high towers on the city walls, for York is one of the few walled cities now remaining in this country. In addition to the various bars, Mr. Caine has laid under contribution all the other subjects of interest, such as the Multangular Tower, St. Mary's Abbey, Stamford Bridge, Clifford's Tower, and the Old Baile, the Red Tower, St. Mary's Tower, Marston Moor, Fishergate Postern, &c. Of these Bootham Bar is perhaps not the least interesting, on account of the fine view of the Minster seen in the background. Of these various illustrations we here present an example, the Manor House of King Henry the Eighth, in which Charles the First resided for a brief period in 1639, a few years before the battle of Marston Moor, so disastrous to this king. The work is classified into periods, opening with the Roman Period, from A.D. 50 to A.D. 426, terminating with the Hanoverian Period, from A.D. 1714.

Amateur's Developing and Toning Outfits.

Messrs. Arthur Schwarz & Co., of Dashwood House, E.C., are sending out sets of Dr. Andresen's developing, fixing, and toning cartridges, which should be handy for travellers and amateurs. The boxes include metol cartridges, the contents of which being dissolved in water form the developer; fixing cartridges; and toning and fixing cartridges for use with either albumen or chloride papers. We have before spoken of the excellence of these preparations, which in this form will, no doubt, be welcome to many.

The Dallastype Shakespeare.

Duncan C. Dallas, 5, Furnival-street.

Of the Dallastype *Shakespeare*, which is a photographic reproduction of the famous first folio (1623) edition, the complete play of *The Tempest* has just been published. We have before commended the excellence of the reproduction, which, when complete, should be much appreciated by lovers of the national bard. We understand that Mr. Walter Crane is preparing a number of illustrations for the series, which should make it additionally valuable.

The Studio.

16, Henrietta-street, Covent Garden, W.C. Monthly, price 6d.

This, the first number of a monthly magazine to be devoted to fine and applied art, is beautifully got up, printed and illustrated, the latter being charmingly unconventional, and, in some cases, highly original in style. Among the illustrated articles are: "Sir Frederick Leighton as a Modeller," "The Growth of Recent Art," "Spitalfields' Brocades," by Mr. Liberty, and "A new Illustrator—Aubrey Beardsley," whose peculiarly original style affords Mr. Joseph Pennell material for a laudatory article. Mr. Pennell says: "The criticism of art to-day is merely the individual expression of persons who mostly know nothing about their subject." His own article is purely critical.

The Lomberg Dry Plates.

E. Stiepel & Co., 80, Bishopsgate-street Within.

Samples of the "Lomberg" dry plates having been submitted to us for trial, we find them of medium rapidity, yielding, with normal pyro-soda development, images of good quality, cleanness, and density. Their rapidity, according to Watkins' system of speed measurement, is 80°.

RECENT PATENTS.

APPLICATION FOR PATENT

No. 9499.—"Improved Hand Camera, by the Use of Hexagonal Drum or Box in Interior." A. T. Davey.—*Dated May* 12, 1893.

PATENT COMPLETED.

Improvements in Apparatus for Regulating Photographic Shutters.

No. 12,029. Henry Hill, 20, Tradescant-road, South Lambeth-road, London, and Arthur Lewis Adams, 81, Aldersgate-street, London.—*April* 1, 1893.

This invention relates to apparatus for pneumatically regulating the speed or travel of shutters for photographic purposes, and consists of a pneumatic regulating device which can be readily adjusted or altered so as to give longer or shorter exposure as desired.

The pneumatic regulating apparatus according to this invention consists of an air chamber capable of having its internal area increased or diminished as desired, by means of an adjusting device secured or affixed to that end or part of the apparatus which is away from, or detached from, any working part of the shutter, while another part of this air chamber is permanently attached to some working part of the shutter so that the leverage between it (the air chamber) and the spring actuating the shutter is never varied, the regulation being obtained according to this invention by varying the size of this air chamber—and this may be done in either of the following manners:—

1. A tube (either cylindrical or of other suitable form) closed at one end and open at the other is permanently connected at its closed end to some working part of the shutter, while its other and open end slides over (or, if desired, slides into) another tube of corresponding form and length (or the length may vary), which it closely fits, the one working within the other after the manner of a plunger.

The outer end of this second tube is closed likewise, and has connected to it a crank arm (like a bell crank) turning on a pivot—the free end of this arm acting as a handle by which to move same, and a dial or index plate may be mounted in combination with the same so as to show exactly the speed at which the shutter is set.

Thus, by moving this regulating handle to its extreme limit on one side, or in one direction, the second tube is drawn out of the first, and thereby the internal area of the combined tubes is greatly increased—thus allowing the shutter to work with more freedom, and consequently greater speed.

By moving the index handle to the opposite extreme, the one part of the air chamber is moved closer into the other part, and consequently the area of said air chamber is reduced, and when the one part or tube is drawn off the other by the movement of the shutter the air is more attenuated, and consequently the speed of the shutter is greatly retarded, while at intermediate positions of this index handle or regulating arm between the two said extreme points intermediate speeds are obtained.

In place of this crank arm for altering the positions of these tubes one upon the other (*i.e.*, altering the internal area of this air chamber), as hereinbefore described, other equivalent mechanical means may be used for doing this; for instance, a slide moving in a line parallel or thereabout with the axial line (*i.e.*, the length) of the air chamber, and having a dial or index, as before, to show the speeds or other equivalent mechanical devices, may be readily applied in order to draw the one tube off the other, or out of the other, so as to vary the internal capacity of said air chamber, as and for the purposes hereinbefore described.

2. A tube of cylindrical or other suitable shape, and open at each end, may be pivoted or mounted so as to be capable of swinging at about the centre of its length, and the moving part of the shutter has a tube or cap (corresponding in shape) attached thereto to slide over, or slide into, this pivoted tube at one end thereof, while at the other end thereof another tube or cap of corresponding shape may be mounted or arranged to slide over, or slide into, this said pivoted tube, this third tube being drawn in or out by means of a slide, bell, crank lever, or other suitable device, so as to vary the internal area of the air chamber thus formed as before described, each of these two slide tubes or caps being closed at their outer end as before, the only difference from the first arrangement being that the air chamber is formed in three parts instead of two.

3. In place of having tubes or the like devices sliding upon one another (as previously described), a regulating action can be obtained by a bellows or the like arrangement, one side or part of the bellows being connected to some working part of the shutter and another side or part of the bellows connected to a device as before, for varying the position of same, so that the internal area of the air chamber in said bellows is increased or diminished.

Thus the air chamber is compressed or extended or both (when the shutter is actuated) in any of the three above described manners, or in any mechanically equivalent manner, and the speed of the shutter can be thus regulated in a very simple manner and without in any way varying the leverage between the air chamber and the operating spring.

The index handle or regulating arm, slide, or lever by which the internal area of the air chamber is varied can be held in position by set screw, or clamp, or in any other suitable manner, as desired.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
May 23	Birmingham Photo. Society	Club Room, Colonnade Hotel.
,, 23	Great Britain (Technical)	50, Great Russell-st., Bloomsbury.
,, 23	Hackney	206, Mare-street, Hackney.
,, 23	Paisley	9, Gauze-street, Paisley.
,, 23	Rochester	Mathematical School, Rochester.
,, 24	Leytonstone	The Assembly Rooms, High-road.
,, 24	Photographic Club	Anderton's Hotel, Fleet-street, E.C.
,, 24	Southport	The Studio, 15, Cambridge-arcade.
,, 25	Camera Club	Charing Cross-road, W.C.
,, 25	Glossop Dale	
,, 25	Halifax Photo. Club	Mechanics' Hall, Halifax.
,, 25	Hull	71, Prospect-street, Hull.
,, 25	Ireland	Rooms, 15, Dawson-street, Dublin.
,, 25	Liverpool Amateur	Percy-buildings, Eberle-street.
,, 25	London and Provincial	Champion Hotel, 15, Aldersgate-st.
,, 25	Oldham	The Lyceum, Union-st., Oldham.
,, 26	Cardiff	
,, 26	Croydon Microscopical	Public Hall, George-street, Croydon.
,, 26	Holborn	
,, 26	Maidstone	"The Palace," Maidstone.
,, 26	Swansea	Tenby Hotel, Swansea.
,, 26	West London	Chiswick School of Art, Chiswick.
,, 27	Hull	71, Prospect-street, Hull.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

May 11,—Mr. W. E. Debenham in the chair.

Mr. E. H. Bayston was elected a member.

Samples of the Lomberg dry plates were distributed among the members.

Potassium Bromide in Mercurial Intensification.

The following question from the box was read: "Why is potassium bromide used with mercury bichloride for intensification?"

Mr. R. P. Drage thought it gave greater clearness to the image.

Mr. A. Cowan said it was recommended with Monckhoven's silver cyanide intensifier.

The Chairman said that Mr. Spiller had stated that the bichloride, unless made acid, formed a combination with the gelatine, and therefore clogged the shadows. A reason for its inclusion in Monckhoven's formula might be that silver bromide was more amenable to treatment with cyanide than chloride.

Mr. R. Beckett used a drachm of hydrochloric acid in twenty ounces of mercury solution. It worked well when followed by cyanide of silver.

"Is the Present Construction of Studios Wrong in Principle?"

Mr. W. H. Harrison read a paper on this subject (see page 310), in which he suggested a south light reflected from a whitewashed wall on to the sitter, the light being controlled by blinds, in preference to a north light.

In the course of the discussion which followed Mr. Cowan said he thought the sun falling across the room would interfere with the sitter. He did not fancy the arrangement would work at all.

Mr. Beckett objected to the plan as likely to cast too strong a light on the backgrounds.

Mr. P. Everitt thought it would give too much top light. Would not the outlay for renewing the whitewash and the cost of construction generally be considerable?

Mr. W. Cobb said he would not like to depend on reflected light alone.

Mr. W. D. Welford said the point was whether reflected light was equal to direct light.

Mr. Cowan said the question whether the reflected south light was more powerful than the direct north light could be tested by printing from a negative in it against one printed in the north light.

Mr. A. Haddon said that photographing a white screen towards the north, with a portion of the sky included, would also answer the purpose.

The Chairman thought Mr. Harrison made a mistake in supposing a north light to have little photographic value when there were clouds about. The light from the northern sky was much more considerable than he had any idea of. If the light, as was said, was chiefly reflected from the floating particles of dust that were always present in towns, more so than in the country, then we should always have more rapid exposures in towns. He (the Chairman) did not think this to be the case. He thought the light greater from a northern sky than from a whitewashed wall, and certainly so when the sun did not shine. Mr. Harrison's suggestion would, it seemed to him, lengthen the exposure. The amount of glass required would be enormous, and the alteration of angle would be exceedingly great. The light from the sky would be less dazzling to the sitter. He did not think the present construction could be remedied.

Mr. E. W. Parfitt asked if, in using a reflector screen for enlarging in the open, the exposure required would be more than would be required if the light from the sky alone were used?

Mr. Welford had tried to print a cracked negative with reflected light from a very white screen, and it did not answer the purpose of diffusing the light. He had also found by experiment that diffused light did not print as quickly as the northern light.

Mr. Harrison, in replying to the various points raised, said that the plan would necessitate the employment of suitable blinds. Two reflections instead of one would be utilised. The north light was light reflected from a dirty screen. The point was, whether the reflected south light was better.

After other discussion a vote of thanks was passed to Mr. Harrison for the paper.

MANCHESTER PHOTOGRAPHIC SOCIETY.

May 11, the President (Mr. Abel Heywood) in the chair.—The syllabus for the summer outdoor meetings was laid before the members; these have been arranged to take place on the Saturdays immediately following the ordinary monthly meetings, thus affording members an opportunity of making arrangements to take part therein. It having been thought by several of the Council that members should have the use of a large camera, a proposal was laid before the meeting for obtaining a 12×10 outfit complete, the scheme propounded being somewhat on the co-operative principle, subscribing members to have the first use, the Society as a whole to have the option of purchasing all the shares. It was considered by such a scheme a first-class apparatus could be obtained without the cost thereof falling on those who did not desire or require its use. After some discussion it was decided to lay the matter more fully before the members by circular, to be sent out before the next meeting. The subject of discussion was the *Development of Hand-camera Exposures*. Mr. Wrigley and Mr. Lawes contributed notes. The former, in addition, gave his experience of working the Frena camera, the only drawback that he experienced being the defective films at present supplied for this ingenious camera.

North Middlesex Photographic Society.—The fourth of the series of Elementary Technical Classes given by the above Society was held on Wednesday, May 10, the subject being Intensification and Reduction of Negatives, by Mr. J. McIntosh. Several of the negatives brought by those interested were operated on with excellent results, formulæ given, and the processes explained in a manner suitable for a beginner. These classes have been greatly appreciated, and interest shown by both instructors and those gentlemen attending is evidenced by the great improvement in some of the work lately exhibited at the Society's outings competitions.

Hackney Photographic Society.—May 9, Mr. T. H. Smith in the chair. Mr. Maxwell was elected a member. Mr. Hensler said he had broken his focussing glass when in New Zealand, but, as he had previously marked his camera in distances, the difficulty was overcome. Mr. Beckett advised using a xylonite film (which would not easily break), but said, in having distances scaled, as mentioned, the trouble was getting the principal focus, *i.e.*, foreground or distance. Mr. Grant used, on emergency, a plate put in hypo till nearly clear, then washed out. Mr. Hudson protected his focussing screen by using a piece of thin wood. From the question-box: "What can be done with hydroquinone formula (Ilford) in which crystals had not dissolved?" Mr. Roofe had had markings on his plates under such circumstances. Some discussion ensued, but filtering was eventually recommended. Another question was asked: "Was it necessary to rock during development?" The reply was: "Yes, as particles might cause stains, and mottled appearance would sometimes result." Mr. Hensler asked for amidol formula for lantern plates, and was recommended, by Mr. S. J. Beckett, to use any, but with plenty of bromide. Mr. Grant asked for probable exposure for ordinary room. Several replies were given, but *f*-22, Sandell plate, ten minutes, was mostly favoured. Mr. A. Barker asked: "Were uranium-toned prints permanent?" Mr. S. Beckett said it was doubtful. He thought that, if developed in the first instance with ferrous oxalate, they would deteriorate. Mr. Sodeau startled the Society with showing a shilling hand camera. He proceeded to explain it worked at *f*-22, amidst much mirth, and numerous questions were asked of an hilarious kind. Mr. T. H. Smith asked what plates were best to use for cloud negatives. Mr. Hensler had used iso. Mr. R. Beckett said they were good when there is a yellow sunset, but for a bright, blue sky the yellow screen should be used. He made an exposure last week on a Barnet rapid *f*-18 one-fortieth of a second, and had a good result. Clouds, he said, were often printed in too deeply; what was wanted was delicate, not hard, clouds. Mr. Cross showed a print from a cloud negative, the negative of which he had taken by cap exposure, using slow plate and developer weak in alkali.

Leytonstone Camera Club.—May 10, Mr. H. E. Farmer in the chair.—The advantages of the multiple film known as the Sandell plate was demonstrated by Mr. Herbert Fry. The lecturer opened by passing round some very fine prints produced by Mr. Sandell. The exposure given evidently showed that the inventor had put the plates to some very severe tests. Their advantages over other plates for hand-camera work was clearly shown and explained, some very fine snap-shot negatives being passed round, the clouds having been retained in the second film. Mr. Fry classified the advantages of the multiple film in the following order, although he considered that No. 4 was the most important:—1st, "Hand-camera Work," in which the top film being rapid allowed for slight under-exposure, the second film absorbing the high lights and preserving the picture in over-exposure; 2nd, "Interior Work," in which the top film takes up the shadows, and the second the high lights; 3rd, "Halation." They almost entirely do away with this bugbear, as the under films catch the rays of light, and, being a very slow emulsion, with a medium exposure, they are retained; but, even if very considerably over-exposed and they have penetrated right through the film, they still have to be reflected back through this very slow emulsion; 4th, "Gradation." The double film gives a much longer scale of the various tones and half-tones compared with the resulting flatness of the single film; 5th, "Exposure." The enormous amount of latitude allowable; in fact, the best results were to be obtained with extended exposure and weak development. The development recommended was that known as Cyclol, consisting of hydroquinone, 30 grains; eikonogen, 100 grains; rodinal, 9 drachms; sulphate of soda, 2½ ounces; carbonate of potass, 2½ ounces; water, 20 ounces. In winter to be used one to three, and in summer one to seven. The Hon. Secretary asked the question as to what extent development should be carried, as he had found that when developing with pyro-ammonia the top film veiled over, and the back had to be watched as to the progress. The Chairman said he had had the same difficulty. Mr. Fry in reply said that the developer had been used too strong, and that by tentative development they should come up as an ordinary film, but required a strong fixing bath, eight ounces of hypo to the pint.

Rotherham Photographic Society.—May 10. Mr. T. Scotton, of Derby, read a paper on *The Platinotype Process*, and afterwards developed a number of whole-plate prints by the cold-bath method. The demonstration was most successful, and the resulting pictures were much admired for their artistic as well as their technical excellence. Dr. Baldwin (President) occupied the chair. On Tuesday, May 2, the members had under their notice Dr. P. Jeserich's *Detection of Crime* paper.

Photographic Society of Ireland.—May 12, Mr. M. Hedley (Vice-President) in the chair. Subject: *T. C. D. Tercentenary and Dublin Views.*—A collection of lantern slides, the joint work of Dr. E. MacDowel Cosgrave and Mr. L. R. Strangways, M.A., was exhibited on the screen. Part I. illustrated the tercentenary festivities which took place in connexion with Trinity College last July. Some very good interiors and exteriors of the University buildings were shown; amongst others the Examination Hall, the Library, the new buildings, &c.; portions of the procession which took place between the College and St. Patrick's Cathedral were also exhibited, in them many well-known figures can be recognised. Part II. comprised familiar and important buildings, monuments, and views in the city, as well as some very amusing scenes in the back streets; these latter, mostly done by Mr. Strangways, caused a good deal of merriment. Dr. Cosgrave acted as lecturer all through the evening, and kept his audience alive with interest, explaining important and historical facts connected with the University and Dublin City, many of which were quite unknown to the majority of those present.

Correspondence.

☛ *Correspondents should never write on both sides of the paper. No notice is taken of communications unless the names and addresses of the writers are given.*

FRILLING OF PLATES.

To the Editor.

Sir,—During the recent few weeks of hot weather which we have had there has been some trouble caused in my developing room by the frilling of plates, and, after careful observation, I have noticed that in nearly every case there was one or more edge of the film entirely free from any tendency to frill. This is not an exceptional experience, but one which all those who are constantly using dry plates will be able to corroborate. It occurred to me that there must be some reason for the plates not frilling on all sides alike, and, after a few experiments, I found that the

edges which had been cut with a diamond after coating the film, were much more inclined to frill than on those which had been coated right up to the edge, and not cut afterwards. Let me add to this the fact that I am seldom or never troubled with frilling at all in large-sized plates (say 15 × 12 and upwards), and never on more than one or two sides.

It is, I believe, the practice of manufacturers to coat large sheets of glass and cut them up afterwards to the sizes required, and I should like to know if there is any distinct advantage in this method over that of cutting up the glass first.

Alum and other astringents are altogether unsatisfactory in use, and often result in even greater annoyances than frilling by being carelessly applied, and, since some makers are able to supply a plate *entirely* free from the tendency to frill, there seems no reason why others should not also do so.

I am quite convinced that plates cut up after coating are more inclined to frill than those coated the size they are intended to be used.—I am, yours &c., ERNEST LAMBERT.

Manager of Lambert & Lambert, of 32 Milson-street, Bath.

[Usually, we believe that all sizes under whole plate are cut from larger-sized sheets of glass, the latter being more convenient to coat. —ED.]

GELATINO-CHLORIDE *VERSUS* ALBUMEN PAPER.

To the EDITOR.

SIR,—As you have invited correspondence *re* the working of printing-out paper, I should like to know how the mounting is done. Seeing a statement some months ago respecting the working, a correspondent said that everything was done just the same as for albumenised, and, liking the paper, a batch of prints was made on it. Now, the way I mount albumenised paper is to make a heap of twenty, and, pasting the top one, to lay on mount and press down with a sheet of paper and roller squeegee; but, on serving the printing-out paper in the same fashion, the gelatine surface sticks to the paper and leaves the mount. I have had the same thing told me by other photographers, and feel surprised no one has mentioned this.

On reading your article on *Rapid Drying of Prints by Centrifugal Rotation*, I turned my tricycle on its side, and fastened a wet negative with two clips to spokes. It dried in three and a quarter minutes. This may be useful to some one in a hurry.—I am, yours, &c., W. R. F.

May 15, 1893.

THE PHOTO-CORRECTOR.

To the EDITOR.

SIR,—May I venture to express an opinion upon the "photo-corrector?" Now Mr. Van der Weyde's appliance is before us, the discussion it gives rise to is of great interest to photographers. It is sufficiently evident that it will require "artistic" judgment in application, but its possibilities are great. Argument about the identity of optical and visual truth can be readily disposed of; the style the portrait lens treats such details as nose, hand, and feet, shakes all belief in that dogma. When a figure approaches the normal eye no violent distortion is observed; the visual angle is, perhaps, twice that of the portrait combination. The eye projects its small image of external objects upon the concave spherical surface of the retina, free from the defects of projection upon the flat sensitive plate. Psychological influences no doubt are at work; but our ideas of form and distance are in great part due to experience and comparison. Pinhole perspective we accept, and get as near it as we can, but here the portrait lens is out of it—it wants help, and we have in this appliance of Mr. Van der Weyde a means of approaching more closely "visual truth" than the portrait lens permits; further, great latitude of posing and arrangement of subject appears possible with it, and the exaggeration of portrait photography can be brought under control. Such, I think, may be taken as the value of the "photo-corrector."—I am, yours, &c. OBSERVER.

33, *Westcroft-square, W, May* 8, 1893.

IRON CARBONYL IN GAS.

To the EDITOR.

SIR,—May I correct two *errata* in my article on above? It was one "gram" produced from 100 grams, or grammes, not "grains." And at the end, I referred to the use of a "lucky" cylinder, not "necky," but referring to the great *difference* observed in some cylinders in this respect, in which difference (and its cause) lies, perhaps, our best chance of a remedy.

I have since been told that coal gas is sometimes "purified" by means of ferric hydrate, and that such gas, even before compression, has been found occasionally to contain iron carbonyl and deposit iron oxide, on ordinary steatite burners. If this is true, we have another possible cause of variation, and another complication. But, however all this may be the question is urgent, and needs to be faced, or we shall be ultimately driven to pure hydrogen, with all its decided disadvantages.—I am, yours, &c., LEWIS WRIGHT.

May 10, 1893.

Exchange Column.

*** *No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance. The full name of the advertiser must in all cases be given for publication, otherwise the Exchanges will not be inserted.*

Exchange Lancaster half-plate Instanto, oxygen generator and gasometer, parrot cage, bamboo tripod, for Burr's C.-D.-V. lens, or two cases for canvassers, 12×10 box for washing negatives, Archimedean studio stand.—Address, L. DIXON, Photographer, Market-street, Colne.

Will exchange several "Seavey" backgrounds lighted from the left for others lighted from the right; also 15×12 camera, one double and one single slide, and 12×10 camera, two double slides, for four-back posing chair and 12×10 camera with three double backs.—Address, LONDON PHOTOGRAPHIC COMPANY, 21, Station-street, Sittingbourne.

Will exchange Thornton-Pickard time shutter, four-inches diameter, for *Magazine of Art*, 1889-90-91, and THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC from 1884 to 1890, all in good condition.—Address, J. DUNN, 1, Laygate-place, South Shields.

Answers to Correspondents.

*** *All matters intended for the text portion of this* JOURNAL, *including queries and Exchanges, must be addressed to* "THE EDITOR, THE BRITISH JOURNAL OF PHOTOGRAPHY," 2, *York-street, Covent Garden, London. Inattention to this ensures delay.*

*** *Correspondents are informed that we cannot undertake to answer communications through the post.*

*** *Communications relating to Advertisements and general business affairs should be addressed to Messrs.* HENRY GREENWOOD & CO., 2 *York-street, Covent Garden, London.*

PHOTOGRAPH REGISTERED:

Rev. Henry Howson, Belmullet, co. Mayo, Ireland.—*Photograph of the late Most Rev. Hugh Conway.*

JOHN S. HELSBY.—Yes, to all of your queries.

A. G. HAYWARD.—Marion & Co. keep such lamps as you describe.

HORACE W. NICHOLLS (Johannesburg).—Thanks. We should be pleased to have the promised article for the ALMANAC.

CHARLES H. HEWITT.—Willesden paper may be obtained of the Willesden Waterproof Paper Company, 72, Watling-street, E.C.

T. HOWELL.—We cannot advise on the matter. We may say, however, that it will be a little difficult to secure a legally good patent for a hand camera just now.

CYMRO BACH.—For neutralising the acid in the paper, bicarbonate of soda is to be preferred to the ordinary carbonate. For the fixing bath carbonate of ammonia is preferable.

T. DAVIES.—1. The experience is not exceptional. A solution of gelatine, by repeatedly being heated, gradually loses its setting properties. 2 We have not heard the rumour. We doubt if it has any foundation in fact.

HIGH PEAK.—You will succeed better in cleaning the Daguerreotype if you employ a stronger solution of cyanide, and allow it to remain on for only a shorter time. The tongue ought not to be allowed to touch the picture.

LIGHTS.—We have known white spots occur on prints such as yours, by tiny air bubbles attaching themselves while in the water. Try the effect of sponging one or two, while otherwise treating the remainder as usual.

C. J. W.—Probably the best photographs in imitation of sepia drawings are those produced by the carbon process, particularly when they are made by the single transfer method on rough drawing-paper, either white or tinted.

E. MARTIN.—A level, such as shown in the sketch, will prove useful to photographers and others, but we attach a good deal of importance to the opinions expressed by the Sheffield makers. Better submit the matter to some of the more energetic London supply firms who advertise in our outer columns.

BIRMINGHAM.—If the paper has a metallic lustre and shows metallic spots when purchased, it should be returned to the vendor. It will be quite futile to attempt to get anything like good prints on such paper. Probably the paper has been in stock for a long time; if not, its preparation was faulty. In any case, the user cannot remedy the evil.

F. M.—1. No copyright exists in Hogarth's engravings, nor does there in those of Bartolozzi. 2. There may be a copyright in a modern engraving or photograph of an old picture, though that in the picture itself has ceased to exist. In that case you may copy the picture, provided you can have access to it, but it would be illegal to reproduce the copy.

W. A. T.—1. Assuming the plate to have been rightly exposed, the pyro solution should be allowed to act, say, for a minute or so before the addition of the alkali. Development in separate solutions is practised by many experienced workers. You should study the *rationale* of development. 2. Swedish filter papers, to be obtained of any dealer. 3. See the toning formulæ given in the ALMANAC.

A. AMERLY.—If by your new process, whatever it may be, you can get a perfect relief in guttapercha, sulphur, or similar materials, there is no difficulty in obtaining a counterpart of it in metal by the electrotype method. Simply blacklead the relief and deposit the copper in the ordinary way. If our correspondent is not conversant with electrotyping himself, any professional electrotyper will do the work for him.

T. BROWNING.—To obtain permission to photograph any of the paintings in the National Gallery, application must be made to the Trustees. This can be made in writing. With regard to the Royal Academy, the exhibitors themselves must be consulted, or the holders of the copyright in the works if that has been disposed of; but, then, we surmise, the work, supposing permission is obtained, cannot be done till the close of the exhibition.

A. T. C. (Liverpool) says: "In works on the wet-collodion process it is sometimes recommended to acidify the silver bath with acetic acid and sometimes with nitric acid. Which is right?"—At one time, when pyrogallic acid was the developer used, acetic acid was generally employed; but, when iron came into use, nitric acid was, as a rule, adopted. For glass positives, by reason of its yielding a brighter image, it was employed from the beginning.

S. I. M. O.—If broken glass could be heard in the parcel before it was opened, the railway man's attention should have been called to it at the time, and the package opened in his presence. By signing the delivery-sheet without comment it is implied that the parcel was received in good condition. The County Court is the only legal remedy, if any, after so great a lapse of time. We should certainly, under the circumstances, have accepted the Railway Company's offer.

B. G. B. will be glad to know whether being a lady receptionist in a photographer's reception-room and wife of a photographer, disqualifies her for competing in amateur classes in photographic exhibitions. B. G. B. has been taking photographs, developing, retouching, and printing them entirely herself without any aid whatever. Being very fond of the work, she has been successful.—In reply, we fear that our lady friend will be disqualified as an amateur.

REPAIRING LEASE.—If the lease specifies that the outside of the studio and premises are to be painted twice, and the inside painted and repapered once during the term of tenancy, and this has not been done, the landlord's claim is quite legal. Through the lack of the painting the woodwork has possibly suffered more than it otherwise would have done, and that has caused the estimated cost of the repairs to be higher than they would have been. Before defying the landlord, as advised, better consult a respectable solicitor.

AN INQUIRER asks:—"1. Is it the place of the apprentice to make good accidental breakages? 2. If the master deducts money from the wages of the apprentice to pay for such loss, what action can the apprentice take?"—In reply: 1. Unless this is a condition in the indentures, we should say it was not, in the case of accidents. 2. Supposing the stoppage to be illegal, the apprentice, if he be under age, must sue the employer through his parent or next friend, we surmise. Perhaps some one better versed in the matter than we are will give their opinion on the subject.

LEWIS writes:—"I have made a lot of opalines with gelatino-chloride paper, which does away with the ordinary gelatine solution, but occasionally a few will begin to peel at the edges; is there anything I can prepare the glasses with to aid the two to stick? A man I know puts on a weak solution of silicate of soda, which has the desired effect of making the paper adhere. Does the silicate affect the permanency of the prints?"—We have had no experience in mounting gelatino-chloride prints as opalines. We see no reason why the silicate should influence the permanency of the picture. However, a weak solution of gelatine flowed over the glass, and allowed to set, would secure perfect adhesion, and that would certainly not affect the stability of the print.

ARTHUR JOHNSON says: "Having been greatly troubled with bubbles appearing on the prints in first water after fixing, I would be glad if you could tell me the cause and remedy. To prevent them I have tried borax in fixing bath, also methylated spirit in both fixing bath and first washing water after fixing, but with no diminution of bubbles. Strength of sensitising bath forty grains; also keep albumenised paper in a cool, damp place this hot weather, to prevent it becoming bone dry. Shall be very grateful indeed if you can help me."—There are several causes that conduce to blisters in albumen prints. Sometimes it is in the paper itself, sometimes in the albumenising, and at others in the sensitising. We should recommend the trial of a stronger silver bath. If that does not prove a remedy, adopt Mr. Richmond's plan, namely, immerse the prints, before washing out the silver, in a bath of methylated spirit. This remedy has never failed in our hands.

R. SHARP.—Calico, under the name of "unbleached sheeting," suitable for backgrounds, can be had up to seven foot six, if not wider, from any of the large drapers or house furnishers. Brown paper, so far as we know, is not sold wider than about five feet. Any paperhanger would canvas a frame and cover it with paper, which could afterwards be coloured for a background of any size that might be required. If the background is for outdoor use, to be fixed against the wall of the building, it might be better to convert the wall itself into the background, by having it cemented over and afterwards painted. That is often done.

PHOTOGRAPHIC CLUB.—May 24, *Halation, its Cause and Cure.* Bank Holiday Outing, Burnham Beeches and Stoke Pogis.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—Technical Meeting, to be held on May 23, at 50, Great Russell-street, W.C. *The Daguerreotype Process*, a demonstration by Mr. W. England.

WE are informed that Mr. Thornton, of Messrs. Hunt & Thornton, Enlargers, 347, Lordship-lane, Dulwich, having retired from the business, it will in future be carried on by Mr. Hunt and his son, under the style of Hunt & Son, at that address.

Apropos of some recent articles on studio construction, Mr. Van Dyk, of 20, Ladbroke-grove-road, Notting-hill Gate Station, whose studio is built on the principle advocated by Mr. H. P. Robinson, will be happy to allow visitors to inspect it on production of visiting card.

LEYTONSTONE CAMERA CLUB.—May 20, Wanstead Park and Flats; leader, Mr. D. G. Riddick. The Club will proceed from headquarters at three o'clock. 24, Demonstration, *Reproducing Negatives*, by Mr. Alfred J. Newton. Chair taken at eight o'clock. 27, Zoological Gardens; leader, Dr. W. Pickett Turner. The Club will assemble outside Portland-road Station (Metropolitan Railway) at three o'clock.

MESSRS. G. HOUGHTON & SONS' 1893 Shuttle Hand camera has several improvements on the original pattern, including a speed accelerator to the shutter, a dial which automatically records the number of plates that have been exposed, and shutters for closing and opening the lens and finder-lenses simultaneously. The camera is now issued in three series—A, for holding twelve plates or cut films; B, for twenty-four cut films; and C, with twelve plate sheaths and twenty-four film sheaths.

THE summer ramble card of the Oldham Photographic Society is embellished with an excellent small group of the members of Council. The following extract from the card may give a useful hint to other societies holding outings:—"Parties of not less than ten third-class passengers are granted return tickets at a single fare and a fourth, upon giving two days' notice to the railway company. To take advantage of this concession, members who intend joining any ramble should advise the Hon. Secretary three days before the date of the excursion."

CENTRAL PHOTOGRAPHIC CLUB.—The capital of the Club Company is 1000*l.*, and not 100*l.*, as we stated last week. We are pleased to hear that a large proportion of the capital has been subscribed among well-known photographers and others, and that the list of intending members is increasing. The Hon. Secretaries—Messrs. W. Fenton-Jones, 12, King Edward-road, Hackney, and C. H. Oakden, 53, Melbourne-grove, East Dulwich, S.E.—will be pleased to receive applications for membership or answer inquiries.

A PHOTOGRAPHIC SOCIETY FOR WOOD GREEN.—A meeting was held at Wood Green on Saturday, May 6, to consider the advisability of forming an Association of those interested in photography and other scientific pursuits. It was unanimously agreed that a Provisional Committee be appointed, with power to add to their number, to make all the necessary arrangements for the formation of such an Association, and twenty-one gentlemen at once undertook the duties in question. It is proposed that the Association may be utilised by those wishing instruction in photography, and that under its auspices, during the season, there will be a course of popular lectures delivered by gentlemen of eminence in their respective branches of science. It was agreed that ladies be admitted as members. Forty-nine names were given in to the Hon. Secretary. Ladies and gentlemen desirous of joining the Association are requested to communicate with Mr. P. D. Coghill, 252, Wightman-road, Hornsey, or with the Hon. Secretary, A. S. Murrow, 32, Park-avenue, Wood Green.

CONTENTS.

THE BRITISH
JOURNAL OF PHOTOGRAPHY.

No. 1725. Vol. XL.—MAY 26, 1893.

NOTICE—PICTORIAL SUPPLEMENTS TO "THE BRITISH JOURNAL OF PHOTOGRAPHY."

The first of the pictorial supplements to be issued with The British Journal of Photography will be given with the number for Friday next, June 2, 1893.

The subject is *A Yeoman of the Guard* (Tower of London), the negative being by Mr. William Brooks. The reproduction is by the process of Messrs. Thevoz & Co., of Geneva, and it is printed on a specially prepared paper, which greatly enhances its artistic effect.

As a largely increased sale of the next number of the Journal is anticipated, the Publishers would be glad to receive orders for extra copies and advertisements as early as possible.

DAGUERREOTYPING REDIVIVUS.

The demonstration of the Daguerreotype process given by Mr. Wm. England on Tuesday evening, in the rooms of the Photographic Society of Great Britain, convinced those who witnessed it that, although care and skill were necessary, there was no difficulty in producing works of the greatest beauty by this discarded but ever-charming photographic process.

Unlike all other systems of photography, the personal skill of the operator is the sole factor in the achievement of success. In other methods much is dependent upon the productions of the manufacturer, as in the case of the collodion or the dry plates employed; but in this the elementary substances must be applied by the operator himself, and upon his methods of doing so depend the position he occupies in the technics of Daguerreotyping; for we are for the moment putting out of sight the artistic element, the skill in posing and arranging a sitter, or in selecting a point of view in a landscape.

In its simplest form, and as it left the hands of Daguerre, the process briefly consisted in exposing a metallic plate with a silvered surface to the vapour of iodine till it became yellow by the formation of iodine of silver, then transferring it to the camera to become impressed by the action of light, developing the latent image by exposing to the fumes of mercury, finally fixing by immersion in hyposulphite of soda solution, and washing and drying. This was the process as it emanated from Daguerre, but it was slow and required a long exposure in the camera; moreover, the image was delicate, and could not withstand the most gentle touch without being destroyed. Both of these objectionable features were speedily removed. An enhanced degree of sensitiveness was imparted by the employment of bromine in addition to iodine in sensitising the plate, while permanence (speaking from the mechanical point of view) was ensured by a species of gilding.

As we know that there exists a hankering among our readers to try the Daguerreotype process on account of certain qualities *sui generis*, we will here give some practical directions by which they can most easily do so without the necessity of importing special apparatus for their trials, for such now are not readily obtainable. In doing so we shall take occasion to speak of some of the bye-paths of the process not to be found in the recognised manuals of that art.

Daguerreotype plates, not being now articles of manufacture or commerce, can only be obtained as a bye-product from the stock of old-established dealers, or from others who may happen to have a few gross, or even dozens, by them as relics of former times. The copper backing is merely the support for the very thin facing of silver in which the picture is formed, hence the plate may be made of brass or any other metal capable of being electro-plated with silver. By whatever means obtained, it is essential that the surface be flat, and after being polished with rottenstone that it receive a high finish by a few strokes of a buff charged with dry rouge. Some prefer the use of lampblack, which, to ensure freedom from grease, should be heated to redness before being bottled for subsequent use. A flat-bottomed vessel of glass or porcelain is necessary for holding the iodine. In proper iodine boxes this pan is encased in wood with an opening in one side to hold a small mirror which, when the plate has been laid face down in a holder over the top of the box, enables one to watch the progress of sensitising, for, after a little dry iodine has been placed on the bottom of the box and the plate exposed to the vapour which arises therefrom, the pure white silver rapidly acquires a golden tint, which passes to a deeper colour on to blue. At the yellow stage the plate is ready to be placed in the camera, provided the subject is a landscape or a copy in which the time of exposure is no object; but for portraiture an enhanced sensitiveness must be given, to which end it is only necessary to transfer the plate from the iodine box to a similar one containing either a little bromine greatly diluted with water enough of which to cover the bottom of the dish being sufficient, or, by preference, lime, to which a few drops of bromine have been added, and shaken up till the whole is of a uniformly pink colour. When the plate is iodised to a deep yellow bordering on rose, and is then bromised to a blue, it has attained great sensitiveness, and a curious thing is that it may be examined at this stage by a light sufficiently strong to entirely destroy it for photographic purposes, but the effects of which exposure are totally destroyed by holding it over the iodine fumes for a few seconds, when the maximum of sensitive-

ness is thus attained. When in the camera and the sitter is seen to have moved during the exposure the value of this will be apparent, for all that is necessary to undo the latent image is to step into the dark room and hold the plate for a second or two over the iodine, when it may be again exposed, the sitter not having left his chair during this bye-play. This is an advantage not to be lightly esteemed. Just here let us pause for a moment to say that some of the finest Daguerreotypes we have seen were made without proper iodine and bromine boxes, ordinary porcelain jelly or jam pots having been used as substitutes, the progress of the sensitising being watched by lifting up the plate and examining it directly.

The development is effected by exposing the plate to the invisible vapour arising from mercury which has been heated to a little over 100° Fahr. The hotter the mercury the quicker the developement, and *vice-versâ*. This discovery is said to have been made by Daguerre's having by the advent of evening placed a half-exposed iodised plate in a drawer over night, and finding in the morning that the image was visible, a search in the drawer revealing the fact that some globules of mercury previously therein had still found lodgment in the chinks. Proper developing boxes have a thin iron bottom with a cavity in the centre for the mercury into which a thermometer bulb dips, the tube of which is carried outside to a scale graduated from 100° to 120°. A spirit lamp placed underneath heats the mercury, and a small square of glass in front near the top enables the progress of development being watched, the plate being placed in a frame on the top and fixed at a slope. A yellow pane in one side permits the flame of a lamp or gas to illuminate the plate while development proceeds. It is here where the skill and experience of the operator comes in, for, if the development be carried too far or not far enough, the picture suffers.

The fixing is done with hyposulphite of soda; but, in course of considerable experience with the process, we found a rather weak solution of common salt answer rather better. All that is necessary with this latter agent is to immerse the plate in the solution and touch it either at the back or one edge with a strip of zinc, when the iodide will disappear like magic. The hyposulphite acts by dissolving the iodide, this by decomposing it. Without allowing the plate to dry, it is then rendered permanent by the application of gold. A soluble salt of gold, composed of hyposulphite of soda and chloride of gold (*sel d'or*) is applied to the surface after washing, enough being poured on the levelled plate to cover it completely. Heat is then applied underneath by the spirit lamp, when, curiously, the image darkens almost to disappearance, which will alarm the tyro; but a slight continuance of the heat causes the darkening to disappear and the image to stand out in a brilliance it did not formerly possess. The lights have now become much brighter, and of a peculiarly delicate pearliness, while the blacks have become intensified; and, whereas formerly the whites and all parts of the image could be removed by the feeblest touch even of a hair pencil, they are now so fixed as to be irremovable unless by polishing powder. Instead of effecting this by heat, it suffices to add a modicum of ammonia to the hyposulphite of gold solution, when the same result is obtained by time—say, ten minutes.

The brilliancy of the image may also be much improved by pouring on the surface a solution of chloride of ammonium and applying heat, by which the solarised portions, which otherwise would be of a bluish colour, become a pure white.

We recommend those specially interested in this suggestive and charming process to visit the rooms of the Photographic Society of Great Britain, and inspect Daguerreotype apparatus of the most approved construction, together with numerous beautiful specimens of Daguerreotypes, coloured and uncoloured, which are there on exhibition, where they will remain for the next month.

THE PERFECT FIXATION OF NEGATIVES.

Considerable stress has been laid upon the necessity for the perfect fixation of gelatine negatives, not only so far as regards the removal of the unaltered silver haloids, but also as regards their conversion into completely valuable bye-products that are capable of elimination by subsequent washing. In order to effect this, it is usually recommended and considered sufficient to allow the negative to remain in the hypo solution for a certain period after the apparent removal of the silver bromide, in order that the more soluble form of the double hyposulphite of soda and silver may be produced.

But there is one peculiar condition of the film, or it may be of the fixing solution, in which mere continued immersion fails to bring about the necessary clearance; and, as we do not remember to have seen special attention directed to this particular phenomenon, we take occasion to notice it here, on account of the increasing liability to its occurrence that the use of thick or double film entails. Most users of gelatine plates, particularly in the earlier days of their preparation when less attention was paid to the evenness of their coating than is now the case, will have noticed, and perhaps been puzzled, by the occurrence of a yellow or brown skin over a portion of the negative some little time after it has been printed from, although when first put out no such discolouration was apparent. In some instances where a more than usually thick corner or edge occurred, the fixation of that portion of the film would be unduly protracted; and, even after the disappearance of the insoluble silver salts, an opalescent appearance would remain in the shadows of the negative quite different from that of the haloid salts.

The phenomenon that we refer to consists in the presence of such an opalescent veil over the whole surface of the gelatine film however thin and even, and which remains even after a more than usually prolonged soaking in the fixing bath. We have noticed this peculiarity in years gone by, and studied it in connexion with certain brands of plates that seemed more prone to it than others, although even they were not invariably attacked by it. On the other hand, it has cropped up unexpectedly with plates that did not usually show it, and with scarcely any clue to guide us as to its cause. Finally, we have recently renewed an acquaintance with it in conjunction with the specially thick films that are now coming into vogue.

It is not, we would have it at once understood, the result of imperfect fixation in the ordinary sense, that is either from too short an immersion in the hypo bath or the use of too weak a solution or one that has become exhausted. On the contrary, if anything, it is more likely to appear with a strong and fresh solution than one that has been in use some time. Nor is it the result of precipitation in the film by the imprudent use of alum or acid "elimination," although in result the appearance is very similar. It seems rather to be due to the deposition in a partially crystalline or precipitated form within the pores of the gelatine of the products of the fixing operation, and in such a condition that temporarily they are not

readily acted upon either by the fixing bath itself or by plain water.

We first noticed the peculiarity some ten years ago, though without considering it a fault, in a particular brand of rapid plates. In these, after fixation, or rather after removal from the fixing bath, the negative presented the opalescent appearance in the shadows to such an extent that it almost seemed to have been treated with some semi-opaque varnish, and this effect was rather intensified than diminished by prolonging the fixing. But directly the plate was washed, especially if under a rose or tap, the veil disappeared, and the shadows became as clear as the glass itself.

Some time after that, we noticed a precisely similar behaviour on the part of some plates of our own make, the emulsion having been prepared by a peculiar modification of the ammonia process. Whether that circumstance had any bearing on the result we cannot decide, but it is a significant fact that it is chiefly with rapid plates, and since the introduction of the ammonia process of preparation, that the peculiarity has been noticed.

In our earlier experiences, as we have said, the opalescence disappeared entirely and without trouble in the ordinary course of washing; but, just recently, we have met with it in an aggravated form, in which simple washing has absolutely no effect whatever. In fact, we have a negative which, after washing for half an hour or so, was found to be veiled in this manner, and was returned to the fixing bath, but without result. No alum or other matter had been used, and, though nothing out of the usual way had occurred to cause such a result, we were inclined to set it down to a precipitation of lime in the gelatine. The plate was, however, well washed for several hours and dried, by which time a decidedly yellow tint pervaded it, and this, after a very short time in the printing frame, developed into a strong brown stain.

Now, at any rate, the matter began to assume a serious aspect, for we found several other negatives beginning to show similar symptoms. A fresh strong bath of hypo was made, and the result was decidedly worse. Believing that the temperature might be in fault, the bath was artificially raised to nearly 70° Fahr., when the veil was reduced, but did not wholly disappear. As before, neither prolonged immersion in the hypo nor washing effected any improvement, and we began to suspect the hypo; but this was from precisely the same stock that we had been using without trouble for a long time past, while it was only with the particular lot of plates that it acted in this manner! So we were forced to lay the blame, if blame there was, to the plates, and to seek a remedy.

After beating about the bush for some time, we found that the trouble arose mainly from the use of too strong a fixing bath; that is to say, that in increasing the strength of the hypo, in order to fix the thicker films within reasonable time, the other trouble was set up; in reducing the strength of the bath a perfect remedy for the opalescence was found, but then we had to face an inordinately protracted fixing. However, this difficulty was surmounted by fixing in the strong bath raised to the temperature of from 60° to 65°, and afterwards removing the plates to a much weaker solution of not more than three or four ounces of hypo to the pint of water.

Another remedy was subsequently found in the acid fixing bath, that is a solution of hypo containing free sulphurous acid. The particular bath we prefer is made by adding two or three ounces of bisulphite of soda to the strong bath of eight ounces of hypo to the pint.

Whatever the material may be that composes the veil, it seems to be mechanically combined with the gelatine in such a manner that the *dense* hypo solution cannot penetrate to remove it. Water has no effect, and it is only by reducing the strength of the fixing solution, and thus giving it greater penetrating power, that it is reached. The free acid, we assume, prevents the formation of the precipitate in the first place.

PHOTOGRAPHY AS A BUSINESS PAST AND PRESENT.

It is, we believe, generally admitted that photography, commercially, so far as regards portraiture, is at the present time in a very depressed condition. Any one conversant with professional photography during the past thirty years can recall a gradual sequence of events that have conduced to this more or less unsatisfactory state of things. It may, however, be interesting, if not useful, to our younger readers to refer to some of the points that have led to the depreciation of portrait photography as a business. Let us go back to the early days of collodion, say, to the time when it had generally superseded the Daguerreotype.

Up to about 1855 the collodion process was more largely practised for glass positives than it was for negatives. Then the price generally charged for a small positive was from half-a-crown upwards. Several houses who worked the negative process then charged from three to four guineas for a whole-plate portrait. This was almost invariably on salted paper, and slightly finished in monochrome. About this time a firm commenced business in the City, and made a speciality of whole-plate portraits on albumen paper for half a guinea, and copies at about three shillings each. Another firm followed soon afterwards with the whole-plate at the same price, and with the half-plate at five shillings, and the quarter at half a crown, with duplicates in each case at half price. These were then classed by some of the older houses as cutting prices. For some time after the *carte-de-visite* became popular, prices were well maintained—they varied from about twelve shillings to two guineas per dozen, and very large businesses were done at these rates, some establishments taking fifty and upward sitters a day. One house at the West-end we have in our mind did a large business in vignetted *cartes*, the price being a guinea and a half for six. Then *employés* all round were paid liberal salaries.

Perhaps the first real step in reducing prices was the introduction of the club system. This, as at first worked, was not so very objectionable. By contracting to take tickets for a dozen portraits—each of, say, twenty persons—a reduction of twenty or thirty per cent. off the regular tariff was made. Competition in this phase of the business soon increased, and eventually the recognised club system, with its enlarged coloured portrait, came into vogue in second and third-rate houses. *Par parenthèse*, this innovation has now culminated in the "Coupon" business, in which a dozen portraits each of four sitters are supplied for ten shillings. This was in the collodion days, and, as we have just said, *employés* were, as a rule, well paid, for they had to possess greater knowledge and ability than is requisite for analogous work at the present time. The plates had to be prepared at the time of using, and considerable skill—only gained by long experience—was necessary in the preparation of the chemicals and in keeping them in the best working condition. Consequently at that time experienced hands were seldom long disengaged.

Twenty years or so ago a good-class photographic business could be commenced with a much smaller capital than now, as then more modest furniture and fittings sufficed. Quality of work counted for more than the appearance of the appointments, and this led many operators to commence business on their own account, generally with prices below those of their former employers. Still, while collodion was the only process, trade, on the whole, notwithstanding competition, continued good and fairly remunerative to most engaged in it.

It is often said that, in the early days, the cost of material was higher than it is now. That is true, but only to such a trifling extent as not to make more than a penny or two difference in the cost of a dozen pictures; indeed, it is doubtful, if the cost of mounts and finishing is considered, if it was so much as now. Good plain white cardboard, with a plain black imprint of the artist's name and address, sufficed for the most expensive portraits. At the period when the highest prices ruled, retouching—an important item in the cost of portraits—was unknown. Hence it will be noted that when prices were at the highest the cost of production, except, perhaps, for labour, was at the lowest.

The introduction of gelatine plates has been of immense advantage to photography. Of that there is no question, but whether it has benefited it from a business point of view, as regards portraiture, is open to question. With a few months'—in some cases weeks'—practice with dry plates sufficient experience is acquired to enable some people to style themselves operators, and offer their services as such. Consequently, the labour market, as advertisements show, is much overstocked, hence reduced wages. Added to this, a system is largely prevailing of obtaining labour for nothing, or next to it, by taking "articled pupils," apprentices, and learners for a term of years, with a premium, at a merely nominal salary. This system is not confined to operators and printers, but extends even to girls for such subordinate work as mounting and spotting. This, of course, has not only brought down wages, but keeps experienced hands out of employment. It may, however, be mentioned that it is not the cutting houses that resort to this means of obtaining cheap labour, they find it more to their advantage to employ experienced hands.

The present unfortunate depressed state of business amongst portraitists is mainly brought about by the continued influx into the ranks of photography both of employers and *employés*. It has induced undue competition in every direction. Prices have been gradually reduced lower and lower, except, perhaps, in some few high-class establishments, that, unless a large business is done, they are no longer remunerative. Added to this, the demand for portraits is far more restricted now than it was some years ago. The contrast between portraiture as a business now and a few years back is great. How is it to be reduced?

Reducing Silver Chloride to the Metallic State.—In conversation with the chemist of one of the most important assay offices in the country, he informed us that, for showing this on a large scale, not for analytical purposes, he greatly preferred the use of iron to zinc. He found it most difficult to remove the last traces of the latter substance, while with iron he experienced no difficulty.

New Filter.—The *Scientific American*, a short while since, described a new filter which, though intended for water for potable use, would be equally serviceable for photographic purposes. It consists of a large porous tube made of exceedingly fine mineral flour; the water is filtered by passing through the minute pores of the cylinders into a compartment below it, into which the cylinder is fitted, the water passing from the outside to the inside of the cylinder. The latter, when beginning to work less freely, can be cleaned by simply brushing the outer surface. The filter as constructed for sale embraces an arrangement for holding ice to cool the water during filtration.

Testing for Bromine, Chlorine, and Iodine.—There is a useful practical note on this subject in the *Journal of Applied Chemistry*, by Mr. F. P. Dunnington, which gives the necessary routine in a nutshell. His process is as follows:—"From a solution acidified with nitric acid, precipitate the silver salts of these acids with silver nitrate solution. Having filtered off and washed this precipitate, test it in a test glass with a few drops of very dilute sulphuric acid on a bit of zinc. When the dark spongy mass of metallic silver is formed, pour off the solution of the zinc salts and examine it for iodine, bromine, and chlorine by the method of Professor Edward Hart."

Mr. Whipple's Successor at Kew.—The post rendered vacant by the loss of the Superintendent, Mr. Whipple, whose lamented death deprived science in general, and photography in particular, of a valuable helper will be filled by Mr. Chas. Chree, Fellow of King's College, Cambridge. It is "one for which," as *Nature* says, "the combination of high mathematical capacity with a practical experience of the apparatus and methods of physical research is especially needed. Mr. Chree obtained in 1884 the hitherto unequalled honour of a First Class in the most advanced parts both of the Mathematical and of the Natural Science Triposes, and he has since been much engaged at Cambridge in experimental and mathematical researches." It is, therefore, evident that the latest additions to the Kew examinations of philosophical apparatus—that of photographic lenses—is not likely to be of any the less value from his accession to office.

"Safety Paper" for Bank Notes, &c.—The *Paper World* does not take sufficient account of photography. We read in its columns that "the large and continually increasing demand for paper which cannot be duplicated by unauthorised parties for use in printing certificates of bonds, drafts, or notes, has led to the production of peculiar designs." It then goes on to describe a new patented process for making paper of this description which is said to produce designs of such infinite variety of configuration and shade that reproduction, except from the original plate, is practically impossible. The process is ingenious enough; it consists, in effect, of applying the inked faces of two lithographic or other surfaces, when varieties of more or less regular smears will be produced; and they can then be printed from to form the ground pattern. It will occur to any reader of this JOURNAL that such a pattern is one, above all others, that could be reproduced with absolute fidelity by means of photography, and in any colour.

Solution of Gold in Cyanide of Potassium.—The last issue of the *Chemical Society's Journal* contains the full text of Mr. R. C. Maclaurin's paper on this subject. The conclusions he arrives at are that, first, "the presence of oxygen is necessary to bring about dissolution; and, secondly, depends upon the strength, a remarkable fact being that the maximum amount lies between the weakest and the strongest solutions tried." It has been recommended that the gold from waste albumen prints might be recovered by the aid of cyanide, the prints being allowed to soak for some time in the solution, then pressed to expel most of the liquid, and the gold recovered by the addition of a suitable reducing agent. There is no doubt that a large amount of gold passes into the "hypo" solution used for fixing prints, and may be satisfactorily recovered, for we have seen assay notes for silver so reduced by eminent refiners in which the value allowed per ounce for the silver has been, on account of the gold present, almost ten per cent. "above" that given for the silver from chlorides.

MM. LUMIERE'S EXPERIMENTS IN "COLOUR PHOTOGRAPHY."

PENDING the publication of the precise details of the modification of M. Lippmann's plan, adopted by Messrs. A. & L. Lumière in their recent experiments in colour photography, the results of which have caused some slight commotion in Paris and elsewhere, the following particulars of the sensitive emulsion employed, which were supplied by MM. Lumière in a paper recently contributed to the Société Française de Photographie, may be of interest. The novelty, or point of departure, in the preparation of the emulsion consists of mixing gelatinous solutions of silver nitrate and potassium bromide, as recommended by Herr Valenta, of Vienna.

The emulsion was constituted as follows :—

A.

Distilled water	400 parts.
Gelatine	20 „

B.

Distilled water	25 parts.
Potassium bromide	2·3 „

C.

Distilled water	25 parts.
Silver nitrate	3 „

One half of A is added to C, and the other half to B, the silver solution then being added to the bromide.

The emulsion is then treated with a solution of a colour sensitiser, such as cyanine, methyl violet, or erythrosine, the plate being coated with the emulsion at a temperature of 40° C. When the plates are set, they are passed through a bath of alcohol, and are washed in water for a brief period, the films being very thin.

This method, according to Herr Valenta, obviates coarseness of grain, and gives a film of great transparency. A too great excess of bromide is to be avoided.

When the plates are dried, they are treated for two minutes with the following solution :—

Distilled water	200 parts,
Silver nitrate	1 part,
Acetic acid	1 „

which augments the brilliancy of the image and increases the sensitiveness of the plate, which, however, loses keeping properties. The plate is again dried, and exposed according to the method given by Professor Lippmann.

The developer employed by MM. Lumière is as follows :—

1.

Water	200 parts.
Acid pyrogallic	1 part.

2.

Water	100 parts.
Potassium bromide	10 „

3.

Ammonia	D = 0960 at 18° C.

The developer being thus mixed :—

1	10 parts.
2	15 „
3	5 „
Water	70 „

The importance of a standard solution of ammonia is clear, as the least variation in strength affects the results. After development the plate is washed and fixed in a solution of cyanide of potassium, 5 to 100. MM. Lumière say that a developer consisting of an ammoniacal solution of copper chloride has given them good results, but they have had to abandon it on account of its instability.

MM. Lumière added that in photographing coloured objects the ultra-violet rays were cut off, and the violet and blue diminished by placing in the path of the luminous rays, in the camera, a vessel with parallel faces, containing a solution of yellow colouring matter, such as Victoria yellow, uranine, or primuline. This was how they obtained the results that have been recently referred to.

AMERICAN NOTES AND NEWS.

Peculiarities of American Journalism.—The American journalists have a neat way of imputing to their rivals any departure from such a branch of ethics as takes cognisance of the coincidence of phrase with fact. One of our New York contemporaries, the *Photographic Times*, is in his current issue admonishing his brother who edits *Wilson's Magazine* for his mal-ethics in recording something of minor and local interest. He does not stoop to that directness of expression not unknown to or unpractised by some accredited journalists in the south and west of the American continent, and which provokes the rejoinder, "You're another," but mildly states that the flagellated rival is losing his sight and must be provided with spectacles. And why? Because they are not agreed as to the titles on a row of books in the background of a portrait, said titles being altogether illegible. It is the scene in the war between the Big-endians and the Little-endians (*vide Gulliver's Travels*) enacted over again.

The Philadelphia Exhibition.—There can be no doubt that the recent Photographic Exhibition in Philadelphia must have been a good one. The names of the competitors in the catalogue, and the critique in the *American Journal of Photography*—a model of terseness—assures us of that. It appears, however, that the exhibits from this country stood out in commercial contrast with those from America, inasmuch as a preponderance of the former were labelled "For Sale," whereas the latter were not; and it is said that the pictures of the two nationalities could be distinguished each from the other by this label alone without necessitating an appeal to the catalogue. But has it not long since been said of us that we are a nation of shopkeepers? It behoves us to speak quietly of the Customs Taxes levied in America on goods entered for exhibition, but which are at the same time "for sale." Of the twenty-six medals (silver) awarded, one went to Germany, while thirteen came to the United Kingdom, the other twelve being captured by Americans. The Photographic Society of Philadelphia are certainly entitled to the honour of having issued the finest and most ornate catalogue yet known in the history of the art science. It is adorned with six full-page illustrations by members of the Society.

The Photographers of America.—A firm of engravers and publishers in Chicago are about to prepare a work on the photographers of America. They anticipate that at least 5000 photographic artists will visit their city during the Convention of the Photographers' Association. It is to contain the portrait, name, address, and biography of every photographer who subscribes five dollars (1*l.*, payable in advance), who in return will receive a copy of the book, which is to be got up in the highest style of the art, printed on heavy enamelled paper, bound in gold and black, 12 × 9 inches in size, containing at least 400 pages and twenty full-page illustrations from prize photographs. Each photographer furnishes his own portrait and biography, the engraving being done at the expense of the Company. Three hundred and sixty dollars (over 70*l.*) are to be given in prizes for the best pictures entered for competition.

The Kodak Victory.—It is known that for some time past an important lawsuit has been going on in the United States of America. The Rev. Hannibal Goodwin, of Newark, N.J., claimed priority in certain processes in the manufacture of sensitive films as employed by the Eastman Company, and he went for the latter in the law courts, in one of which he gained the day. But the decision has been reversed by the Commissioner of Patents, who, it seems, has decided not to grant Mr. Goodwin his patent. Probably by this decision something like a million dollars will remain undisturbed in the coffers of the American Eastman Company.

METOL.

WITHOUT committing oneself to the absolute statement that the last new developer is better than anything before it, it is, perhaps, possible

to claim that it possesses good features that none of its predecessors do. I have tried most of, if not all, the modern introductions that have been intended to supplant pyro, but have not yet found the one that will, to my idea, do so. In metol I think we have the nearest approach to a developer possessing the same range and power as pyro, while it is undoubtedly free from the objectionable features of the latter, notably its dreadful staining proclivities.

It has, however, I think, one feature which will be considered by many a decided advantage over pyro, a feature which, although I am not a believer in "one-solution" developers, I cannot help recognising as having its value. I refer to the power it gives of modifying the character of the image by simply varying its strength without altering the proportions of its constituents. This is a quality possessed to some extent by pyro, and, indeed, more or less by all the newer candidates for favour; but in none, so far as my experience goes, is the range of power so great as in the case of metol. By varying the proportions of the stock solutions (where separate solutions are employed) as recommended in the formulæ issued with the metol, a great alteration can be made in the character of the image; but this is, of course, impossible where a one-solution developer is employed. In this case, however, if the stock solution be made of such a strength that, used alone or with a given proportion of water, it represents the highest degree of energy desirable, and with a given exposure renders the greatest softness, simple dilution with a further proportion of water will effect all that is necessary in the way of giving greater contrast.

As regards the necessity for the use of bromide, although I am always partial to a small addition even in commencing development, I think metol shows less absolute want of such addition than any other. For short or normal exposures, indeed, if the dish be well shaded during development, I can see little difference if the bromide be omitted from the solution until all the details are well out; at that stage, or where intensification begins, bromide is a necessity with every developer, but more especially with pyro. On one occasion, after mixing up a fresh stock solution of soda with hot water, I inadvertently applied the mixed developer in a quite lukewarm state, but the only effect was that the image appeared almost instantly and developed as rapidly as one on collodion. A strong addition of bromide, however, instantly checked it, and brought it within easy management.

Those who are not greatly enamoured of one-solution developers are more likely to take to the system with metol than with any other, for, strange as it may appear, repeated use to the extent of three or four times, at any rate, does not seem to greatly alter its action. But a better plan than relying on the single solution, where economy is to be practised, is to employ two separate developers, or one developer and one intensifier. Thus, say, half a dozen plates are to be developed, I would set aside one portion of developer sufficient, to cover the plate, with which to bring out the details of the picture, using it at its full energy. To another portion, in more dilute form, I should add a few drops of a ten per cent. solution of bromide, and use that as the intensifier, as it will continue to operate upon the image after the details are out without any further development.

This plan can be followed either with single or separate stock solutions, and, if only half the work of finishing the negative be thrown upon each of the two working solutions, they will hold out very well for half a dozen developments, provided always the exposures have been sufficient. In my own way of working, I prefer to use a fresh quantity of solution for each plate, and this I apply at full strength—*i.e.*, the fullest working strength—until details are out, and then dilute it according to the appearance of the image, adding promide as the action proceeds. The latter must be carefully used, as it is very powerful in stopping the action of the solution on the finer details, and if added in excess will produce hardness.

The published formulæ for use with metol are rather puzzling in their nature, but may be greatly simplified. I take it that for normal development from two to three grains of metol, and about twenty grains of carbonate of soda to each ounce, form suitable proportions. If a stock solution of metol containing six grains of that substance and a drachm of sulphite, and one of soda crystals containing two ounces to the pint, be used, they may be conveniently mixed to form any desirable combination. Let the stock solution be :

A.

Metol	120 grains.
Sulphite of soda	1200 grains.
Water	1 pint.

B.

Soda crystals	2 ounces.
Water	1 pint.

For normal development use equal parts, and add a little water if the subject is one that wants contrast. For under-exposure use more of A than B, and *vice versâ*, bromide also being added in ten per cent. solution in the latter case.

A single-solution developer, where such is preferred, is made as follows :—

Metol	120 grains.
Sulphite of soda	3 ounces.
Soda (crystals)	2 „
Bromide of potassium	10 grains.
Water	20 ounces.

One part of the above diluted with an equal volume of water forms the normal solution, more or less water being used in proportion to the length of exposure. W. B. Bolton.

JOTTINGS.

To call an exhibition of photographs a "Photographic Salon" is a piece of affectation bordering on snobbishness. To add another to the already plethoric number of photographic exhibitions that are held in the autumn in and about London invites and deserves failure. To run an opposition show to the Photographic Society's Exhibition practically at the same date and only about 500 yards away is the mean revenge of a vindictive clique still smarting under their whipping of two years ago, and made furious by the circumstance that the Society they deserted is getting on better without them than with them. To say that the photographs to be hung will be of "pictorial merit" only, and will be selected by a Committee, chosen, of course, by those we can all easily guess at (with power to add to their number), and that therefore "the puhlic" will have an opportunity of seeing "the best productions of photography from a pictorial point of view," implies that no such opportunity has before been given to "the public," which is untrue.

Habitual readers of these "Jottings" will remember that I foreshadowed the "Photographic Salon" last August—nay, even gave the name of the street in which it is to have its home, Piccadilly. On one point connected with it I was, however, wrong—namely, as to the medals. There are to be no awards, it seems. But, to make up for their absence, I know what will happen. The organizers of the Salon will pay special attention to the representatives of the lay press, and trade upon their ignorance to secure effusive and puffy notices, so that the public may be deluded into the belief that the Salon really has a monopoly of the "best productions of photography," and this of course will send up the commercial value of the pictures, arrangements for the sale of which will be made "at a commission of fifteen per cent." I wonder who will do the *Times* notice? Mr. Maskell?

That the Photographic Salon is a deliberate and carefully planned attack on the Photographic Society's Exhibition nobody can deny. This is a free country, thank goodness! and I am sure the Society and its friends are not the people to be dismayed by a little opposition, so long as it is of a fair and legitimate nature. But that of the Photographic Salon is not. The support which the malcontents and their satellites are giving to it is a thing which causes no surprise, but there are many other persons on the Committee whose presence there I cannot understand, except on the ground that the Society, according to their ideas, *has* neglected "pictorial merit," and has *not* shown "the public the best productions of h ography from a

pictorial point of view," a proposition which, of course, is absurd. Hence the Society has a grievance at seeing so many of its best men in league with its enemies, and I therefore beg to invite the various members of the Photographic Society of Great Britain who are on the Salon Committee, to explain to the photographic public how it is that, having themselves been successful exhibitors, or judges, of the Photographic Society for years past, they are now supporting a rival show whose only claim to attention is the coolly impudent way in which it is trying to arrogate to itself the right or duty of taking "pictorial merit" in photography under its wing? The attitudes of these gentlemen are so equivocal that explanation is almost imperative in the interests of their own reputations.

"Audacious Operator," in the JOURNAL for April 28, does me the honour to ask me for a "critique to the point" on the question of the determination of the speed of plates, and at the same time he points out with some force that the sensitiveness of a plate probably varies with its age, but that the speed number originally given to it remains. The vastness of the subject deters me from attempting to tackle it in the course of a single paragraph, and I can therefore only deliver myself of a brief reference to it. By far the larger quantity of dry plates made are manipulated by professional photographers and habitual plate-users, among whom I fancy the only kind of plate speed required is uniformity of rapidity. Let a dry-plate maker send out plates which do not appreciably vary in speed and quality, and the photographer will be quite content to work them without the assistance of speed and sensitometer numbers. It seems to me that the adoption of different speed numbers for each batch of emulsion made puts a premium on irregularity of rapidity without assuring that the relative rapidities with which the plate boxes are marked will be confirmed by the camera test. Thus it is conceivable that a given brand of plates may, within the space of a few days, possess half a dozen degrees of sensitiveness, and be put on the market by the maker without a pang, whereas in pre-Hurter & Driffield days he might have hesitated to use an emulsion which showed an appreciable decrease or increase of sensitiveness for a plate of standard rapidity. Both sellers and buyers would, I fear, be likely to be confused by the multiplication of speed numbers which would follow upon the universal adoption of the Hurter & Driffield system, which, however, is not likely to happen yet.

I must thank Mr. H. W. Peal for his courteous reply to a former jotting of mine, asking for evidence upon which he based a statement that amidol allowed one to reduce the exposure to about one-third that required for pyro. It seems that Mr. Peal was not comparing the two developers for general work, but for very slow plates used for copying, the pyro developer against which amidol was pitted being, he says, very well restrained, the amidol having only a very small quantity of bromide. This, of course, is no comparison, and had Mr. Peal been reported in the sense in which he writes I should not have commented in the matter. Amidol will no more allow a photographer to successfully give a third of the exposure required with pyro than hydroquinone, as claimed upon its first introduction a dozen years ago, will allow him to give one-half. I have proved both statements wrong by simple experiments; and as regards amidol—which possesses many good points, especially in rapidity of working, suitability for bromide paper, and possibly some advantage in bad cases of under-exposure—the opinion I expressed a month ago as to its not allowing one to reduce exposures for pyro two-thirds is curiously confirmed by one or two speakers in your report of the meeting of the London and Provincial Photographic Association for May 4, which is given on page 301, May 12.

In pointing out that a plate which has been simply exposed in the camera and, without development, fixed, leaves a deposit which may be intensified as it were by acid development, Mr. Hermann Schnauss, in his paper on *Physical Development*, suggests the equally interesting fact of the known difficulty of entirely destroying the developed image in a plate. I have applied all kinds of reducing solutions to gelatine negatives without obtaining perfectly clear gelatine free of some kind of deposit which did not admit of slight accretion under intensification. An image of some sort remains behind, the precise nature of which is open to doubt, although it is possibly a compound of gelatine and silver. This opens up a field for speculation as to whether development is responsible for the whole of the deposited image, or whether the exposure does not at once reduce a portion of the haloid to metallic silver in some unfamiliar form, which at once enters into combination with the gelatine, the development of the sub-salt acting as an intensifier of the original image, to which the term latent is therefore a misapplication. At any rate, the undoubted presence and persistence of the undeveloped and developed impression in a plate seems to me to be a point worthy of notice in any theory which seeks to explain the nature of the photographic image.

The idea of the Manchester Photographic Society in providing a large camera, with the "usual trimmings," for the use of members, on the co-operative principle, is one that other Societies might adopt. Most photographers at some time or another feel the want of a large camera, and, if it could be obtained from their Photographic Society, the small fees charged would help to pay for its cost. Optical projection and enlarging apparatus are also things which every amateur cannot afford to possess himself, and for the loan of which he, no doubt, would be willing to pay a fee to his Society. When such things are wanted, they are wanted badly. Certainly Photographic Societies could do worse than add to their attractiveness and usefulness in such a direction. As regards a large camera, I should think it only the correct thing for a Society to possess a camera of its own for official use, as, in case an exposure by artificial light is desired to be made, it is a handy thing to have. Might it not also be an inducement to beginners to join a Society in which a camera was kept with which they could take their first plunge into the small sea of troubles which photography has in store for all its votaries? A further addition to the usefulness of Photographic Societies would be the general adoption of a systematic plan of laboratory and field instruction for novices, such as I am glad to see put in practice by the North Middlesex and other Societies.

I rub my eyes at reading a complaint of frilling in your last number. I do not think that Mr. Lambert's suggestion that the evil of which he has had such recent experience, after all of us had grown to regard it as a thing of the past, can be, except in extreme cases, due to the cutting of the plates. Otherwise every quarter, five by four, half, seven and a half by five, and the many intermediate "odd" sizes issued from the manufacturers would be open to suspicion on that account—an idea which does not hold water. COSMOS

SELECTIONS.*

THE SKY PORTION OF A LANDSCAPE.

WE will now consider the treatment of the sky portion of a landscape. Many photographers capable of doing most excellent work content themselves with turning out prints with white, or only slightly tinted, skies, instead of supplying proper cloud effects. The trouble of adding these is so very trifling, in comparison with the improvement they effect, that I am surprised not to see them more universally adopted than they are. Cloud negatives themselves are very easily made, although there seems to be a genuine and wide-spread idea that cloud photography requires some special skill, different from the usual kind. Given clouds, it is quite as easy to photograph them as anything else, perhaps more so. The only *imperative* condition is *absence of haze*. A white dress, covered with white lace, is infinitely more difficult to deal with; only, start fair, knowing the kind of negative wanted, which will be a thin one, with good contrasts. Stop the lens down to *f*-64, use a moderately slow-backed plate, and give about half a second exposure. Use a well-restrained developer, and the thing is done. A very rapid plate, with a drop shutter exposure, will *not* produce such *suitable* negatives *for printing-in* skies as the slower process.

Plates containing iodide are to be preferred. One precaution is never

* Concluded from page 314.

to have the sun itself visible on the negative unless covered by clouds of more or less density, or something equivalent to them. If a sun or moon is wanted in the picture, put a small, round, opaque spot on the negative to do duty for it, using artists' licence as to the size, which will be two or three times as large in proportion as it would be if photographed. Moreover, with the sun full on the lens, there is generally fog or a patch of blurring in addition, quite spoiling the negative. Clouds, although less effective as "cloud effects," are more useful for printing in if taken looking *away* from the sun, and at the same time more appropriate, the majority of landscapes being more often than not lighted at varying angles from one side or the other, and not from the front. In a great many negatives the sky is so cut up by foliage that mere indications of clouds are sufficient, and if the lighting of them is different to the landscape, unless it is very pronounced indeed, the error would rarely be noticed, if at all. I am afraid I lay myself open to a wigging for making such an assertion; at the same time, I believe it to be a fact. If we are to be so critical in respect of clouds in a photograph, why not be equally so of those in a painting? Artists of the brush and palette I am afraid err as much as those of the camera in this respect.

In close connexion pictorially with the sky in the photograph is water, especially large sheets of it. If it happens to be still with a good reflecting surface, only sky reflected in it, the clouds should be printed on it *lightly in reverse*—that is, by turning the negative over and printing from the wrong side—but in proper position with regard to those clouds of which they are supposed to be reflections. If only a small patch of water comes white in the print, that can be rubbed down with spirit or a tint printed on, for a white spot of that kind is always an eyesore. Rubbing down or tinting will harmonise it with the rest of the picture.

Exposure and Density.

"Exposure and density" has been a somewhat contentious subject, so I will say little about it more than that a *full exposure* for all general work gives us better results than we can *possibly* get with the least under-timing. A negative, perfect from a chemical point of view, does not always produce a print perfect, in an artistic sense, with respect to atmosphere. I have an idea that the best prints are *always* from *slightly* over-exposed negatives, from the pretty negative point of view. It is a popular fallacy that by *fully*, not over, exposing a landscape the distance is buried. In an under-exposed negative, this *is* generally the case if the detail in the darker parts is properly brought out. The time of development necessary to get out detail in these shadowy parts does assuredly over-do the distance; but in a well-judged exposure the detail in the foreground (unless in exceptional cases) comes up nicely with the distance, and the harmony throughout is retained. In some cases brush development is exceedingly useful, and indifferent exposures may be made to pass by its judicious use. Few rules have no exceptions, and in this matter, if a slight haze exists at the time of taking the negative, a shorter exposure is warranted. The least over-exposure under *such* conditions would be undoubtedly a mistake, tending to over-density in the distance.

Development.

A word or two about development. A good estimate of the quality of a developer is that it shall with the *least density*, or rather opacity, *print the strongest image*. The developer that comes nearest to this standard is the one to choose, for I prefer that the printing qualities shall chiefly depend on the colour of the image rather than on its opacity. Some negatives of a very non-actinic colour are quite ghostly in appearance, and yet produce the most charming prints. There is, in fact, a softness, richness, and brilliancy in such prints that is quite unapproachable by any other class of negatives; moreover, such *clichés* lend themselves to almost all processes better than other kinds. In development I prefer flooding the plate in the first instance with the developer minus the alkali, adding this afterwards a little at a time, according to the effect produced, my favourite mixtures being pyro-soda for indoor work, and pyro-ammonia for outdoor. For very dark interiors rodinal is, I think, as good as anything I have tried; it had rather the advantage in a competitive trial with ammonia on an ill-lighted room, half an hour being given to each exposure. It produced more detail in the shadows than the ammonia did. The chief objection to the amidol and cikonogen class of developers is, they have to be made *apparently* denser than they ought to be with pyro developers for a standard, and lose some printing delicacy in consequence, as well as being somewhat deceptive as to their printing force.

Reduction in the Hypo Bath.—Some interest has lately been exhibited in the effect on bromide prints of prolonged immersion in the hyposulphate bath. Reduction will take place in a *negative*, irrespective of the developers, if the plate is left soaking for some hours in it. I have several times found soda and ammonia and pyro images *almost entirely obliterated* by leaving them all night in the bath. At the same time, I have let similarly developed negatives remain quite as long in it with scarcely any alteration of density. Why some should fade and others remain unchanged I am unable to say authoritatively, but in all probability the bath was stronger at one time than the other, for with the hypo bath, so that it was sufficiently strong to fix in a moderate time, I have never considered the strength of much importance.

Halation.

The subject of halation or blurring has also been to the fore of late and is a matter to which I have been obliged to give considerable attention, especially since the advent of rapid dry plates. I think you will agree with me that this fault has increased in ratio with the sensitiveness of the films. With *highly sensitive* films, *no* precaution that I know of will altogether prevent or even mitigate it if the subject is highly reflective or possessing strong and abrupt contrasts. Having at one time or another had considerable experience with interior work, to which I am very partial, I do not think I can over-rate the importance of securing plates and conditions as little liable to this fault as possible. There is no doubt that careful development will mitigate the trouble, but given a very rapid bromide plate, and a subject of a trying nature, neither development, backing, nor anything else, so far as I know, will prevent it. On this account I prefer a rather *slow plate, containing a fair amount of iodide*, as best for such subjects, and calculated to give as great a freedom from blurring as we can hope to get. It seems to me that a thick film *unless heavily charged with silver salts*, is worse than a thin one, because there is more probability of, and opportunity for, lateral dispersion of the light in the film itself. Rapid films, from their colour and coarseness, favour blurring. The wider separation of the opaque particles in a transparent, or semi-transparent, medium, like thick gelatine, permits of an easier infiltration of the light through its substance than the finer and more dense conditions of the bromide, and therefore slower films.

If blurring depended entirely on reflection from the back of the glass, then a good backing would be a certain cure in all cases, which we know from experience it is not. Many plates of considerable density and yellowness without any backing are almost free from this fault, for the reason just stated. An additional drawback to very rapid plates is their tendency to *reversal*, a more annoying fault, if possible, than blurring; it does not appear so unsightly on the negative, for the image remains clear and distinct, and, unless in some conspicuous place, may be overlooked, but in the print there is no fear of this oversight. I have had some otherwise excellent negatives ruined by it, for they set doctoring at defiance, unless of the most elaborate description. When plates are very prone to this effect, they are useless for *good* interior work, and so for many reasons I prefer to work with a plate of only moderate rapidity, and think better general work is obtained on them by far than on those of the very rapid.

Edward Dunmore.

COMPOSITE HELIOCHROMY.

[A Second Paper on Photography in the Colours of Nature, read at the Society of Arts.]

The heliochromoscope was first publicly exhibited one year ago in London, before the Royal Society, the Royal Institution, and the Society of Arts, in connexion with demonstrations of the process of composite heliochromy upon which I have been working for several years. As was explained in my paper of May 25, published in the *Journal of the Society of Arts* of May 27, 1892, the heliochromoscope and its triple photograph, or chromogram, are calculated to reproduce the colours of nature as readily as the stereoscope and stereogram reproduce binocular perspective.

The photographic process by which the colours of nature are reproduced, was perfected in theory nearly five years ago, and its capabilities were demonstrated at a meeting of the Franklin Institute, in Philadelphia, in November 1888. In order, however, to operate the process advantageously, it was necessary, not only to provide a special optical lantern for superposing on the screen the three images of the chromogram, but also a special camera which would enable the triple negative to be made by the exposure and development of a single sensitive plate, as in ordinary photography. I designed such a camera in 1891, and by means of the heliochromoscope, a modification of the camera, by which the three images are blended without either lantern or screen, I reduced the method almost to the simplicity of stereoscopic photography.

Owing, however, to certain inherent defects in the photographic negative-making process, which have long been known to affect the rendering of gradations in monochrome photography, and, therefore, must also affect the colour-rendering, I have since given much study to realisi

the most favourable conditions for reducing such defects to a minimum, and to defining the nature and extent of the limitations which they impose. Much experiment has also been devoted to overcoming other difficulties which I shall mention, and, although a truly astonishing illusion of nature is realised in the heliochromoscope, I estimate that it may take another year to carry out all the experiments, and make all the measurements necessary to enable me to finally demonstrate the capabilities, and accurately state the limitations of the process, and to publish complete and satisfactory instructions for operating it.

Meanwhile, having been called to London on business of another kind, the Council of the Society of Arts honoured me with an invitation to "report progress."

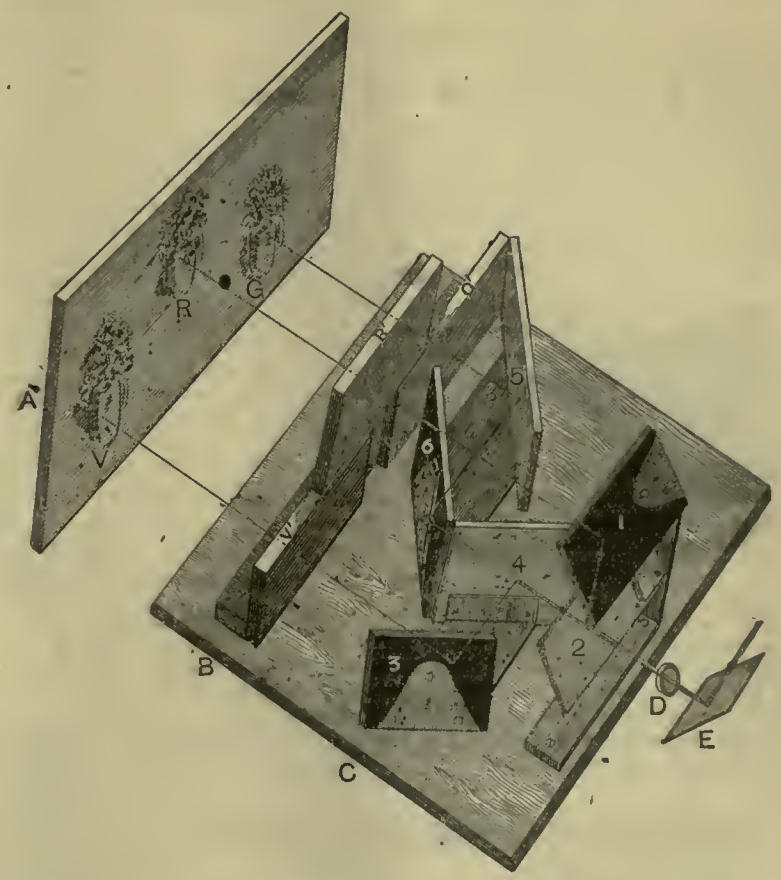
As was fully explained in my paper of last year, my own process of composite heliochromy consists, first, in the production of a triple photograph, to represent the effect of light from the object upon the three separate fundamental colour sensations, in accordance with the Young-Helmholtz-Maxwell theory of colour vision; and, second, in the blending of the three images into one, either optically, by means of the triple lantern or the heliochromoscope, or otherwise, by the superposition of three transparent colour-prints. Although the three fundamental colour sensations are red, green, and blue-violet, the three images of the triple photograph are not made through red, green, and blue-violet glasses, nor by the action of red, green, and blue-violet rays, but each by the joint action of all rays that have power to excite the respective fundamental colour sensation. Not only do the red rays, but the orange, yellow, and yellow-green rays also excite the fundamental red sensation; the orange rays affect it even more powerfully than the pure red. The photograph, to represent the effect upon the red sensation, is, therefore, made by the action of all these rays, and in due proportion, in accordance with Maxwell's measurement. The photographs of the green and blue-violet sensations are also made by the joint action of rays of various colours, in proportion to their power to excite the respective fundamental sensations, according to the measurements of Maxwell and Abney. But, when the images of the triple photograph are blended into one, by means of the triple lantern or the heliochromoscope, the photograph of the red sensation is illuminated by red light only, the photograph of the green sensation by green light only, and the photograph of the blue-violet sensation by blue-violet only. In other words, the three images of the chromogram represent the action of all incident light upon the respective fundamental colour sensations, and the light by which each image is illuminated in the lantern or heliochromoscope represents the sensation itself. The result of blending into one the three images of the chromogram—each being illuminated by the kind of light intended for it—is a faithful reproduction of the object photographed, in all its subtleties of light, and shade, and colouring.

Last year my projections on the screen were made with the lime-light, the performance of which was very unsatisfactory to me in comparison with sunlight projection which I had employed at my house in Philadelphia. Now I am provided with a lantern adapted for electric light, and will repeat my demonstration with it before proceeding to describe the colour-camera and heliochromoscope. In this lantern a single arc electric light is the source of illumination. After being collected by a condenser system in the usual manner, the light from the arc is sub-divided into three portions by means of a system of mirrors, some of which are transparent, so as to both reflect and transmit light, substantially as in the heliochromoscope camera, which I shall describe later on. In the path of each divided beam of light is placed a smaller condenser and a colour-screen; in front of these a chromogram; and then the objectives by which the images are projected and superposed. This device differs from all others that have been proposed for the purpose, in that the disc of light on the screen remains white when the electric arc varies its crater. The systems formally proposed for use with a single light would be quite useless under such conditions.

I commence by demonstrating the production of white light by mixing the red, green, and blue-violet rays. In the heliochromoscope the intermediate rays—the yellow and blue-green—are entirely suppressed, only comparatively narrow bands of red, green, and blue-violet showing if a spectroscope is applied to the eyepiece. The colours that I am now using in the lantern are not quite so pure; the spectroscope shows broader bands of colour, but they are still separated from each other by darker bands in the yellow and blue-green parts of the spectrum. With these screens the illumination is sufficient for projections of moderately large size, and the colours are pure enough to demonstrate the fact that the red and green light mix to produce yellow, and that the addition of blue to the yellow makes not green but white. The insertion of one of the chromograms shows that the infinite variety of the colours of nature can be obtained by the intermixture of the three colours, red, green, and blue-violet, in various proportions.

Scientists have known these facts about the mixture of coloured lights for a long time, but I take advantage of every opportunity to repeat the demonstration, because many people still doubt the facts.

I must also take this opportunity to again emphasise that it would be quite impossible to obtain any such result as that now shown with any



system employing the same colour screens both for photography and for projection, as was advocated by all other writers upon this subject previous to my publications in 1888. The science of composite heliochromy cannot be understood without knowledge of this fact, which I have repeatedly pointed out and explained, but which certain well-known writers have, nevertheless, persistently ignored.

The subjects that will now be projected upon the screen will illustrate the capabilities of this system of colour-photography, as adapted to lecture illustration, better than was possible with the lime-light lantern used here last year.

The illusion of nature will be found even better in the heliochromoscope than on the screen, because the colours are purer, and the illumination is better.

The method of superposing three images upon a screen, by means of three separate objectives, is sufficiently known, and need not be described in this paper. The system employed in the heliochromoscope is not only a very different one, but, I believe, quite different from anything else that has ever been suggested. I shall try to make it clear by reference to a diagram, showing the construction of the perfected instrument.

A is the chromogram, B, C a removable baseboard, carrying the colour screens, B, and the mirror system, C. D is an achromatic objective lens, and E a silver mirror.

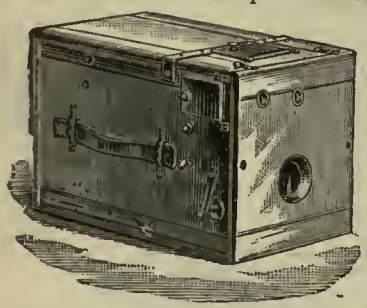
Light transmitted by the image of the red sensation, R, passes through the [red colour screen, R', to the silver mirror—1, downwards to the transparent mirror, 2, and forwards (except the portion which passes through the transparent mirror and is lost), through the objective, D, to the inclined mirror, E, and upwards into the eyepiece, under which a rednced image is formed by the objective, D.

Light transmitted by the image of the blue-violet sensation, V, passes through the blue-violet colour screen, V', to the silver mirror, 3, sideways to the transparent mirrer, 4, forwards through the transparent mirror, 2, and objective, D, to the inclined mirror, E, and upwards into the eyepiece under which a blue-violet image is formed, exactly coincident with the red image. That portion of the light which passes through the transparent mirror, 4, is lost, and also that which is reflected downwards by the transparent mirror, 2. F. E. Ives.

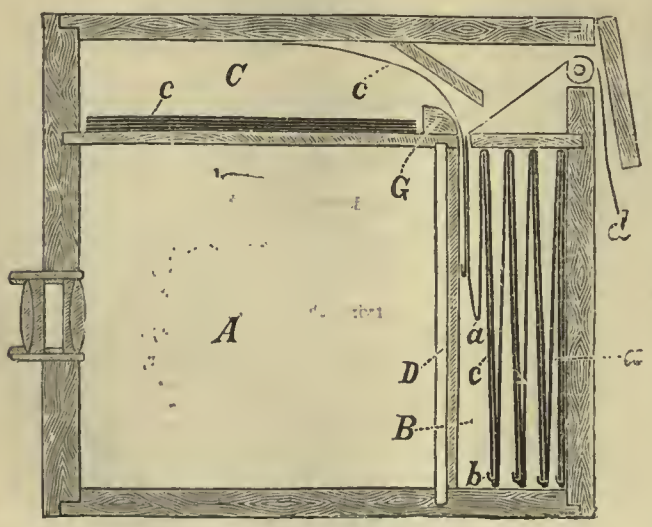
(To be continued.)

MARION'S NEW SUMMER AND SEASONABLE NOVELTIES.

On the occasion of a visit to Marion & Co.'s, Soho-square warehouses, we were shown a hand camera the invention of Dr. Krugener and possessed of excellent features. Numerous are the inventions that have been introduced to solve the problem of the transference of sensitive films to the camera and their exposure with the maximum of certainty and the minimum of risk and trouble. This is claimed by the firm to have been attained in their Simplex Film Camera, an external view of which we here give, and in which provision is made for bringing fifty films into the field, transferring them to the focussing plane of the camera, and, after exposure, storing them in a reservoir, where they remain secure from the action of light. In what way all this is accomplished we shall endeavour to explain.



The films are cut to the size required and are flexible. A long band of opaque paper is provided, and is folded to the size of the plate. At certain intervals there are narrow slips of paper pasted on the band, underneath which one end of a film is slipped. The band is then folded zigzag fashion, a, b, c, when the second of the series of paper slips comes to the proper place for receiving another film, which is retained *in situ* by a repetition of the folding of the band; and this is repeated until the whole of the fifty films have been put up in a packet, which is then inserted in a recess at the back of the camera. Meantime, the front fold of

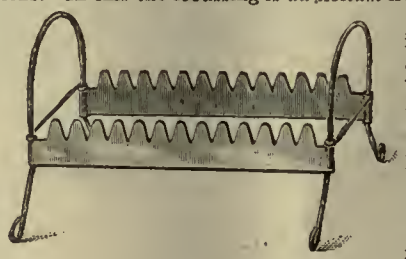


the band has been passed over a roller, and brought out through a slot behind ready to be grasped by finger and thumb. The exposing or focal plane is a plate of opticlly worked glass, and by means of a spring behind the package is pressed against it. On drawing out the projecting end of the band D, the first of the series of films is brought up, hard pressed against the glass focussing plane, B. After expoaure, D is pulled, when the exposed film, C, rises, and, caught against the sloping cover, falls forward and flat down into the reserve, C, above. A continuation of the pulling at D results in the next film in the series replacing the previous one, and in due conrse it, too, is deposited on the antecedaneous pile, C. This goes on until the last of the fifty films have been exposed and lodged in the chamber above, when the services of a dark room or a changing bag must be had recourse to in order to affect the depletion of the chamber C and the refilling of chamber B. The other parts of the camera, its lens, shutter (time and instantaneous), focussing details, and other matters, including its two finders, its level, the means for applying tension to the shutter spring, can be easily conceived of. The stand is a species of alpenstock, the limbs of which are jointed a few inches from the top, and which when expanded yields a flat solid table on which to place the camera, with a mechanical contrivance for enabling it to be pointed upwards or downwards when the ground is uneven. This stand, we may observe, is adapted for other cameras than this.

The Radial, a camera of Marion & Co. has developed into half-plate size, its dimensions being $15\frac{1}{2} \times 6\frac{3}{4}$ wide and $7\frac{3}{4}$ deep. As those who have seen it know, it holds twelve plates, any one of which may be exposed at will, and after exposure may be returned to the place from whence it came. An addendum to this system consists in having an additional set of sheaths, which may contain quarter-plates or any size intermediate up to those for which the camera has originally been adapted. This gives an additional power to the holder of this new size, in which the greater is thus made to include the less.

We were shown a large quantity of the fixing and developing cartridges of which we spoke in a recent issue, and which we are told are being much demanded.

We were also shown an exceedingly low-priced hand camera, "The Alphoto," the prices of which commence at 8*s.* 6*d.* each, with achromatic lens. In this the focussing is *ad libitum* from two yards to infinity.



The Collapsible Plate Rack is one of those handy pieces of apparatus that occupies but little space when folded up, but when expanded it affords space for a dezen plates being racked np for drying.

The foregoing cut shows the rack so well as to render further description unnecessary. It will prove convenient to pack away amongst one's travelling impediments.

A very pretty and simple way of storing and displaying negatives or transparencies was brought under our notice. It consists of a series of sheaths hinged together, capable of being folded up in small space, or of being in a moment opened out, so as to show the negative or transparency at a glance. This form of putting up negatives certainly must approve itself to those who in the rush of business desire to pick out a negative or transparency at a moment's notice. It is only necessary to undo the fastening, when at once the whole contents are displayed for examination.

In the rooms devoted to frames and mounts, we might well feel excused from breaking down altogether in our powers of note-taking. An exceedingly beautiful example of the adaptation of English-dressed antelope skins, made up as frames with corner piece and entourages in silver, are without doubt the most elegant forms we have seen in which photographs can be set. These range in sizes from *carte-de-visite* midget up to panel. We also saw close imitations of the above in other skins, mounted both in silver and in imitation, at a much lower price of course.

We have already, some time since, spoken of a series of artistic prints specially made by Downey which were sold at a marvellously low price (eight shillings a dozen). A third series of these, of larger size, 19 × 16 net size of print, is now in course of preparation, and is expected to be ready in a month. From the specimens we saw, we would suggest their great utility in the show-room.

In this department were also to be seen antique miniatures, which consisted of carbon opals, painted and unpainted, in those old-fashioned flat ebony frames of a former period. These ought to be useful to portrait photographers; ivorine frames and easels suitable for every class of pictures, and made in sizes from cabinets upwards; also an

Excelsior Album with specially thick mounts, but which, alas! will not be on the market for two months yet. We must not, however, omit to mention a series of direct sepia platinum prints, by Edwards, of English historical buildings, nor of a large variety of designs for Birthday, Christmas, and New-year's mounts, folding and plain, in which artistic and mechanical genius has been laid extensively under contribution. If these, and quite a large number of chaste and elegant forms of mounts for every size of portrait, and in every variety of tints, including some quite new, do not give a fillip to business, we know not what will.

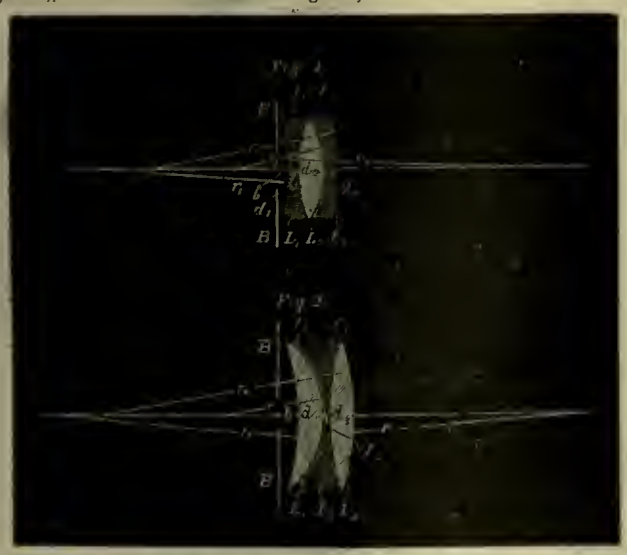
PATENTS COMPLETED.

IMPROVEMENTS IN PHOTOGRAPHIC LENSES OR OBJECTIVES.

No. 4692. PAUL RUDOLPH, Carl-Zeiss-strasse, Jena, Saxe-Weimar, Germany. *April* 22, 1893.

THIS invention relates to photographic objectives, and its purpose is to remove the indistinctness of the marginal portions of the image by reducing, as much as possible, the "astigmatic" aberration. As indicated by their name, these aberrations are caused by "astigmatism," that is to say, the property possessed by the rays of an oblique pencil of light transmitted through an objective of not uniting in one and the same point the rays lying in the primary or meridional section of such pencil uniting in one point, and the rays lying in its secondary or sagittal section uniting in another point; or, in other words, the focal length of the rays in the primary section differs from the focal length of the rays in the secondary section. Thus are formed two partial focal points. The distance of these two partial focal points, or the difference of the two focal lengths, is called the "astigmatic difference." The latter is termed positive when the focal length of the ray in the primary section is greater than that of the rays in the secondary section, and it is called negative when the focal length of the rays in the secondary section is greater than that of the rays in the primary section.

As it is possible to so compose or construct lenses as to cause them to manifest a predetermined astigmatic difference, either positive or negative, this astigmatism supplies in itself a means for obviating its prejudicial effects. With this object the objective can be constructed with two distinct or separate lenses, or systems of lenses, for example, one of which is so composed as to produce a positive astigmatic difference, whilst the other is so arranged as to give rise to a negative astigmatic difference, the said two differences being caused to neutralise each other. Such a double objective, or "doublet," as it is called, is described in the Specification annexed to British Lettera Patent, No. 6023, dated April 21, 1890. In this double objective the correction of the said astigmatic aberrations is obtained by combining an achromatic lens, the positive member of which, being the collecting lens, is made of glass having a higher refractive index than the glass of its negative member (that is to say, the dispersing lens to which it is cemented), with a second achromatic lens, the refractive indices of the two cemented members of which are contrarily graduated. The neutralising effect obtained by this reversed or inverted composition of the members of a doublet relatively to the astigmatic aberration is principally dependent on the fact that, in virtue of the said combination, the inner surface, or "surface of union," in the one member (that is to say, the surface on which the component lenses of the member are united together), is caused to act as a collecting lens, whilst in the other member the



surface of union is made to act as a dispersing lens, and so with regard to the influence upon the focal length, as well as upon the spherical aberration of the respective member.

Now, the present invention consists in a new organization or combination of achromatic lenses, whereby the same neutralisation or correction is brought about within a single system of lenses cemented together. For this purpose the system is composed of three individual lenses, in such a manner that the inner member is a collecting lens, and has cemented to it on each side a dispersing lens, one of the latter having a greater and the other a smaller refractive index than the collecting or intermediate lens, or that the said inner member is a dispersing lens and the said two outer members cemented thereto are collecting lenses, one of which has a greater and the other a smaller refractive index than the dispersing lens situated between them.

It is evident that by means of either of these two combinations one of the inner surfaces, or "surfaces of union," produces a positive refraction, that is to say, the effect of a collecting lens and the other union surface a negative refraction, that is to say, the effect of a dispersing lens.

In the annexed drawing, examples of the two new arrangements of triple lenses are represented in section in Fig. 1 and in Fig. 2 respectively.

In both figures L_1 L_2 L_3 denote the three lenses cemented together, l_1 l_2 the inner surfaces, or "surfaces of union," and B the diaphragm.

Fig. 1 illustrates that type in which the inner chamber L_2 consists in a collecting lens being biconvex, whilst the outer members, L_1 and L_3, are dispersing lenses, the former being biconcave and the latter concavo-convex. In Fig. 2 the inner member, L_2, consists in a biconcave dispersing lens, and the outer members, L_1 and L_3, are formed by collecting lenses being respectively concavo-convex and biconvex. In either case the lens L_1, being the member nearest to the diaphragm B, is assumed to have the smaller refractive index.

The letters r_1 r_2 r_3 r_4 denote the radii of curvature of the surfaces of the lenses, and d_1 d_2 d_3 the central thickness of the lenses. b indicates the distance between the lenses and the diaphragm B.

There is now no difficulty in obtaining glass of suitable quality for making achromatic lenses of the kinds required for carrying out the present invention. The practical question as to whether, in a combination of the above description, it is possible to obtain a sufficient astigmatic correction, and, at the same time, to comply with the other conditions required in photographic objectives, has been answered in the affirmative by theoretical and practical investigation of both types of the new triple lens.

Guided by the annexed drawing and the following tables, in which are given the elements of construction of two typical examples, an optician skilled in the construction of lenses or objectives will be enabled to numerically determine or calculate according to known methods those elements of construction (radii, thickness of lenses, and distance between the lenses, and the diaphragm B) which are necessary to properly compensate astigmatic aberrations.

The letters employed in the following tables correspond with the letters marked on the drawings. The kinds of glass to be employed are determined by the indices of refraction n D and n G_1, relating respectively to Fraunhofer's D. line and to the IIz line of the spectrum of hydrogen. All dimensions are expressed by proportional numbers, the focal length of the whole objective being taken as unity. A simple multiplication of these numbers with the focal length actually required will suffice for obtaining the dimensions of any objective wanted.

EXAMPLES.

Table I.

Objective, the inner or intermediate member of which is a collecting lens.

Fig. 1 represents this objective calculated for a focal length of 500 millimetres. Maximum effective aperture, 0·063. Angle of field, about 90°.

Radii.	Thickness of Glass.
$r_1 = -0·1058$	$d_1 = 0·0060$
$r_2 = +0·1210$	$d_2 = 0·0145$
$r_3 = -0·0496$	$d_3 = 0·0091$
$r_4 = +0·1043$	Distance of Diagram B.
	$b = 0·0091$

Kind of Glass employed.	
n D.	n G_1.
$L_1 = 1·51510$	1·52673
$L_2 = 1·57180$	1·58643
$L_3 = 1·62350$	1·64457

Table II.

Objective, the inner or intermediate member of which is a dispersing lens.

Figure 2 shows this objective calculated for the focal length of 500 millimetres. Maximum effective aperture, 0·077. Angle of field about 90°.

Radii.	Thickness of Glass.
$r_1 = -0·1423$	$d_1 = 0·0167$
$r_2 = -0·0547$	$d_2 = 0·0052$
$r_3 = +0·2073$	$d_3 = 0·0139$
$r_4 = -0·1260$	Distance of Diaphragm.
	$b = 0·0104$

Kinds of Glass employed.	
n D.	n G^c.
$L_1 = 1·52246$	1·53373
$L_2 = 1·46724$	1·58092
$L_3 = 1·61120$	1·62483

By correspondingly modifying the elements of construction, lenses having the same, or approximately the same, effect as the typical lenses hereinbefore described can likewise be obtained with the aid of other kinds of glass, provided that the latter enable the conditions necessary for achromatisation to be complied with, and also enable suitable differences of the refractive indices to be established on both sides of each of the two union surfaces of the triple lens. The external shape of the latter must, in every case, be either that of a meniscus or that of a biconvex lens, with very unequal external curvatures, and the surface having the least curvature must be turned towards the diaphragm B. The outer member, next to the diaphragm, may be composed of glass, having the smaller refractive index, as assumed in Figs. 1 and 2, or of glass having the greater refractive index.

An achromatic lens of the kind hereinbefore described may be advantageously employed for the construction of objectives comprising but one composite lens, such as a landscape lens or for making doublets, and in the latter case it may

either be combined with a triple lena of the same kind, or with an ordinary achromatic lena.

By combining two equal lenaes constituted according to this invention, so as to form a symmetrical doublet of the ordinary aplanatic type, objectives are obtained in which the advantages of the double objectlve described in the hereinbefore cited Specification, No. 6028 of 1890 are united with the peculiar advantage of the symmetrical systems of ensuring tne most accurate resemblance between the object and the image. According to the rules governing the construction of symmetrical syatem, such double objectives are obtained without any change in the elements of construction set forth in the preceding tables, by oppositely arranging two equal triple lenses, the place of the diaphragm indicated in the tables being made the geometrical centre of the doublet.

By the combination of a triple lens constructed according to to this invention with a second lens of the aame description but of different focal length and other curvatures or with an ordinary achromatic lena, two valuable modificatiena of the unsymmetrical (anastigmatic) double objective described in the aforesaid Specification are obtained. The compensating effects which are brought about in the said unsymmetrical system by the co-operation of its two members are obtained in the modified system in each member separately, or in one member alone for the entire system.

In employing the new triple lens in either of these unsymmetrical double objectives it is evidently necessary to modify the elements of construction hereinbefore given in the tables, because in such system the best result is obtained not by correcting each member separately, but by compensating a rest of aberration in one member by an opposed rest of aberration in the other member. The alterations to be made must depend on the requirements of each special case, and can be ascertained by means of methods of calculation well known to opticians.

Having now particularly described and ascertained the nature of my said invention, and in what manner the same is to be performed, I declare that what I claim is :—An achromatic photographic lens or objective, composed of three lenaes cemented together, the refracting index of one of the outer lenses being smaller, and the refracting index of the other outer lens being greater than that of the middle or intermediate lens, substantially as hereinbefore explained.

An Improvement relating to Photographers' Roll-holders.

No. 8503. David Roy, 6, Holyrood-place, Plymouth, Devonshire. *April* 22, 1893.

This invention, which relates to photographers' roll-holders or slides, has for its object to provide a check against more than one exposure of the same length of film, and consequent spoiling of pictures.

The invention consists in providing that the shutter, when replaced after exposure of a length of film, is locked and is not free to be again withdrawn until a fresh length of film has been unwound from the feed drum or roller.

Locking and unlocking are effected by means of a lever catch pivoted to the body of the roll-holder. This lever catch, which is acted upon at its inner end by a spring, is shaped at the opposite or outer end to form a wedge-shaped hook, which, when the shutter is locked, engages with a fixed stop provided on the shutter. When a proper length of film has been unwound from the feed roller, an arm attached to the winding indicator passes under a lug formed on the lever aforesaid, and the latter is thereby raised, causing its catch end to become clear of the atop on the shutter. The shutter is thus unlocked and made free to be withdrawn.

In replacing the shutter, after exposure of the film the hooked end of the lever is acted upon by a tongue pivoted to the shutter, and by this means the lever is turned on its pivot to a sufficient degree to withdraw the arm aforesaid out of engagement with the lug. The lever catch then falls and re-engages with the fixed atop on the shutter. The latter is now locked, and is not again free to be withdrawn until a fresh length of film has been unwound from the feed roller.

Improvements in Plate-changing Devices for Photographic Apparatus.

(A communication by Dressler & Heinemann, of 45, Theatinerstrasse, Münich, Germany.)

No. 11,149. William Phillips Thompson, F.C.S., M.I.M.E., 6, Lord-street, Liverpool. and 6, Bank-street, Manchester, Lancashire, and 323, High Holborn, Middlesex.—*April* 22, 1893.

In this new plate-changing device, the photographic plates intended for exposnre are inserted backwardly in the camera, and are maintained against a case by means of a spring attached to the removable back of the camera ; this case may be inserted in the camera from above, from below, or from the sides. This case has, at its lower hinder edge, a slot of such a size that a plate or a frame containing the same may be easily inserted in the case. Clamp springs, acting against one another, are arranged in this case. The case, when inserted, presses down a sheet spring attached to the bottom of the camera, and bent upwards at right angles, which spring, being released when the case is drawn out, springs up, and thus, as will be hereinafter described, forms a rest for the plates or frames pressed up against it ; the usual opening of the objective is provided, on which a suitable closing device may be arranged.

The mode of working of the improved plate-changing device is as follows :—

The plates already exposed are contained in the aforementioned case, those to be exposed in the space behind the same. If the front one of the unexposed plates is to be exposed, the case is simply raised up. A projecting part of the case, or other suitable device, prevents the case being entirely drawn out.

The following takes place when the case is drawn out :—

Firstly, the spring attached to the bottom of the camera springs up, which was hitherto held down by the case, then the plates in the chamber are pressed forward by means of the spring, so that the front one, which previously rested against the hinder wall of the case, now stands with its lower part against the curved up part of the spring, whilst, at the top, it rests against a projection formed by the bottom of the case. Thereupon, if the objective shutter be removed, timed or instantaneous exposures may take place, and then the case is pushed back again into the camera. The foremost plate, which has just been exposed, thereupon passes into the case through the slot in the same, where it is held by the two springs, and places itself at the back of the plates already contained in the case.

The two springs, or their points of contact, press against one another in such a way that the plates entering the case are pushed slantwise with their lower ends projecting forward, in order to keep the slot free for another plate to enter. The unexposed plates are pushed slightly backwards by means of the tapered surface of the back wall of the case, when the latter is inserted, and the plates again rest against the back wall of the case.

If a fresh plate is to be exposed, the above-described process is repeated.

Improvements in or relating to the Manufacture of Sensitised Films for Carbon Printing.

No. 11,254. Joseph Thacher Clarke, 3, College-road, Harrow, Middlesex. —*April* 22, 1893.

In carrying out thia invention I may conveniently proceed by using the apparatus set forth in the Eastman Patent, No. 19,896, of 1889, and carrying out the process set forth in the Eastman Patent, No. 19,897, of 1889, and I produce gelatino-carbon films of the usual kind made of gelatine and colouring matter, with the optional addition of soap, dextrine, or the other materials commonly used in the trade. When the film is to be sensitised in the manufacture, bichromate of potash is added.

In manufacturing such carbon films it has been customary to place the film upon a backing of paper, and after the exposure, which renders portions of the film insoluble, to dissolve out the remaining portions. As, however, this method produced the insoluble surface or image upon the outer side of the film, it was necessary to transfer the entire film to another backing, after which, on removing the original paper supports, the prints could be obtained by treatment with warm water in the well-known manner.

In carrying out my invention, instead of employing the paper supports, I form such support of a film of celluloid or transparent insoluble gelatine, sufficiently thin to allow of the image being received by the sensitive material through said film. The film is ready for use without the necessity of transferring it to any other support or removing the original support, and the soluble portions of the gelatino-carbon film may, after printing, be removed by washing in the usual manner.

A further advantage of the method is that the image it not reversed as regards right and left, as is the case in the transfer process.

Having obtained the carbon image upon the celluloid or insoluble gelatine support, the picture may be mounted upon cardboard of suitable colour, or upon glass, if it be intended to be seen as a transparency.

I do not bind myself to use only "carbon" as the pigment or colouring matter of the film, neither do I restrict myself to the subjects of the beforementioned Patents, Nos. 19,896, 1889, and 19,897, 1889, as the invention is applicable to films prepared by other processes.

Having now particularly described and ascertained the nature of my said invention, and in what manner the same is to be performed, I declare that what I claim is :—1. The combination with a "carbon" or "pigment" film or tissue of a transparent backing, whereby the image can be obtained through the back. 2. A celluloid transparent backing to a "pigment" film for photographic purposes substantially as and for the purpose described.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

May 23, Technical Meeting, Mr. Horace Wilmer in the chair.

Tele-photo Lenses.

Mr. G. Houghton exhibited the new telescopic lens, which we described last week, also examples of enlarged photographs produced by it.

Mr. T. Bolas said that one of the examples showed slight curvature of the field, and asked Mr. Dallmeyer whether, in his tele-photo lens, he had discarded the rectilinear lens as the primary lens on that account.

Mr. T. R. Dallmeyer said that two years ago he had adopted a form of the tele-photo lens having a single positive and a triple negative. With a single form it was impossible to correct it for the excentrical pencils throughout the field. He had succeeded in doing so, but it gave pincushion distortion and aberration towards the edges. In the later form, knowing that the front lens was corrected, it was impossible to correct it throughout the field with a single combination. To obviate the drawback of having to correct the excentrical pencils, he eventually decided upon a lens convex on both exterior surfaces, in conjunction with a particular type of portrait lens. The reason for that was that if the separation was correct for a certain distance, and the positive element be moved, the correction for spherical aberration could not be perfect. In that particular form of portrait lens the correction was perfect for a near object, and if the magnification was moderate those aberrations existing in a marked degree on a high power did not manifest themselves. The lens shown by Mr. Houghton was identical with one described by Steinheil, who employed an antiplanat. The positive element gave a rather pronounced curvature of the field towards the lens, the triple negative employed producing the opposite curvature. This flattened the field, but the lens still gave prismatic excentrical pencils. The instrument shown was not of a powerful nature; with a weaker negative he should have expected that the constructor would have made it much more rapid. He had been through this particular construction, and had discarded it on account of its difficulties; although stopped down for landscape work, it was, no doubt, a valuable instrument.

The Daguerreotype Process.

Mr. W. England prefaced a demonstration of the Daguerreotype process by a brief description of it and the exhibition of a number of examples, a collection of which was on view in the Society's rooms. Mr. England said that the polished silver plate was first treated with tripoli and the buff, and then sensitised in a box for that purpose with iodine and bromine in the order named, and finally with iodine, when the plate appeared of a steel-blue colour. Considerable skill was required to get the exact tint. If the plate was accidentally exposed to light, treatment with iodine would restore it. The exposure required was about double that of wet collodion. Development was affected by exposure to mercury vapour at 120° Fahr. for seven to fifteen minutes. The picture was fixed and gilded over heat in a solution as follows, the brilliancy and beauty of the image depending on the success with which this operation was carried out:—

1.

Gold chloride	15 grains.
Distilled water	16 ounces.

2.

Hyposulphite of soda	4 drachms.
Distilled water	16 ounces.

The solutions being mixed by pouring the hypo into the gold. After the gilding, the picture is washed in distilled water and dried over heat. Mr. England then went through the practical part of sensitising a plate, developing an exposed plate, fixing, gilding, and drying, passing round two portraits made in this manner, which were highly admired. He said the pictures were the first he had taken for twenty years. They had had a minute's exposure in a glass room. In reply to a question, he said the mercury was fixed under the gilding. If a Daguerreotype got tarnished, it should not be rubbed, but should be cleaned by flooding it with alcohol, rinsed in water, and placed in a weak solution of cyanide, five grains to the ounce; for bad cases of tarnish a strength of ten grains to the ounce might be used. It should finally be washed in distilled water and dried over heat. To tell whether a Daguerreotype was gilded or not, let the corner be rubbed with something soft, and if it were not gilded the mercury would come away. The largest Daguerreotypes made were probably 15×12, by Mayall.

Mr. W. E. Debenham mentioned that he had employed pure hydrochloric acid for removing tarnish.

Mr. J. Traill Taylor said he had practised the Daguerreotype process a good deal, and had found that he had got the best results by fixing in common salt, a strip of zinc being placed in contact with the back of the plate, when the iodine was immediately freed. The American photographers brightened their Daguerreotypes by applying, with heat, solutions of ammonium chloride, which had a marvellous whitening action; carbonate of potash, alum, cyanide, &c. To this was due the superiority of American Daguerreotypes. It was the only process that depended on the man, and not the chemicals. Sufficient credit had not been paid to Fizeau for his discovery of the gilding process. In reply to Mr. Bolas, Mr. Taylor said that cyanide would not remove colour from a coloured Daguerreotype. The late M. Claudet found that even a Daguerreotype could be produced too sharp, and so used a prism to produce a slightly fuzzy effect. As to the use of bromine for increasing sensitiveness, it was discovered by Goddard of Philadelphia, and Goddard of London, almost simultaneously, but the Americans had until recently given the credit to the Englishman.

Mr. T. S. Davis said that Daguerreotype portraits were superior to portraits now produced, as it was impossible to obtain a correct portrait from a professional, the negative being so much worked up; would it not be possible to add to the posterior portion of the lens a combination that would reverse the image in a similar manner to that adopted by M. Claudet?

Mr. Taylor said it might be done by placing a reflector in front of the lens.

Mr. Debenham said an erecting arrangement at the back of the lens (as suggested by Mr. Davis) would lose more light than a prism. The loss of light with a prism was trivial.

Mr. Taylor said the loss of light from a polished silver surface was only five per cent. In the course of further remarks, Mr. Taylor said a piece of silvered glass for the purpose might be cheaply made by purchasing a small piece of looking-glass and removing the backing with benzole.

A vote of thanks was passed to Mr. England for his paper and demonstration.

Mr. H. A. Lawrance said that in his paper on the work of the Congresaer, Mr. Warnerke had referred to a suggested method of determining the speed of plates by the changes of colour they underwent in light. He exhibited several strips which had been exposed to sunlight and had discoloured, and asked for information on the point.

Some discussion took place, but no information was elicited.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

May 18, Mr. Charles H. Oakden in the chair.

Mr. S. G. B. Dicker was elected a member.

Edwards' Varnish.

Samples of Messrs. B. J. Edwards & Co.'s cold varnish for plates and films were distributed among the members.

Mr. W. H. Barnes exhibited a film negative that had been varnished with the varnish, and had been in use for printing purposes five months.

Mr. Cowan subsequently treated a plate with the varnish, which dried very quickly.

The Lomberg Plates.

Mr. J. S. Teape passed round two negatives made on the Lomberg plates distributed at the previous meeting. They were exposed in Epping Forest at six o'clock in the evening for three and ten seconds respectively with *f*-24, and developed with pyro-ammonia. The exposures were about correct, and the negatives were of good quality.

Silver in Dry Plates.

Mr. P. Everitt alluded to the recently published results of a French experimentalist who had given the quantities of silver contained in commercial dry plates, and asked Mr. Haddon, who had promised to undertake a similar series of experiments, whether he approved of the method adopted.

Mr. A. Haddon disagreed with the method employed, and promised soon to start on his experiments.

Astigmatism.

Question from the box: "What is Astigmatism?"

Mr. W. E. Debenham said it was a difference in the focal planes of rays of light which pass from the margins of the field, and are brought to a different plane of focus by different parts of the lens.

P. O. P.

Mr. R. Beckett exhibited a portrait print on P. O. P., which had been exposed to light for about two months, one part having been covered up. The print seemed to have gained in colour in the covered parts.

A Spray Producer.

Mr. Jameson, in connexion with the demonstration of the Air Brush, given some months ago by Mr. Harrison, exhibited a spray producer, the liquid being forced out in the form of a jet by blowing through a tube. Patterns could be made on paper by the use of a stencil plate. For making sensitised paper, he thought the instrument would answer perfectly well.

Being a Lantern Night, slides by Messrs. Cooke and Freshwater were shown.

North London Photographic Society.—May 16, Mr. W. Bishop in the chair.—Mr. Herbert Fry lectured on *The Sandell Plate.*—A collection of prints from negatives on these plates was exhibited, and evidenced that the claims advanced in respect of them were well founded. The long scale of gradation and the freedom from halation were most remarked. Mr. Fry, in reiterating the fivefold advantages belonging to the plate, a statement of which has, more than once, been communicated through "the usual channels of public information," said that the multiple-coated plate was not put forward as the be-all and end-all of photography. The use of it would not make every novice a medal-taker, and it could be misused. But the introduction of it had put a better tool in the hands of the careful worker than could be obtained heretofore. If any one thought he could go one better, the sooner he did so the better for photography. Mr. Fry explained the tentative mode of development best adapted to get good results out of the plate, and inveighed strongly against the practice of using any developing solution more than once. The plates could be intensified or reduced in the usual way, but these processes were only necessary when there had been a slip in the development. In concluding, he warned his audience not to follow in the wake of certain experimentalists, who advised wilful over-exposure, followed by stripping off the top film. A vote of thanks was passed to Mr. Fry for his lecture.

Hackney Photographic Society.—May 16, Mr. R. Beckett in the chair.—The Hon. Assistant Secretary announced that the attendances at Wanstead Park the previous Saturday amounted to twenty-one. From the question-box: "Wanted, a cure for pinholes." The Chairman gave a description of pinholes as absence of films and silver, dust, and air-bells, and fragments of glass. Mr. Hensler said he used a deep dish, and gave the plate a sharp knock on the side when developing. Mr. S. J. Beckett said Indian ink was about the best thing to use if pin-holes were caused. Mr. Hensler could not dissolve the metabisulphite of soda as recommended by Mr. Dresser. Messrs. Nunn and Fenton Jones had found no difficulty in doing so. Mr. Moore asked how to clear a negative from green and red fog. Mr. Sodeau said Captain Abney recommended to convert the whole of the silver into its haloid condition, and

redevelop. Bromine water would convert, or ferric chloride. The conversion is to a grey fog, which does not matter much. Mr. T. H. SMITH asked cause and cure for iridescent marginal stains on plates. Methylated spirit on wash-leather (to rub on plate) will remove it easily. Mr. W. Fenton Jones then proceeded to open the discussion on *Plates* versus *Films*. He spoke of great portability in films, and use for carbon work—advantages over plates. Good for clouds, as they would print either way; are said to be free from halation. On the other hand, one thing which had done much to retard the progress was faulty emulsions, and tendency to curl when developing. Incidentally he said Mr. Dresser had overcome this by the introduction into his developing tray of a square, heavy framing, which rested on the rebate, and caused films to lay flat. A question that occurred was, "When developing, will films stand heat?" Mr. Sodeau explained an Eastman roll-holder, and said he rather favoured films, had easily worked his; said the films were well coated, and, by wetting his dish first, easily got them to lie flat. Mr. Hensler had taken out films to New Zealand, and found them a great advantage. Mr. A. BARKER had some good films, but others were bad. Mr. F. HOUGHTON used them in the Frena with good result, but some of the bits of film had at times blistered or floated off. Mr. GOSLING asked, "Were films advisable for a beginner?" Mr. S. J. Beckett said, "No," and generally objected to films; had thirty-three and one-third per cent. failures on films to five of plates. Mr. POULSON said, in larger sizes there was a danger of backing. Mr. W. Fenton Jones said he had found film emulsion sometimes thin, and gave, as a test for thinly coated plates, the holding of one before a gas flame, and, if the flame could be seen through, it obviously showed thin emulsion. The Chairman had not found films prevent halation, as had been stated.

Putney Photographic Society.—May 18.—The members travelled to Woking, and from there proceeded along the Basingstoke Canal in the direction of Byfleet and the Wey Navigation. As there was a bright diffused light, a number of good negatives were obtained of the beautiful scenery along the route, additional interest being given by the grouping of a few children, which the leaders had previously engaged to meet the party.

Richmond Camera Club.—March 15, Mr. Ardaseer in the chair.—The President (Mr. Cembrano) delivered a lecture on *Architectural Photography*. He divided the subject into three broad divisions—Apparatus, Process, and Subject. Under the first head, tripods, cameras, lenses, and accessories, such as focussing glasses, levels, and flash lamps, were fully dealt with; under the second were considered plates, exposure, and development; while the third comprised hints as to the choice of subject, whether exteriors or interiors, lighting, and pictorial effect. The lecture was of a most practical nature, and, by way of illustration, some of Mr. Cembrano's well-known architectural pictures were thrown upon the screen, the lecturer remarking that there was no more suitable and effective mode of showing photographs of architecture than through the lantern.

Brixton and Clapham Camera Club.—May 16, the President (Dr. J. Reynolds, F.R.G.S.) in the chair.—Mr. W. THOMAS read a paper on *A Photographic Picture, and Some Notes on its Production*. The paper dealt fully with composition, light, and shade, balance, printing in clouds, printing processes, use of stops, mounting and framing. The lecturer's remarks were illustrated by numerous specimen pictures and blackboard illustrations. Mr. Thomas himself used cold-bath platinotype paper for his pictures, and strongly recommended its adoption by his hearers as being exceedingly simple to use and beautiful in its results. He advised members to lay in a large stock of cloud negatives, and said that great care should be taken, when printing in clouds, to see that the clouds were lighted in the same manner as the landscape itself. Considerable discussion took place at the conclusion of the paper, and, in answer to a request, Mr. Thomas promised to take the members out for a practical lesson in the field, in order that they might put his principles into practice under his supervision.

Ashton-under-Lyne Photographic Society.—May 12 to 15.—An exhibition of over 100 photographs of the land of the Broads, lent by the Great Eastern Railway Company, who have a great number of these views in their railway carriages. The photographs were inspected by a large number of members and friends with very great interest, and many expressed their desire to visit the places depicted. Many also said they should visit Norfolk with the camera, so the Society may expect to see more views before very long from that most delightful county.

Gosport Photographic Society.—May 16, Mr. W. B. Smith in the chair.—Mr. BELTON, of the Paget Prize Plate Company attended, and gave an instructive demonstration on *Printing-out Opals and Plates*. The specimens handed round were much admired, and at the conclusion of the demonstration Mr. Belton was thanked for the able manner in which he had dealt with his subject. During the evening the CHAIRMAN announced that the Rev. E. Paske-Smith had been elected to a vacancy on the Council, and that Mr. Reginald E. Green had been chosen joint Hon. Secretary. The Chairman also presented Mr. T. E. Williams with the silver medal, and Mr. A. Fisher with the bronze medal, won in the late National Lantern-slide Competition, and congratulated them on their well-merited success.

Correspondence.

☞ *Correspondents should never write on both sides of the paper. No notice is taken of communications unless the names and addresses of the writers are given.*

THE CONCENTRIC LENS.

To the EDITOR.

SIR,—I note the letter of Mr. F. H. Burton, as to which I have a few words to say. His pretended inference that "Mr. Stillman makes 10 × 8 negatives with an eight-inch lens, attached to a camera with a cracked front, and cuts out the centre of his prints," &c., with the pinhole theory, needs no other reply than that I sent no "prints," but the negatives, as he would have seen if he had read my letter. I send now two prints made from 18 × 24 centimetre negatives with the Concentric lens, one at *f*-16 and the other at *f*-64, as a practical demonstration of the truth of what I have stated. I do not say, and have never said, that the lens will *cover* as large a field with the same sharpness when used with *f*-16 as with *f*-64 but that it will focus as sharply. No lens can be made which will define a close foreground with a distant view, with a stop as large as *f*-16, nor can the Concentric be strained to cover a plate whose longest dimension is greater than the focus of the lens without falling off at the corners; but I use my ten-inch concentric on an 8 × 10 plate, always focussing with the largest aperture, and when the subject permits it, working with it, which is the case in a large majority of cases. On any given object I can focus as sharply with *f*-16 as with any smaller stop, and, if Mr. Burton cannot, it only proves, not that the lens will not do it, but that he does not know how; but his want of knowledge only proves its own existence, not that the lens in competent hands will not do what I claim for it. Any one can, of course, focus at *f*-22 and then by stopping down, get a sharper image, but any *competent* person using a finely ground screen, can get a focus, absolutely finer than the print will render at *f*-16, and I have often done it at *f*-12; but with so large an aperture there is too great a concentration of illumination to give more than a very small available field.

In the two negatives from the same point taken at *f*-16 and *f*-64 I focussed on the telegraph-pole at which I have put a cross; but lest this should not prove my case I send some other prints from negatives taken within a few days. If I were asked to make negatives for enlargements, as I often do, I should use the smallest stop as a rule, but for any other purpose I only use a smaller stop than *f*-16 when I find the light too strong for my shutter as ordinarily and conveniently arranged, to adjust the exposure accurately. The prints I send are the ones I happen to have by me, none having been taken with especial care.

Of course I, too, advise duffers to "stick to the *f*-22 to *f*-32"—that is safe and requires no especial delicacy of hand or eyesight, but at the same time I must say that a man who can't get a sharp picture with *f*-16 *has* "no claim to the title of an expert."

Another word of explanation! The view which I send in double has in the extreme distance the palace of the Quirinal, with the flag flying, to denote the presence of the king. This is just a kilometre in a straight line—the dark window in the nearest building is about forty feet from the position of the camera. Save that the *f*-16, though made with a drop shutter, is much over-exposed, I do not think that Mr. Burton could tell the difference with his naked eye in the sharpness of either.—I am, yours, &c., W. J. STILLMAN.

Rome, May 17.

P.S.—As prints are somewhat unsatisfactory as to absolute definition though good enough for gelatine, I have made two negatives especially as trials of *f*-16 as against *f*-64, which I enclose, and which I beg you to hold open to the inspection of any one interested in the question. In the prints I have sent I made no especial effort at extreme accuracy of focussing, taking it as satisfactory when it seemed so on the screen, and not using a focussing glass. In these I have been more careful, but have only employed ordinary spectacles, which at sixty-five will be excused me —by younger men. W. J. S.

MOUNTING GELATINO CHLORIDE PRINTS.

To the EDITOR.

SIR,—In answer to "W. R. F." *re* mounting gelatino-chloride prints, any method used for mounting bromides is applicable. Our way is to place a piece of moistened *papier mineral* next the surface of the print with some ordinary paper on that, and then squeegee into contact as usual, All trouble of prints sticking to the paper instead of the card then disappears. One word of advice, dry the prints out of the way of all dust. as the surface very readily receives any that is about and does not freely give it up again.—I am, yours, &c. A. M. BROWN.

Dulwich, May 22, 1893.

To the EDITOR.

SIR,—Referring to the trouble your correspondent "W. R. F." seems to have experienced in mounting gelatino-chloride, I would say that I have found this not an uncommon mistake. But I have found that where the formula sent out with the paper was strictly adhered to, the trouble referred to was invariably overcome. I allude to the prints being soaked in *alum*, either before or after toning, and not being subjected to *too prolonged* a final washing. At the outside, one hour and a half I have found ample, with continual changes, to remove all traces of the fixing-salts.—I am, yours, &c., A DEMONSTRATOR.

May 20, 1893.

To the EDITOR.

SIR,—I believe I made the statement some months ago to which "W. R. F." refers, viz., that gelatino-chloride paper may be mounted in the same manner as albumenised; so it may, using a little "Opie's medium." Does "W. R. F." use ordinary *sized* paper? If he does, and it does not stick to the wet gelatine surface after being squeegeed on to it, he ought to have more cause for surprise.

If the blotting-paper referred to in my former letter is used, and the print rubbed down by hand, no difficulty will occur; but so much rubbing down or squeegeeing is unnecessary. Use a fine, damp sponge, which cleans the surface as well as pressing the print into contact. Never omit the alum bath, especially if the sulphocyanide bath is used; *ceteris paribus*, the method of working is the same as for albumenised paper.—I am, yours, &c., T. FITZGIBBON FORDE.

May 19, 1893.

MR. DRAGE'S RESIGNATION.

To the EDITOR.

SIR,—As the disagreement between myself and the members of the London and Provincial Photographic Association has been made so public, will you kindly favour me with a small space, as I am told many cannot understand the matter?

May I state at the outset that I am perfectly neutral as regards the "Spirit" question? and Mr. Beckett (one of our members), bringing forward a resolution repudiating statements in the Spiritualistic Press, as regards the attitude taken up by the London and Provincial, had worded it so, that, as I pointed out to him before the meeting, it was bound to cause a great deal of harm.

Out of an attendance of forty, only fifteen members voted, the rest abstaining; the Chairman duly declared the resolution carried.

On hearing, a day or two afterwards, that the Association would most certainly suffer considerably if that resolution was circulated, worded as it was, I used my utmost endeavours to stop the publication of it in the photographic journals, and I also refused to enter the resolution on the minutes, holding that, with a membership of 200, it was not right to allow such a small number as fifteen members to cause, by their votes, such an upset to the Association.

I found that I was totally unsupported in my action; the members therefore dispensed with my services, by directing the Chairman to enter the resolution on the minutes.

Acting, as I considered, in the best interests of the Association, after my experience of three years as Hon. Secretary (and which, I may say, has been a very pleasant experience for me), I regret exceedingly that the members did not support me in this instance in my efforts for the well-being of the Association.—I am, yours, &c., R. POULTER DRAGE.

95, *Blenheim-crescent, W., May* 18, 1893.

A CONFERENCE OF EXHIBITION JUDGES.

To the EDITOR.

SIR,—At the meeting of the affiliation delegates, held on March 24 last, it was resolved to invite to a conference those gentlemen who have most frequently acted as judges at recent open photographic exhibitions, to agree upon lines of action to be followed in judging, and to offer suggestions for the guidance of Societies with regard to exhibitions.

I am directed to inform you that in accordance with the above resolution, an invitation has been sent to thirty-eight of the best-known judges, but as some names may have unintentionally been overlooked, the Committee will be glad if you will make it known that any gentleman who has acted at least four times at open exhibitions will be welcome to join in the deliberations of the Conference. The meeting will be held during the month of June, and due notice will be given of its date and place.—I am, yours, &c., R. CHILD BAYLEY,

Photographic Society of Great Britain, Secretary to the Affiliation.

50, *Great Russell-street, Bloomsbury, London, W.C., May* 20, 1893.

GLACIER PHOTOGRAPHS.

To the EDITOR.

SIR,—Many of your readers must be thinking of a start for the Alps, and many must be near great ranges and extensive glaciers in New Zealand, the Dominion, and even the Himalaya. The lantern slides which profusely illustrated Mr. Conway's discourse at the Alpine Club meeting the week before last, when St. Martin's Town Hall was filled with an audience of both sexes, show what can be done in this way by travellers.

Let me appeal to those who take an interest in grand scenery to help the good cause by photographing glaciers in all parts of the world, with a view to collecting documentary evidence of their increase, diminution, advance, or retreat. Also anything bearing upon the question of the share borne by ice in formation of lakes.

Such photographs should be taken far more for these purposes than as artistic views, and even one to be shuddered at may, in spite of its atrocity, be valuable as illustrating some point. Only, pray, let the perpetrator always give compass bearings, date, and approximate distance of some prominent object in the field of view.

A sub-committee of the Alpine Club has been appointed and charged with the collection of information, more especially regarding glaciers within British territories. The contributions of prints (and negatives to be spared) will, it is hoped, assist largely.

I see a letter in your last issue from Mr. Ponton, whose father so much to advance the science of photography. I have taken some negatives with the camera he mentions, which is the size, but not the weight, of those "Church Services" ladies so frequently carry. My photographs were only fair, but I have some very good ones indeed with these little boxes. It would be interesting to try one's luck with a few in the big mountains and report progress. The optical theory of pinhole work will have to be worked out much further than at present, and a difficult problem it is! The pinholes are beautifully true and circular in those I have seen. Their insignificant weight is a great thing in their favour. Personally, being of somewhat lazy habits, I have never carried anything larger than a 5 × 4 hand camera on any fatiguing expedition. But I leave such details to the sundry writers who have already given us valuable *wrinkles* on traveller's work.—I am, yours, &c.,

Easterton, Parkstone, R.S.O., Dorset, May 20, 1893.

MARSHALL HALL.

REGULATORS.

To the EDITOR.

SIR,—In reference to R. R. Beard's communication in yours of the 12th, I really do not know what he means, as I never mentioned "600 lbs. pressure," "lubricant," or "fatty matters," and the drawing of the apparatus I sent him, instead of only four inches, has a possible pressure of thirty inches, and I have never seen a lime that would stand thirty inches of water pressure. What have I to do whether gas compressors favour or condemn the use of grease? Then he begins to prophesy about the failure of my anti-friction cock, the construction of which he is wholly ignorant of; then he advises me to get a cylinder of compressed gas. Really, if Mr. R. R. Beard has any friends, they should keep an eye on him.

According to published evidence, I am the first person who ever used a regulator for the limelight. In conclusion, let me say that a man may be able to make clear to other minds what is clear to himself, but it is very difficult to make clear to others what is not clear to oneself.—I am, yours, &c. WILLIAM BIRRELL.

Airdrie, May 22, 1893.

THE PHOTOGRAPHIC SALON.

To the EDITOR.

SIR,—As chairman of the Organizing Committee of the Exhibition or Salon of photographic pictures, to be held at the Dudley Gallery next October, may I say a word to correct the impression that there is intention to clash with the usual Exhibition of the Photographic Society?

The same reason which actuates the Photographic Society in selecting the autumn compels us to take about the same period, and that reason is the difficulty of obtaining a suitable gallery at any other season. We certainly intend to have the best possible picture exhibition, but not to intrench on the usual lines of the Photographic Society, nor in any way to form opposition. Assurance on these points may be gained by a reference to the influential list of our Committee; and, further, it may be pointed out that, with one exception, all the Judges at the Photographic Society's Exhibition are prominent members of the Salon organization.

The two Exhibitions will probably be complementary, and even mutually helpful, by taking place at the same time.—I am, yours, &c.,

May 20, 1893. GEORGE DAVISON.

Exchange Column.

*** *No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance. The full name of the advertiser must in all cases be given for publication, otherwise the Exchanges will not be inserted.*

Dallmeyer's 2B, in perfect order, offered in exchange for cabinet lens of longer focus or for a 3D, Ross' Universal or other rapid lens of about ten-inch focus.—Address, H. PARLOW, Hythe, Kent.

Ross' 10×10 Spanish mahogany camera, complete, long focussing screw, as new, cost 8*l.*; exchange for light-pillared balustrade or pedestal.—Address, J. HORTON, Central Photographic Studio, Caroline-street, Cardiff.

Wray's 8½×6½ view lens, *f*-8, twelve-inch focus, also Thornton-Pickard special double blind shutter to fit above lens, works to one-two-hundredth of a second; exchange for quarter or half-plate set. Cash adjustment.—Address, J. BERNARD, 101, Goldhawk-road, W.

Answers to Correspondents.

*** *All matters intended for the text portion of this* JOURNAL, *including queries and Exchanges, must be addressed to* "THE EDITOR, THE BRITISH JOURNAL OF PHOTOGRAPHY," 2, *York-street, Covent Garden, London. Inattention to this ensures delay.*

*** *Correspondents are informed that we cannot undertake to answer communications through the post.*

*** *Communications relating to Advertisements and general business affairs should be addressed to Messrs.* HENRY GREENWOOD & Co., 2 *York-street, Covent Garden, London.*

E. N. D.—The gold can be precipitated by a solution of protosulphate of iron.

H. SUSMANN.—The address is Harrington Bros., Shandon Chemical Works, Cork.

FRANK OSBORNE.—Better mix the colouring matter with varnish, and apply this to the slides.

PERPLEXED.—Information as to mounting gelatino-chloride prints is given in our "Correspondence" columns this week.

L. CLAY.—Your only course is to proceed against the shopkeeper in the County Court for the value of the picture.

LIVERPOOL.—In selecting a camera-stand, bear in mind that rigidity is the primary consideration, and portability and lightness a secondary one.

W. G. HONEY.—1. The idea is a useful one, but not, we think, patentable. 2. Communicate with the Prisons Department, Home Office, Whitehall, S.W.

DR. J. H. SMITH & Co. (Zurich).—Messrs. S. Guitermann & Co., 35, Aldermanbury, E.C., advertise celluloid in the sheet and rollable form for coating purposes.

W. COPE.—The markings are doubtless caused by impurities in the mounts—we have seen many similar cases. Without analysis it is impossible to indicate the precise cause.

F. G. HILL.—It depends upon the nature of the backing whether the stains on the front of the negative caused by it can be removed. If it is soluble in water, it probably may not be difficult to do so by prolonged washing.

L. VOSS.—No work is published on dark rooms and their fittings, and none is required. Every one fits up his dark room according to his taste or requirement, or, we might say, more often than not according to the space or apartment at command.

A. C. GODDARD.—What matters the appearance of the solution so long as it develops well? The slight discolouration was, no doubt, caused, as surmised, by the stopper being left out of the bottle for several weeks. Certainly the pyrogallic acid must not be blamed.

E. MOORE.—The positive process is usually worked with collodion. Dry plates for the purpose are supplied by Mr. Jonathan Fallowfield. Formulæ for working are supplied with the plates. Any of the dealers in photographic goods will supply dark tents for any purpose that may be required.

CHAS. KERR (Colombo).—1. We are much interested in the photographs of races, which are very good. 2. Probably Mr. Spooner, of the Strand, could obtain photographs of the finishes of races for you. 3. We know of no shutter faster than the one you mention. At present one-five-hundredth of a second is probably the greatest rapidity of English shutters.

T. MARKS.—1. A half-plate portrait lens will do quite well for enlarging from quarter-plate negatives; indeed, it will be better than the quarter-plate wide-angle rectilinear. 2. In working with daylight a condenser is quite unnecessary. 3. In making enlarged negatives, ordinary plates will do quite as well as the more rapid ones; in fact, we should prefer them.

R. W.—There is no mistake in the matter. Glycerine mixes perfectly well with alcohol in all proportions. It may be added to collodion if necessary. Castor oil will also mix with collodion, and generally is contained in the collodion used for enamelling prints. If you are so dubious in the matter, why not make an experiment or two to satisfy yourself on the point?

T. BANKS sends us some prints, and complains of their lack of sharpness. He says he is working with a fixed focus lens, and asks whether the fault rests with the lens, or the shutter not working quick enough?—It is quite clear that the lens is not set to the right focus. There appears to be no fault with the shutter, as the moving objects are quite as sharp as the brick walls and houses.

CONSTANT READER.—There is nothing to hinder you from taking out the patent yourself. The next time you are in London you can obtain the requisite forms, free of expense, on applying at the office adjoining the east front entrance of the Law Courts. You may also apply at the Post-Office of your village, but it is doubtful whether you can obtain them in such an unimportant place.

T. C. H.—It is impossible to give any idea of the cost of building a studio on the top of a house, and a staircase up it, simply from the dimensions given. It often happens that the structural alterations of the main building to receive it, and the approaches to it, entail a much greater cost than the studio itself. We can only suggest that you prepare plans of what is required, and then submit them to one or more of the local builders, who will give an estimate for the work.

C. B. writes: "Can you give me information respecting Switzerland? Are the Custom-House officers likely to examine your plates? Is it necessary to get a pass, if so, from whom?'—Perhaps some of our readers will supply the desired information. No passport is required for Switzerland, but in all cases when travelling abroad it is well to be provided with one. It may sometimes be the means of avoiding trouble.

R. A. J.—The lighting of the portrait is very good so far as the dominant light is concerned, but the shadows are much too heavy. This may in future be remedied by using a reflector to soften them. A white sheet, or a few newspapers on the domestic clothes-horse will answer admirably. With judicious management of the light, quite as good portraits are to be obtained at a large bay window of an ordinary room as in the orthodox studio.

TRURO writes: "We are having the electric light cable laid down here. What candle-power arc lamps (or other lamps) shall we require for lighting studio? Who could you recommend to fit it up? Would it cost over 40*l*?"—A light of five or six thousand candle-power will do. Messrs. Gwynne & Co., Brook-street Works, Holborn, make a speciality of electric lighting plant for photographers. Better write to them for an estimate.

CYPHER says: "I had some negatives out printing, and a shower of rain came on, and wetted the frames. They were wiped, and put away till next day to finish printing. On opening the frames, I found the paper had stuck to the negatives, and, on pulling it off, the film pulled away in places, and the other parts are stained. Can anything be done to remedy the evil?"—No, except to make fresh negatives from any prints that may be in existence.

A. S. KING.—If you imagine that you are going to obtain sharp negatives of interiors of cathedrals with a hand camera, if the camera be held in the hand, you will be greatly disappointed. If, however, the camera be used on a stand or other rigid support, then a hand camera will answer perfectly well. Pictures so obtained cannot be styled hand-camera work, and to enter it as such in any competition would not be fair.

O. M. says: "In trying the experiment of making chloride of gold, as described in last year's ALMANAC by G. W. Webster, not being able to get a digester, I used a white porcelain jug, with the result that all the gold—twenty shillings' worth—is gone into the jug. What do you advise to do with it? Is there any way to separate the precious from the vile? I have succeeded perfectly since by using an oil flask."—It is difficult to see, if a *porcelain* jug were used, how the gold could get into the ware. Probably, however, the jug was common earthenware. If the gold is still in the ware, it ought to be recoverable. Probably the most practical way will be to reduce the jug to a fine powder, and send it to a refiner.

PHOTOGRAPHIC CLUB.—May 31, *The Daguerreotype Process.* June 7, *Plates versus Films.*

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.—June 1, *Angle of View*, paper by Mr. P. Everitt.

THE studio of Mr. Vandyck, of which we made mention last week, is situated at 20, Ladbroke-grove-road, Notting Hill Station, W.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.—Mr. J. L. Mackrell has consented to give a practical demonstration on *Enlarging, &c.*, on Wednesday, June 7, from twelve to half past one, and on Thursday, June 8, from one to half past two. Excursion, Saturday, May 27. Bebington, half day. Leader, Mr. G. A. Carruthers. Train leaves James-street Station (Mersey Tunnel) at fifty minutes past one for two.

AMATEUR PHOTOGRAPHIC SOCIETY OF MADRAS.—The first Open Exhibition of Photographs will be held in a suitable hall in Madras during the month of December, 1893; it will remain open for a period of one week. All exhibits must be in the hands of the Hon. Secretary by December 1, and all charges for carriage to and from the Exhibition must be paid by the exhibitors. All exhibits should be clearly addressed to the Hon. Secretary, Amateur Photographic Society of Madras, of whom full particulars of classes, &c., may be obtained. The following classes are:—Open to the world, Class A.—Silver medal, for the best set of four landscapes; silver medal, for best set of four figure subjects; silver medal, for best set of twelve lantern slides; silver medal, for the second best enlargement; bronze medal, for second best of each of the first three subjects. Open to amateurs only, Class B.—Silver medal, for the best photograph, any subject; bronze medal, for second best photograph, any subject; silver medal, for best set of four figure subjects; silver medal, for best set of four other than figure subjects; bronze medal, for best set of six lantern slides; silver medal, for best enlargement; silver medal, for best set of hand-camera shots; silver medal, to be awarded by Judges for any exhibit of special merit not included in the above classes.

JOURNAL OF PHOTOGRAPHY.

No. 1726. Vol. XL.—JUNE 2, 1893.

WHOLE-PLATE BINOCULAR PICTURES, AND HOW TO SEE THEM.

It is well recognised that, the farther the eyes of an observer are apart, the greater is the increase in the perception of the varying distances of objects. By way of experiment we, some twenty years since, constructed an instrument by which the eyes were effectively separated a distance of twelve inches, and the effect obtained, while exceedingly instructive, bordered on the ludicrous, especially when the subjects examined were situated at only a moderate distance. But this increase of base gave to distant objects a real charm, inasmuch as the effect of solidity, by which all objects near at hand and seen by both eyes are characterised, was extended to those situated at a great distance.

Arising out of a number of desultory experiments entered into at the time was a telemeter, by which the distance of any object within one or two miles of the point of observation could be ascertained with approximate accuracy for those most distant, while, for those nearer at hand—say about half a mile—the accuracy was sufficient to enable the sighting of a rifle to be effected. We may some day publish this as a useful adjunct to the employment of fixed lenses of longer range than is usual.

By a principle analogous to that by which the previously expressed ideas were carried into practical effect, Sir Howard Grubb had it applied to the examination of stereoscopic pictures exceeding in dimensions those of the usual size, and we willingly accord to this gentleman the credit of this application. It is now known to every intelligent reader of stereophotographic literature that, in order to the comfortable examination of binocular pictures by one of the ordinary stereoscopes now so readily obtainable in commerce, the pictures should be mounted at a distance apart not exceeding three inches. Now, three inches is a size of picture (from side to side, for there is no fixed limit to its height) that does not give satisfaction to every one, even when viewed through eyepieces from six to eight inches in focus.

Bearing in mind the Grubb principle enunciated two decades ago, and its capabilities, we have constructed, by means presently to be described, a stereoscope qualified to show distinctly, from centre to margin, a stereoscopic print of somewhat enormous size, seeing it is composed of two whole-plate photographs placed side by side on one sheet of board. Now, seeing that the centres of the elementary pictures composing this monster stereogram measure six and a half inches apart, the height of each being eight inches, the bringing of these into coalescence evidently cannot be effected by a prismatic or lenticular stereoscope of the usual form.

Those acquainted with Wheatstone's stereoscope are aware that in this instrument the pictures were large, but they had to be mounted on separate boards and had to be inserted facing each other at the opposite sides of a large box, or, at any rate, a framework, capable of holding them in this position. They were viewed by two small mirrors, one opposite to each eye, but inclined at an angle of forty-five degrees, by which, when the eyes were directed straight forward, they saw the pictures that were mounted at the sides of the box quite stereoscopically, but reversed as regards the right and left of the picture.

Now, let it be remembered that our pair of whole-plate photographic prints are pasted side by side upon one mount, that they are non-reversed and that their centres are six and a half inches apart. In order to bring each eye virtually opposite the centre of each print, two small mirrors must, as in Wheatstone's stereoscope, be mounted diagonally, one opposite to each eye, and at three inches apart. A second pair of mirrors must next be mounted, each parallel, or nearly so, to the first pair, and at a distance of one inch and three quarters from the surface of each. These second mirrors must also be rather larger than those nearest the eyes, else will not the whole of the print be seen. With a pair of prismatic or even ordinary simple lenses in front of the eye the stereoscope is completed.

What is imperative is, that the mirrors be silvered on the front surface, by depositing thereon metallic silver by one or other of the methods described in so many of our Almanacs, and which need not here be recapitulated. The way to do it is to select a piece of patent plate, and, having cleaned the best surface, deposit the silver on it, and then, when dry, cut pieces the right size from it by a diamond.

Sir Howard Grubb's system of employing diagonal prisms, instead of mirrors, to cause the rectangular alterations of the path of the light is to be commended on account of its elegance; but it is objectionable on account of its necessarily high cost, for the glass of which the prisms are formed must be very pure and free from defects. We have sought to construct analogous ones of water by enclosing the fluid in a square tube, the ends of which were cut to an angle, and covered by cementing thereon with pitch squares of selected small pieces of glass, each of the square tubes employed being cut open to permit of small squares of glass being let in at opposite top and bottom ends, so as not to interpose any opaque matter which would bar the passage of light from the picture to the diagonal end pieces, and thence to the eye. Those who have the patience and mechanical skill to construct such a substitute for the prism will be well rewarded for their pains, for not only will it serve the special purpose for which it was made, but it will also answer for inspecting distant

objects—the prismatic eyepiece being removed—and seeing them under the circumstances alluded to in the opening sentence of this article.

It is not necessary that the whole-plate picture of which we have spoken be taken direct, for an enlargement obtained from the negatives, taken in a stereoscopic camera of the usual size, will serve the purpose equally well, for poor indeed must be the negative that will not bear being enlarged to two diameters, all that is necessary for the purpose now advocated.

OUTDOOR GROUPS.

The present season of the year initiates a period during which a vast amount of photography covered by this title is undertaken. Much of it is so capable of improvement that a short discussion upon the subject may lead to a fuller understanding of the conditions governing or limiting success. We do not propose to discuss it from an artistic standpoint, for that has been very completely done before; the mechanical aspect would, perhaps, describe best the mode it has been least treated.

Naturally the lens comes in for first consideration; and here, at the outset, let us say we have no intention whatever of singling out a particular maker as supplying the most suitable article. As need not be here said, any lens will take a group; but for general use a landscape lens gives too curved and limited a field, and an ordinary portrait lens too limited a field, hence choice will be confined to one or other of the many symmetrical or rectilinear types of instruments. But, as groups have so frequently to be taken under conditions requiring very short exposures, it is evident that a lens whose aperture is *f*-16 would frequently be put out of court, and an objective purchased specially for group-taking would advisedly be chosen from the doublet type capable of being worked at *f*-7 or *f*-8 at will.

For important groups, however, *f*-12 or *f*-16 will be the most probable aperture, for not only has flatness of field to be considered, but depth of definition. Makers vary much in their statements as to the covering power of their instruments, but, broadly speaking, it would be wise, in selecting a lens, to choose one with a focus, at the very least, of about one-half longer than the longest side of the plate it is to be used for. There are lists before us in which sharp covering power is put down at all proportions, from a plate as long as the focus down to less than the proportion we recommend. So much depends upon what is looked upon as sharpness. A degree of definition that would be excellent in a landscape would be very imperfect in a group where, for instance, the figures were not more than an inch high. We therefore very strongly recommend any lens-purchaser to see the lens itself rather than be guided by the dimensions of covering power as given in the printed lists. We do not here for a moment impugn the good faith of the makers—we draw attention to the need of understanding thoroughly what is meant by covering power.

There is another reason for choosing a lens of long focus in comparison with the size of the plate, and that is the curvature of the field. The nearer an object is to the axis of the lens, the less is this curvature perceptible; but when, say, a twelve-inch focus lens was used for a twelve-inch plate on a group of people raised, for example, on a long terrace, it would require a very small stop indeed for those sitters who came near the edge of the plate. We must not be understood as suggesting that this benefit from a small stop is produced by its flattening the field, we need scarcely say it would not do so; but the depth of definition would be so increased by the small pencils that the departure from exact focus at the edge would not then be noticed. With, however, a lens of focus double or even half as much again, curvilinear distortion would be far less troublesome.

So far as to the lens to be used; we may next discuss how to use it. A group is arranged, let us say, and the image is noted on the screen. If, as would be natural to do, the sitters are arranged mainly in a straight line, or about a line, it will be too often observed when using the full aperture that curved fields are by no means things of the past, and the sharpness will be wonderfully increased by placing the figures about a curved line. The section of a saucer is often suggested; but with some lenses, and by good makers, it will be found that a section of a horse-shoe will almost be needed for a ground plan of the group. One word or two on this point will be reasonable. Although a great increase of sharpness is discernible when arranging the group on a curved line, such arrangement is not universally applicable. The further the figures are removed from the camera, the less can the curvature of the field be reduced by this means. Many a photographer who has been in the habit of taking groups of a dozen, or two or three, and managed to his satisfaction in this manner, has been puzzled when he has essayed a hundred or two at once. They cover so much ground that, even if he could marshal them to position, they are so near the distance beyond which all objects are in focus, that to effect curvature by bringing those at the margin nearer to the lens to lengthen the focus at that part would make the whole ridiculous. We dwell upon this point, as it is of such importance when using a lens with fairly large aperture.

So far we are assuming that the negatives are to be taken direct of the required size, but it is well worth the photographer's while, when he has large groups to take, to consider whether he should not take his first negative on a small scale, and enlarge it afterwards. The enlarging of negatives has now been brought to such perfection that, not to speak of direct bromide enlargements, the results so obtained might be of high-class character. The advantages of such a mode need scarcely be enumerated. The smaller the lens used the more likely it is to possess crisp defining powers, and the less perceptible will be the curvature of field; the depth of focus will, with equal exposures, be (the standpoint being the same) far greater; and, lastly, a larger number of exposures can be made, and in more rapid succession than with large plates, while when great rapidity is needed, and there is only one available standpoint, the long-focus lens, giving the same depth as a small one, is placed completely out of court.

The Queen's Plate.—Her Majesty has given permission to our contemporary, the *Gentlewoman*, to photograph her gold plate at Windsor Castle. The pictures if well reproduced by a photo-mechanical method will prove highly interesting, particularly to lady readers. It may not be generally known that Windsor Castle contains a well-appointed photographic studio and dark room that would be the envy of many London photographers, and so would its furniture and fittings. It is here that a large proportion of the Royal portraits have been taken.

Relics of Ancient London.—Another of the old City churches is doomed. This time it is St. Mary's in the Minories. Amongst many of the City churches that have been pulled down during the past couple of decades have been some of Sir Christopher

Phototypie F. Thévoz & Co., Geneva. Negatif by W. Brooks, Reigate.

A TOWER WARDER.

(Beef Eater.)

Wren's finest examples. Were photographs of them, externally and internally, taken before they were demolished? If not, why not? Surely it is not too much to expect the authorities of the wealthiest city of the world to, in their official capacity, secure, and retain, photographic records of all interesting and instructive relics before they are swept away for ever. That the City does think of something beyond business and bustle is evidenced by the fact that since the Gilbert pictures have been at Guildhall they have proved a great attraction, from 700 to 1000 persons a day having visited the exhibition. The City is proud of its ancient traditions and relics. Why do they not perpetuate, by means of photography, the latter, before they are destroyed?

Photographic Convention of the United Kingdom.—The Right Worshipful the Mayor of Plymouth, Mr. W. Law, will open the proceedings on Monday, July 3, at the Western Law Courts, the Guildhall, after which a *conversazione* and a lantern entertainment will be given. On the Wednesday the group will be taken in the Guildhall Square at noon. On the evening of the same day there will be a second reception at Devonport by the Worshipful the Mayor of Devenport, Mr. W. Waycott. The dinner and smoking concert will, as usual, take place on the Friday, at the Western Law Courts, the Guildhall. During the week of the Convention, an Exhibition of photographs and photographic apparatus will be held in the Art Gallery of the Plymouth Institute. The public will be admitted by ticket obtained at the door. The headquarters will be the Royal Hotel and the Westminster Temperance Hotel.

Coins as Weights and Measures.—It has often been pointed out how the current coin of the realm may be utilised as weights. This has recently been done once more by Mr. Newton, late of the Royal Mint, who says that "a sovereign weighs a very safe quarter of an ounce for foreign postage," while the crown piece is just on the right side of one ounce, and the half-crown, or its equivalent in smaller coins, will do quite well for the half-ounce. With reference to bronze coins, three pennies, five halfpence, or ten farthings respectively, make up an ounce. A halfpenny is also an accurate measure of one inch. It will often be handy to photographers to know how English coins can be extemporised as metric weights or measures. A sovereign equals eight grammes, and a crown piece twenty-eight grammes as nearly as may be; while a penny, for most practical purposes, may be used as a ten-gramme weight, it being but about three grains less. As measures, the diameter of a farthing is as exactly two centimetres as a halfpenny is an English inch, while a penny is the merest fraction over three centimetres Thus it will be seen that our coins may be, on an emergency, used for both English and foreign weights and measures with approximate accuracy.

Trouble at the Chicago Exhibition.—We briefly alluded a fortnight ago to the discontent amongst the foreign exhibitors at the Chicago show, with reference to the system of awards. Instead of subsiding, the dissatisfaction has extended and taken a decidedly practical form. The Commissioners of no less than seventeen foreign countries have withdrawn their exhibits from competition for awards. Their reason for this unusual step is the unsatisfactory replies to their communications on the subject, and that they consider that it is now too late for an International jury to be formed. Amongst the countries who have withdrawn beyond the European ones are mentioned Japan, Siam, and Brazil. The Commissioners' protest is regarded as of considerable importance by the authorities, one of whom, Mr. St. Clair, of Western Virginia, when the matter was under discussion, said that the matter was a serious one, that the Exhibition was threatened by it, and, if the matter were not settled quickly, it would result, he thought, in a lasting injury to the Fair, and bring disgrace to the country. We fancy he is not far wrong. Who, out of America, ever heard of awards being made upon a testimonial signed by a single expert? Imagine photographs being so adjudicated upon at an International Exhibition! However, English exhibitors, photographic and otherwise, may be content that their interests are carefully watched by the British Commissioners and their energetic Secretary, Sir H. Trueman Wood. By the way, the "big show" is not up to the present proving, financially, the great success our American cousins anticipated. A recent telegram stated that the daily admissions did not meet a third of the day's expenses. Since writing the above the Commissioners of the foreign countries have decided to establish a board of jurors independent of those in the American section, and to issue diplomas in disregard of the American awards.

GLASS POSITIVES ON GELATINE PLATES.

At a recent Whitsun fête down in the country, one of the attractions was a booth or tent at which portraits were taken, the proceeds to be devoted to a local charitable purpose—the artist being of the sterner sex, while a bevy of fair damsels did the canvassing, flitting about amongst the crowd of country folk with specimens, and bringing the customers "up to the scratch." A brief examination of one of the samples showed that it was of the old glass positive type, but though a very fair picture, it was evidently not on collodion, being wanting in the extreme delicacy and brilliancy of the better class of that style of portrait.

Feeling somewhat interested, I accepted the invitation of an acquaintance to accompany him inside "to be taken," not feeling equal to facing the ordeal myself. On entering, I found myself in a plain square tent, entirely devoid of ornamentation of any kind, and bare of furniture except for a single chair, and the camera mounted on a tripod stand. One corner was partitioned off, and from the square of coloured medium visible, evidently formed the dark room. The first thing of importance that attracted my attention was a small heap of paper that had been thrown out of the dark room, and apparently consisted of the wrapping of ordinary dry plates; and indeed it soon became evident from the short exposures given that gelatine films were the means employed.

One portion of the roof of the tent was open to the sky, in approved country-fair fashion, and there were no unnecessary complications in the way of blinds, screens, or curtains to modify the lighting of the sitter, all that being left to the chance of the "pitch"—which may, of course, have been intentionally chosen. At any rate, in all the examples I saw, the lighting was fairly good, and free from excessively heavy shadows or contrast.

After my friend had been taken, he was requested to call back again in an hour's time, a slip of paper bearing a written number being handed to him for presentation when he claimed his picture. As the business done seemed to be fairly good, I was still more puzzled to account for how the plates were developed, washed, dried, blacked, and mounted in an hour's time; so we returned punctually, and fortunately found the "studio" empty, a lull having occurred in the business. The portrait—a by no means bad one—was at once handed to its owner, and consisted simply of the glass plate, previously blacked or varnished, and backed up with a piece of dark-coloured paper, and the edges bound after the manner of a lantern slide, an entirely novel style of finish so far as I am aware.

Explaining that I dabbled a little in picture-making by photography, I got into conversation with the artist, who turned out to be a local amateur—one of the hateful "shamateurs" again—though as there was, I was told, no professional photographer within ten miles at least, the poor fellow was perhaps doing nobody any great harm. He proved very agreeable, and in no way reticent as to his mode of working, having undertaken the task, as he explained, "for fun," and to add something to the organ or harmonium fund to which the proceeds were to be applied. He employed, he said, no special plates, a fact I had already satisfied myself of by picking up a set of developing instructions from the heap on the floor, those he used for ordinary work answering his purpose perfectly well.

In reply to a question as to how he got the necessary positive appearance so comparatively unusual with gelatine plates, he replied that the plates he used, when developed clear of fog or stains, always in his hands gave a fairly good positive after drying when viewed through the glass, but that he had been struck by the great improvement in this respect when using some of the newer developers, especially para-amidophenol, which was the one he used. So marked was this effect that he had been induced to try to still further im-

prove it for merely experimental purposes long before he ever dreamt of his present task, and this is simply how it was done.

The exposure given was a "full" one, rather over than under, what was absolutely necessary, under-exposure being fatal; the development was commenced with a solution of normal strength, but containing a good dose of restraining bromide. With this the image was brought out until the picture was visible in all its details, but without allowing a vestige of veil to appear in half-tones or shadows. When the right point was reached the plate was at once dropped into a dish containing a thirty-grain solution of bromide, where it remained for a minute or so. If, on examination by transmitted light, the image did not appear quite strong enough, another application of the developer was made, which acted as an intensifier only, producing no more detail and no fog unless needlessly prolonged. The fixing was performed in the acid bath, which my informant considered gave clearer shadows, the all-important point.

"But how about finishing in so short a time?" I asked. "You cannot have a very perfect system of washing here under present circumstances, and as for drying——" "On the contrary," he remarked, with a smile, "I pride myself upon my system, although it may not be perfect, and with the assistance of an efficient staff—but step this way, sir." I accordingly followed into the partitioned-off portion of the tent, a part only of which was dark room. Here I found the staff consisted of a couple of youngsters of about twelve and ten years, to whom I was introduced as the "manager of the drying department" and the "chief varnisher." "I am rather short-handed at present, so we have to do the best we can, and I expect my staff to make themselves generally useful; but in the early part of the day I had a 'manageress of the mounting department,' but she got tired of it."

With this brief introduction my new acquaintance then proceeded to develop, wash, dry, and finish a plate, several of which, of "sitters" he was acquainted with, were put aside for future development. The development has been described, and, when fixed, the picture was left to soak for two or three minutes (or more if there happened to be anything else to do) in a dish of water. Repeated jugs full of water were then poured over it from a bucket, the same water being used over and over again; the same operation was then repeated over a second bucket, the water in which he explained was "not quite so thick," and then, after pressing between blotting-paper, the plate was dropped into a dish of alcohol. I hazarded the suggestion that that surely was not sufficient washing, especially after many previous plates had been treated in the same water. "No," he replied, "it is not finished yet," and taking the plate out of the alcohol and holding it up to the light in the open air, he pointed out that the unremoved hyposulphites had been precipitated in the form of a fine opalescent deposit. Upon again placing the plate in water for a few minutes the alcoholic "greasiness" and the opalescence disappeared, and, after again blotting off the surplus water, a second soak in alcohol followed, and it went into the "drying department."

Here a small paraffin stove was provided, and also a simple fan rigged upon a wooden framework and worked by treadle. Holding the picture over the stove and vigorously working the fan at the same time, the elder of the two lads, sons of the chief operator, very soon had the film dry, a careful watch being kept that no symptoms of the film dissolving appeared, in which case less heat and more draught were applied. Next it was varnished by the younger boy, and in the absence of the proper mounter it became any one's duty to finish it. The whole process, however, occupied little over half an hour from commencing development.

I have brought this matter forward not merely to show that positives can be taken on ordinary gelatine plates, but also because in the *modus operandi* there are one or two points that may prove useful at a pinch, notably, the combined operations of rapid washing and drying. The use of alcohol in the removal of hypo was proposed in Paris some years ago, but has never been generally employed, although it may often prove useful.

In conclusion, I may add that I have since succeeded in turning out very respectable positives on several different brands of commercial plates, but as a rule I find the slower kinds give the best results.

W. B. Bolton.

CONTINENTAL NOTES AND NEWS.

Messrs. Lumière's Coloured Photographs.—At a meeting of the Académie des Sciences last month, M. Lippmann exhibited several coloured photographs by Messrs. A. & L. Lumière, by the interference method, on orthochromatic plates, prepared according to the formula given last week (p. 325). The subjects included the solar spectrum, a painted landscape, a bouquet of artificial flowers, a Newton's disc in coloured glass, and several chromo-lithographs. It is stated that the whites of the subjects were correctly rendered, but were only visible at the regular angle of reflection, otherwise they were seen as of a brown tone.

Absence of Halation from Photo-Micrographs.—*Apropos* of M. Monpillard's paper on *Orthochromatism applied to Photo-micrography*, which is referred to in this month's "Lantern Record," the author was asked at the meeting of the Société Française, where it was read, if he had observed that halation was absent from the objects reproduced. M. Monpillard having confirmed the observation, M. Lippmann was of opinion that the absence of halo was due to the smallness of the angle of the rays from the objective acting on each point of the plate. At the particular angle, the dimensions of the halo were so reduced as to become inappreciable.

Artificial Clouds.—What is termed a new and original method of producing artificial clouds was recently brought before the Amateur Photographic Club of Vienna by Herr Anton Einsle. He covers a drawing-board with white paper, studding it at regular intervals with long, headless drawing-pins. Inclining the board slightly backwards, he covers the drawing-pins with large flakes of wadding. Above the board is fixed a small incandescent lamp, which, in a dark place, is said to give the effect of natural clouds. The composition is photographed, with the focus not too sharp, and the cloud negatives so obtained are said to serve for printing-in clouds in photographs.

Hydroquinone and Rodinal.—The *Deutsche Photo-Zeitung* recommends the following combined hydroquinone and rodinal developer, as giving harmonious results without the hardness of the one or the want of contrast of the other.

A.

Hydroquinone	10 grammes.
Rodinal 1·10	40 „
Sodium Sulphite	50 „
Distilled Water	500 „

B.

Potassium Carbonate	30 grammes.
Distilled Water	500 „

For normal development start with A, and if it develops slowly add little by little of B; for instantaneous work take equal parts of the solutions.

Reducin.—This is the name which the Berlin Society of Chemists has given to the very newest developer, which is one of the series of which amidol is the best-known type. It develops without alkali, according to Dr. Vogel, who is also reported to have said that it is superior to pyro. The following is the formula:—

Sodium sulphite	50 grammes.
Water	1000 „
Reducin	5 „
Sulphuric acid	12 drops.

The latter neutralises the alkalinity of the sulphite, which, in an alkaline state, immediately discolours the solution. Amidol, diamidophenol, metol, glycin, reducin, in less than a year! Next, please!

The First Balloon Photograph.—In the last number of the *Paris Photographe* there is a reproduction of a view of Paris

taken from a balloon in 1858 by M. Nadar. It is said to be the first photograph of its kind.

Prefers Wet Collodion.—Herr Fritz Luckhardt, the well-known Viennese photographer, has expressed a preference for the old wet-plate process over modern gelatine plates. Since the employment of the latter he thinks that portrait photography has considerably retrograded. Dry plates, he said, do not permit the photographer to judge immediately of what the negative is like, particularly in regard to the expression and pose of the sitter, which an expert operator often sees occasion to modify. For these reasons Herr Luckhardt extols the old process. We do not, however, gather that he has decided to revert to it.

A Monochromatic Light.—For those engaged in photo-micrography the following method of producing a monochromatic light is given by the *Revue de Chimie Industrielle*. A mixture of bromide and bicarbonate of soda is agglutinated with gum tragacanth and moulded into small discs, 4 mm. by 12-15 mm. These are placed in the flame of a burner which consumes them at the rate of two or three centimetres per minute.

NOTES ON SOME PECULIARITIES IN THE ACTION OF HYDROQUINONE (QUINOL) AND PYROGALLIC ACID DEVELOPERS, AND ALSO OF WATER, ON GELATINE DRY PLATES.

It is customary with some photographers to immerse a gelatine negative plate in water for a few seconds before development, in spite of the opinion of some that such treatment is apt to lead to the formation of "air bells;" whether this be the case or not, I do not think it is generally known that such an immersion makes a considerable difference in the time the image takes to develop. The following account of some experiments which were made during an investigation not yet finished may be of some practical interest to photographers who use pyro-ammonia or hydroquinone developers.

The plates used were Ilford ordinary. All the solutions were freshly made and quite colourless. Fresh developer was used in each experiment.

1. A plate was cut in halves, one half immersed in distilled water for thirty seconds, the other half untouched. The two halves were then placed in a dark slide, exposed on an ordinary open landscape, chosen so that the picture was of sensibly uniform character as regards colour, light, and shade, and the two halves were developed together in the same dish by an ordinary pyro-ammonia developer (Edwards's).

Result: The half which had been immersed in water developed more rapidly and made a stronger image than the other.

2. A plate was cut in halves, one half (A) immersed in water for thirty seconds, the other half (B) untouched; both were exposed together in the camera, and *before development* the half A was left as it was, whilst B was immersed in water for thirty seconds; both were then developed together, when no differences were discernible in the rate of development or in the character of the developed image. Thus the action of the water in accelerating development, which is very decided, seems to be purely mechanical, for it acts as much if the water be applied after exposure as before.

The practical inference from this is that with an under-exposed plate water immersion before development may be useful, with an over-exposed plate it must make the development more difficult to control.

The remaining experiments prove a remarkable difference between the action of the two developers—hydroquinone and pyrogallic acid.

3. One half of a plate (A) was immersed for thirty seconds in a hydroquinone developer (Thomas's)—*i.e.*, both developing solutions mixed, and thus containing hydroquinone, sulphite, bromide, and sodium hydrate—the other half (B) in water for thirty seconds; exposed together, and both developed together with the same (Thomas's) hydroquinone developer. The half A developed far more rapidly than the half B, and, moreover, showed more detail.

Thus hydroquinone developer, applied wet to a plate before exposure, markedly increases its sensitiveness over a water-wetted plate, *and, à fortiori, over a dry one.*

4. A similar experiment to 3 was made with one half wetted for thirty seconds with pyro-ammonia developer—*i.e.*, containing pyrogallic acid, bromide, *and ammonia*—the other half placed in water for thirty seconds, then exposed together, and developed with pyro-ammonia. The result showed that this developer acts in precisely the reverse way to hydroquinone, the water-wetted half having fogged over before before the other had developed. The pyro-ammonia half developed very slowly, and gave an image showing all the detail visible in the other, but "strong," with remarkably clear shadows.

5. To compare a plate wetted with pyro-ammonia with an untouched plate, a similar experiment showed that the pyro-ammonia half developed *very much more slowly* than the untouched, and with much the same differences noticed in 4.

(Developer, pyro-ammonia.)

6. Similar experiment to 5. One half soaked thirty seconds before exposure in the solution of *pyro* only (*i.e.*, no bromide or ammonia), the other untouched, showed that pyro alone is a *very* powerful retarder, the untouched half being fully developed before anything was visible on the other half; and yet the action seemed one of *retardation only*, for eventually there was little, if any, perceptible, difference in detail between the two, though the pyro half gave a powerful negative, whereas the other was weak and over-exposed-looking, though both had received the same exposure.

(Developer, pyro-ammonia.)

7. A similar experiment to 6, made with a solution of hydroquinone, sulphite, and bromide only, *i.e.*, Solution I. of Thomas's developer), showed that the hydroquinone solution greatly accelerates a dry plate, and, moreover, seems to enable it to show greater detail.

(Developer, hydroquinone.)

8. Thinking that the acceleration produced by the hydroquinone developer might be due to the disodic sulphite, itself a reducing agent, a plate was cut in half, one half immersed in a solution of sulphite, the other half in water, each for thirty seconds, the two halves exposed together as before, and developed with hydroquinone, the image appeared a trifle earlier on the sulphite half, but there was little difference in the character of the two images, hence the sulphite alone has very little effect. This was repeated with the same result.

9. An exactly similar experiment—one half immersed in sulphite solution, the other in a solution containing hydroquinone only (no sulphite or bromide); result: the hydroquinone half developed its image a little before the sulphite half, so that neither sulphite nor hydroquinone *alone* produced any marked difference when compared with a plate simply wetted with water.

10. In this experiment, a solution of hydroquinone and sulphite mixed was used on one half, sulphite solution alone on the other. The result (as was to be expected from a former experiment) was that the half which had been immersed in the hydroquinone sulphite, developed far more rapidly than the other, and, moreover, produced a far more "plucky" negative, the sulphite half, in spite of its coming out more slowly, showing fog, whereas the shadows in the other were very clear.

From this it would appear likely that the sulphite and hydroquinone together form some compound whose reducing action greatly exceeds that of either constituent separately. T. C. Ponten.

PHOTO-ASTRONOMY AT THE CAPE OBSERVATORY IN 1892.

II.

As will have been noticed on the photographs already referred to, there are a series, or rather two series, of parallel lines at equal distances apart. These are produced by exposure of the plate behind a *réseau*. This *réseau* is a square of optically worked glass on which a film of silver has been deposited, and then placed in a ruling machine, where the lines are drawn with a fine diamond point at a distance apart of five millimetres. Parellel light is allowed to pass through these lines so as to impress an invisible image of the lines on the sensitive film, which is then ready for exposure in the photo-telescope. When the plate is developed, should the film either expand or contract, the lines expand or contract with the film: and as star measurements are made, not by reference to their distance apart measured direct on the film, but by their distance from the lines whose distances are already known, the expansion or contraction of the film is a negligible quantity. Thus one of the difficulties detrimental to exact astronomical measurements by photography is, thanks to Dr. Lohsë, completely done away with. A difficulty met with in all astronomical measurements by eye is found in the vibrations of the atmosphere due to ascending and descending currents of air. Now, when a photograph is taken of a star, should these vibrations be very considerable, the size of the star disc is enlarged; but the result is a circular image, the centre of which is capable of exact determination under the measuring machine. Two of the photographs sent

home give a remarkably good example of photography applied to exact astronomy. The star α Centauri, which was the first star whose distance was determined (at the Cape Observatory, I may mention in parenthesis) is in other respects a remarkable star. It is a very fine double star, the componenta of which revolve round a common centre in seventy-five years. At one period of the revolution the two stars, as viewed from the earth, appear nearly to coalesce; at another period of their revolution they are well separated. At the present time they are about their maximum distance apart. The photographs show a series of exposures of four seconds each, one-half of which exposures have been taken with the telescope with its aperture stopped down to three inches, and the other half have been taken with the further addition of a wire gauze screen. The double wavy line down the centre is produced by stopping the clock, and allowing the telescope to remain still. The two stars thus produce trails as they pass across the field of view, trails which print down, as it were, every vibration of the atmosphere. Measurements of these plates give a result which eye observations can scarcely equal, certainly not surpass.

The last photograph, that of ω Centauri, is a fine example of the powers of photography, an accurate delineation utterly beyond the powers of the observer by eye. This cluster, made up of stars of about the twelfth and fourteenth magnitudes, is one of the most beautiful telescopic objects in the heavens. It is just visible to the naked eye as a faint nebulous star. The whole area shown in the lantern slide is about equal to two-thirds of the moon's diameter. It has been enlarged from the original negative, and gives a fair representation of what would be seen in a powerful telescope such as the ten-inch guiding telescopes provided with the instruments used in the international star chart. It was exposed for three hours on an exceptionally fine night. Now, to measure and plot down all the stars in this magnificent cluster is a task that the most devoted astronomer might well shrink from. It would be a long but still a comparatively easy task to do so in the study from the photograph. We shall not live to know what changes take place in the galaxy of ω Centauri, but future generations may be able to deduce from photographic records important knowledge of the structure of a universe.

And now to leave the sensational and come to the more sober and prosaic details of the scheme, which many observatories are now busily engaged in; less sensational only in its immediate results, for it is to form the foundation for reference of all future astronomical observations, as well as to leave to the future generations a reliable record of the stellar sphere in its present state depicted with a refinement as well as speedy and economical fulfilment which by any other available means would be beyond the present resources of science.

There are two pieces of work to be done. The first is to consist of a series of plates with short exposures that shall show all stars up to about the eleventh magnitude, which series of plates shall be submitted to measurement, and every star catalogued, in order that the astronomer may have a full and complete series of points from which to refer all future observations. The second is the long-exposure series, that shall record all stars up to about the thirteenth magnitude.

Now as to the catalogue plates. The various zones have been distributed amongst the co-operating observatories, and each region has been divided upon a uniform plan. A little over two degrees square can be taken on each plate, and the centres of the plates are to be taken, as nearly as can be conveniently arranged, just two degrees apart, so that there shall be just a small amount of overlap. But, as the stars at the edges of the plate are not depicted as sharply as those in the centre, and as it is advisable, moreover, to duplicate each observation, a second series has been arranged, so that each plate of the second series shall overlap the adjoining quarters of four plates of the first series. The arrangement of the slates on a roof is not unlike the arrangement of star plates thus determined on. But it is necessary that the position of each plate shall be correct, and, as the stars are not distributed so evenly over the heavens as to give a star exactly in the centre of each plate, the nearest star to the centre as given in our present catalogues is chosen, and its distance from the centre calculated. The guiding telescope has an arrangement by which the eyepiece with its attendant cross-wires can be shifted exactly that distance away from the optical centre. The star chosen, therefore, is a means of exactly setting the instrument, as well as a guide for the observer to tell whether his clockwork is following accurately, and, if not, to apply the necessary correction.

The observer, therefore, sets his clockwork going, exposes his plate behind the *réseau*, transfers it to the metal dark slide of the photo-telescope, sets off his calculated measurements on the micrometer of the observing telescope, points the instrument, and having the star centered on his spider line, or cross wire, commences the exposure. On a night of fairly good definition he gives an exposure of six minutes, which should give good measurable images of stars up to the eleventh magnitude. He then shifts his micrometer, and also his instrument, through the small space of half a minute of arc, corresponding to half a millimetre on the plate, and gives an exposure of three minutes, which shall give him a just visible image of an eleventh magnitude star. Shifting micrometer and instrument to a similar amount, he gives another exposure of twenty seconds, which should give him a just visible image of a ninth magnitude star. This done, he puts the plate away and takes another centre. Should the night be poor for observing, he increases the exposure, always taking the proportions of eighteen, nine, and one. After a number of plates have been thus exposed, a comparison area is taken. A certain number of areas near the celestial equator have been selected by Professor Kapteyn, of Groningen, such area having an easily identified bright star in the centre, and having a moderate number of stars of the ninth and eleventh magnitudes near it, the magnitudes having been carefully determined by Professor Pritchard. The area receives exposures similar to the catalogue plates, and is at once a standard by which to determine whether the catalogue plates have received sufficient exposure, and also as a means of comparing magnitudes. It is not always a safe guide, as at this Observatory, for instance, the definition to the north may be better or worse than that to the south; it is, of course, the observer's business to note the definition, and so given some guide to the checking of the plates. A further guide is given by comparison of the overlapping images of plates taken on different nights. The area taken, work on the catalogue plates is once more proceeded with. At this observatory, all plates are developed in the morning, well washed, examined, and accepted or rejected when dry. Of course, this inspection is not final; when the plates come to be put in the measuring machine will afford the best test, but it is advisable to at once weed out ruthlessly all those that do not come near the mark. At the Cape Observatory in 1892, some three hundred or more catalogue plates were taken without counting those put aside as not satisfactory. There are nearly fourteen hundred assigned to the Cape in the zones marked out for us, a larger number than any other observatory is debited with; but it is hoped, nay, expected, that the catalogue part of our work will be finished by the end of the present year, and, in addition, some little progress on fine nights will be made with the longer-exposure chart plates.

The chart plates only number one-half the catalogue plates. It is not so absolutely necessary to obtain the second set overlapping the first. Of course, it would be better to do so, but time and money have to be taken into consideration. The chart plates will be exposed on the best nights for about one hour, and only one exposure will be made on each plate; for when so long an exposure is given, and so many stars impress themselves, the taking a triple series of exposures on each plate would only mean confusion. Even on some of the catalogue plates it is evident that some additional special plates may have to be exposed, as an occasional close cluster of bright stars is rendered difficultly measurable, owing to overlapping images.

The chart plates, with the expected multitude of stars they are likely to reveal, are not to be measured, and the method of reproduction and publication has yet to be considered. The measuring of the catalogue plates will be no light piece of work, and the means of its accomplishment will have to be considered, though the way is obvious. As to the way of measurement, I may conclude with a brief account of what is done when a plate is submitted to measurement.

The measuring machine made by Repsold for the Cape Observatory has a circular motion for measuring angles, which are read off by microscopes bearing on the graduated circle. It also has two lateral motions at right angles to one another, with scales for measuring right across the plate in both directions. The first important thing to be done is to determine the values of every distance between the *réseau* lines on the *réseau* itself; and this should be done before the *réseau* is taken into use, lest any accident happen to it in the course of work. The measuring machine has also a microscope with cross wires at right angles, capable of moving across the whole field of view, and with micrometer heads to tell exactly the amount of movement. The finished negative is put into its place, and adjusted with the *réseau* lines exactly parallel to the cross wires in the micrometer eyepiece. In the centre of the field of view a five-millimetre square is adjusted, and the cross-wires are passed over from *réseau* line to star, and to opposite *réseau* line, then back again. Every star measured in that particular square, the next one is taken, until the whole 676 squares have been passed in review, and the positions of the whole of the stars determined. The measurements then pass into the hands of the computers.

C. Ray Woods.

BACKING AND BLURRING.

One would have thought that the advantages of backing plates with some non-actinic compound of about the same refractive index as the plates themselves would have been settled years ago, considering the numbers of exhaustive experiments that were undertaken, and the invariable improvement in the results in comparison with unbacked plates when the process was adopted. Not that the effects were always the same, for it was found very much depended on the character of the film and method of development. Now, even more than formerly, our negatives become afflicted with blurring and halation, which seems to increase with the rapidity of the plates, and affects all classes of work from copying to high-class portraiture. It has been definitely proved that, in *all* cases where the subjects possess great contrast of lights and shadows, backing is an advantage; but, in less trying subjects, little or no difference was perceived *with some plates*. With others, again, it was a distinct advantage all through, whatever the subject happened to be. There is no doubt that very much depends on the emulsion itself, independent of any other cause whatever. A dense yellow film rather slow, backed or not backed, is rarely affected by halation or blurring in any except very extreme cases; but with a thin, whitish film of considerable rapidity it is almost impossible to get an image entirely free from it, and with difficult subjects and every precaution used blurring will take place.

Of course, this blurring or halation—I use the words indiscriminately—may be present in such small degree as to escape observation, or only so much that a few bright spots of light will have softened edges. It may be that there are very many small portions of a picture white or nearly so in contact with darker parts, all of which would be affected in the same way. The general brilliancy of a negative would thus be depreciated without it being possible to say with certainty it was suffering from blurring, or it might escape notice altogether, probably would. The same subject, however, taken on a plate free from this fault, would be much the better of the two. A *very rapid* plate almost *invariably* blurs under trying conditions, and often when conditions are less exacting, backed or not, no matter how the development is managed, which, by the bye, has considerable influence on the result: but, apart from this, a thin, rapid film is practically unworkable for any subject with violent contrasts, and I do not think the reason far to see. With such films the particles of silver bromide are considerably larger than with a slower preparation, and being more loosely aggregated offer less resistance to the passage of light *in all directions*, not only as reflected from the support, but in the film itself, from particle to particle. In support of this view, the bromide diffused through a large quantity of gelatine suffers halation in proportion to the amount of salt enclosed in it. A thick film, with a comparatively small proportion of bromide in an exalted state of sensitiveness will be very rapid, but the image produced will lack brilliance, even to fogginess; thus the extra difficulty of working rapid plates will be understood, as, the more rapid they are, the looser and larger are the particles of the silver bromide - a fact recognised soon after emulsions were used. An interior whose illumination is derived from a white-glass window directly in front, taken on a rapid plate, is absolutely certain to show this defect in a very pronounced manner in defiance of any precaution that may be taken to prevent it. I remember a case on which I expended many plates and every precaution I knew to avoid this trouble, but it was not until I adopted some slow plates that I could obtain a presentable result, when the affair worked like a charm, and, except in a very trifling degree, was entirely free from blurring.

Backing the plates will always *improve* the quality of the image *if the film is easily penetrable by the light*, because, light reflected from the back surface of the plate is thus rendered innocuous; but, owing to the dispersion of light in the film itself, is only a partial remedy, and the difference in plates in this respect has undoubtedly given rise to diversity of opinion on the advantage of backing. Beyond a certain point, every increase of sensitiveness is adding to the difficulties of working, and at the present time there is such an irrepressible desire for rapidity that every other quality is more or less sacrificed to it. Very rapid films, besides blurring, are much more prone to *reversal*, an equally annoying defect when an exterior view is wanted in combination with an interior—a view through a window, for instance, will show as a positive without the slightest trace of blur, but the effect on the print is equally disastrous, and more difficult to doctor.

I am inclined to think that lateral diffusion of light in the film of a gelatine plate is the chief reason why wet collodion is preferred for photo-mechanical processes, and the reproduction of line work in general. Given a *thin gelatine* film, so far as substance is concerned, well charged with not over-sensitive silver salts, the resulting image will be quite as free from veil, and the dark lines rendered as clearly as with collodion. The exigencies of much photographic work necessitates a certain degree of rapidity, especially portrait work in the studio, when other qualities are sacrificed to secure it. However, some of the finest work extant has been produced on only moderately rapid films. There is no doubt all additional speed beyond a certain point induces difficulties that the most skilful development will not always overcome. Take for instance a sitter, habited in yellow-coloured velvet and white lace, intermixed with a quantity of white silk drapery, on a very rapid, and also on a moderately rapid, or slowish plate, and compare the results, both plates being backed. The slower plate will be found to give very much more detail in the light parts, and the pattern of the lace will be well made out, sharp, and distinct, and the darker velvet will not be partially obscured by blurring; but, in the rapid, there will be considerable falling off in both respects —the lace will be less distinct, and the edges of the darker parts will be blurred, and very small portions of the dark will be almost obliterated. The effect is identical with the blurring round the windows of an interior. If this effect was owing to reflection from the back of the glass, the backing would prove a perfect remedy; but, owing to the short exposure, and the amount of light falling on the sitter, there is not so much damage to the image from this cause as from internal reflection, which is, of course, entirely independent of that from the back surface of the plate. A rapid film, on any other support than glass, is liable to this kind of blurring. I have seen films on paper entirely spoilt by blurring where there could be no possible reflection from the support.

In all probability, multiple films should be more free from this defect, so far as the lower or *less* sensitive strata are concerned; but I can scarcely think that, from the point of view I take, the more sensitive layers should enjoy immunity from it, than when such sensitive layers are in direct contact with the glass. However, this is mere supposition on my part, as I have not worked with the films in question; but I cannot realise to myself that a subject that would blur with an equally sensitive film alone would cease to do so in superposition on another slower one. But perhaps I have been misinformed on this subject, upon which I hope before long to have practical information. A very strong, sharp light impinging on a film in the camera illuminates the whole surface of the plate and interior of the camera in the form of diffused light, but is too weak to injure the image, unless the camera is filled with, so to say, a cloud of dust, vapour, smoke, or the inside of the camera itself being somewhat shiny, which would be sufficient to reflect the light partially from its direct course, and to depreciate the quality of the image. In the old wet-plate days black velvet moistened with water or glycerine and water was placed in the camera during exposure, not only to delay the drying of the plate, but to catch any dust that might be there. In outdoor photography dust, vapour, and smoke are very common conditions in which some kinds of work have to be done, and it is necessary to get the camera as free from them as possible, or the results would be anything but satisfactory. When the light impinges on the film to form the image, it becomes diffused in all directions within the film, penetrating more or less according to amount of resistance offered by the haloid in *compactness* and *colour*; very much in some cases, and in some so little as to cause no perceptible difference to the brilliancy of the image. When the particles of silver bromide are very closely aggregated together as in most slow plates, we have a barrier interposed to the reflection of the light, and the film is, so to say, opaque—the light neither passes though nor disperses itself laterally during the time necessary for exposure. But, if instead of this opacity we have a considerable body of gelatine, with the bromide particles widely separated and large in size, there is not much resistance to the passage of light in any direction, which consequently induces the faults of blurring and fogginess.

Backing stops reflection from the glass and is so far useful, but the lateral dispersion goes on just as energetically as if there was none, and we fail to get a clear, brilliant image. This effect does not occur so much on collodion films, hence the preference given them for line work. It is simply because the actual thickness of the film is so much less than with gelatine. I believe, if the collodion film was made thick as gelatine, its superiority in this respect would cease, and the effect of blurring would be the same as when the haloid is enclosed in gelatine. If the gelatine coating was made as thin, and to carry as much salts as the collodion, the two preparations would, in all probability, be very similar as far as blurring and halation are concerned. A gelatine film has always been supposed to excel collodion in rapidity, but I think, if the same attention had been paid to collodion as that given to its rival, an equal rapidity would have been secured by this time. This is, however, somewhat deviating from the subject of this paper; but one thing seems so dovetailed into another in matters photographic that we find very few effects limited to single reasons, so that in discussing one we insensibly run into

another. Whatever the real cause of halation may be, nine times out of ten backing the plates will reduce it; but, if we wish to get absolutely rid of it, the quality of the emulsion is principally to be relied on. Plates of a moderate speed, containing iodide, are best, and those of great rapidity worst, of all in this particular.

EDWARD DUNMORE.

COMPOSITE HELIOCHROMY.*

LIGHT transmitted by the image of the green sensation, G, passes through the green colour screen, G′, to the silver mirror, 5, thence sideways to the silver mirror, 6, forwards through the transparent mirrors, 4 and 2, and the objective, D, to the inclined mirror, E, and upwards into the eyepiece, under which a green image is formed, exactly coincident with the red and blue-violet images. A portion of the green light is lost by reflection from the transparent mirrors, 4 and 2.

The fact that the light rays from R, V, and G travel equal distances before entering the eye, and have a common axis after emerging from the mirror system, secures a direct blending of the images, which must otherwise be projected upon a matt surface in order to be seen as a single image. Prismatic devices, as proposed by Du Hauron and others, fail in this respect, and are therefore useless.

An optician will readily see in the instrument as described various apparent defects, none of which, however, are evident in the instrument as constructed. In the first place, in the absence of colour screens, the image of the green sensation, formed of light reflected from a central silver mirror, is much more brilliant than the other images, formed of the weaker portions of light reflected from the central transparent mirrors, which are unsilvered, plane-polished glasses. But the band of pure green light in the spectrum is very much narrower than the bands of red and blue-violet, and this apparent defect is therefore, in reality, an advantage, because it permits of the use of a screen that transmits the light of only a very narrow band of spectrum green, instead of the broader band that would otherwise be necessary to make up white light. Another apparent defect is that, if the transparent mirrors have parallel plane surfaces, they will, if clear, give a doubled instead of a single image. This defect can be removed by making the mirror 4 of canary-yellow glass, which transmits both red and green light freely, but destroys all the blue-violet light that is not reflected from its first surface; and the mirror 2 of a cyan-blue glass, which freely transmits both green and blue-violet light, but destroys all red light that is not reflected from its first surface. This method of correction is objectionable, because it reduces the intensity of illumination by nearly one-half. The method that I have adopted is to use thin glass, having the two plane surfaces inclined to each other just sufficiently to make the two reflected rays coincident at D. Another apparent defect is found in fact that the amount of light reflected from the plane glasses used as transparent mirrors varies with the angle of incidence. With the arrangement shown in the diagram, the top of the image of the red sensation will appear brighter than the bottom, and the outside of the image of the blue-violet sensation brighter than the inside. The disc of light seen in the heliochromoscope—when the chromogram is absent, and the instrument directed towards a white sky—will be white only in the centre, the outer portions showing a delicate tint of blue on the one side, yellow on the other, pink at the top, and green at the bottom. This defect has been removed by the simple expedient of inclining the colour screens, so that the stronger ray passes diagonally through the coloured glass, and the weaker ray straight through.

The mirrors are attached to brass supports, and are adjustable by small screws pressing them against the springs by which they are held in place. But the adjustment is such a nice matter that a twentieth of a turn of a single screw, having fifty-six threads to the inch, would make the instrument useless until it had been readjusted.

One of the cameras I use for making the chromogram negatives is a converted heliochromoscope, the eyepiece serving as an objective, projecting an image that includes nearly 50° angle of view. It may be readily reconverted into a heliochromoscope by substituting a chromogram-holder and *pure* colour screens for the plateholder, and *selective* colour screens. In this instrument, transparent axial mirrors are used for the images of the green and blue-violet sensations, and a pair of silvered mirrors for the image of the red sensation, because the latter must be made many times brighter than the others on the sensitive plate employed. This is a more compact and convenient form of camera than any other that I have devised for this purpose, but the aperture of the eyepiece is so small that it is necessary to give very long exposures—up to ten minutes on well-lighted landscapes with ordinary isochromatic plates.

When circumstances do not admit of the longer exposure, I use another form of camera, in which the mirror system is arranged in front of three separate objectives. This camera, in comparison with the compact inverted heliochromoscope, is somewhat clumsy, and includes a smaller angle of view, but has an effective aperture of about *f*-16 for the image of the red sensation, and requires not more than thirty seconds' exposure for objects illuminated with clear sunlight.

I now come to the consideration of the defects of the system as a means for reproducing the colours of Nature. One of the greatest photographic authorities has said that no method depending upon the production of photographic negatives by known processes can possibly be made to secure accurate reproductions of colour, because no known photographic negative-making process will accurately reproduce monochrome light and shade. This statement is strictly true, and the fact must not be ignored, even though the defect referred to affects the success and value of colour photography scarcely more than it does the success and value of monochrome photography, which can be made to give reproductions of the majority of monochrome subjects good enough to be generally accepted as true facsimiles.

In monochrome photography the contrasts in the middle shades of a correctly exposed negative are always more or less exaggerated, at the expense of both ends of the scale. The positive print from such a negative will, upon critical comparison with the original, appear more or less weakened or bleached in the lighter shades and heavy in the shadows, with undue contrasts in the middle shades, especially if the original shows strong contrasts of illumination. In composite heliochromy the same defect must evidently be present, making colours appear as if slightly faded in the lighter shades and dull in the deeper shadows, with undue strength and contrasts in the middle shades. This defect is seldom noticeable in reproductions of evenly illuminated objects when photographed upon the highly sensitive and soft-working photographic plates available for this work. The defect, however, may be offensively evident in reproductions of objects showing strong contrasts of illumination.

Another consequence of the same defect in the photographic negative-making process is undue intensification of the stronger elements of mixed colours in the deeper shades of the picture. For example, an orange, which is a mixture of four parts of red to one of green (physiologically), if it act with exactly four times the force in producing the negative of the red sensation that it does in producing the negative of the green, will be represented by more than four times the density of deposit, in case only a moderate exposure be given (because the density is always disproportionately great in the middle shades of the negative), and will, therefore, be reproduced as a slightly redder orange than it really is. A full exposure corrects this defect, and an excessive exposure, by bringing the green element into the middle shades of its negative and the red element into the high lights of its negative, either reverses the defect, making the orange too yellow, or, in case it is originally impure (*i.e.*, mixed with a small proportion of white light), may even produce a suggestion of brick-red in the reproduction.

This defect is not as serious as might be expected, because it is really only an exaggeration of effects produced upon the eye in ordinary vision, by corresponding variations in the illumination of the object, for which the judgment, from mere force of habit, instinctively makes allowance. In this connexion I quote from Rood as follows:—

"Coloured surfaces undergo changes of tint when they are seen under a very bright or a very feeble illumination. . . . . The violet of the spectrum is easily affected; when it is feeble—that is, dark, it approaches purple in its hue; as it is made stronger the colour changes to blue, and, finally, to a whitish grey, with a faint tint of violet-blue. The changes with the ultramarine blue of the spectrum follow the same order, passing, first, into sky-blue, and, finally, into white. Green, as it is made brighter, passes into yellowish-green, and then into whitish-yellow; for actual conversion into white, it is necesssary that the illumination should be dazzling. Red resists these changes more than the other colours; but, if it be made quite bright, it passes into orange, and then into bright yellow. . . . . Colour sensations, which are due to the joint action of two sets of nerves, speedily diminish when the colour is darkened, and are replaced by the primary sensations—red, green, or violet. The sensation of orange is produced by those light waves in the spectrum, which have a length such as to enable them to stimulate the red nerves strongly, and the green nerves to a lesser degree; hence, when orange-coloured light is made very weak, it fails to act on the green nerves, while feebly stimulating the red. For similar reasons the sensa-

* Concluded from page 330.

tions of yellow and greenish-yellow pass into green, as do also those of greenish-blue and cyan-blue; in the same way, the sensations of blue, ultramarine blue, and violet-blue pass into violet."

In short, we have in this colour photography imperfect rendering of the relative intensities of colour in the different shades of the picture, corresponding to the imperfect rendering of gradations in monochrome photography, and also exaggerations of the visual effect of varying intensities of illumination upon colours, due to the same defect in the negative process.

I will take this opportunity to suggest that the similarity of the photographic defect to an inherent defect of colour vision may be taken as an argument in favour of the theory that colour vision is itself essentially photographic. It appears to me that there may be in the retina three light-sensitive chemical substances, each of which, when acted upon by light, reacts upon the nerves of vision to produce a definite sensation, which is one of the recognised fundamentals. We may assume that one of these substances resembles, in its optical properties, a coal-tar dye, which is sold as "multiple yellow," and which shows an absorption curve very much like Captain Abney's curve to represent the action of spectrum rays upon the fundamendal blue-violet sensation; that another substance similarly resembles aniline magenta, which shows an absorption curve similar to Maxwell's curve for the action of spectrum rays upon the fundamental green sensation; and that a third similarly resembles an aniline blue, that shows an absorption curve similar to Maxwell's curve for the action of spectrum rays upon the fundamental red sensation. Such substances may be in liquid form, like solutions of the dyes, and the mixture, like a mixture of the dyes, would absorb all the spectrum rays that excite vision. The spectrum rays at Fraunhofer line D would be absorbed about equally by the blue and magenta substances, thereby exciting about equally the two fundamental sensations red and green, which make up the compound sensation of yellow. All other compound sensations would be similarly explained. Solarisation in one of these substances, by bleaching or destroying some of it, would temporarily weaken the corresponding sensation, but, at the same time, increase the sensitiveness of that portion of the retina to other colours by giving some of the spectrum rays freer access to one or both of the other two substances. It seems to me that no other theory will explain so much as this. But my paper is not on the subject of colour vision, and I must, therefore, reserve further consideration of this subject for another occasion.

Under favourable conditions the photographic defects which I have mentioned are so small as to pass unnoticed by the ordinary observer, to whom the reproduction seems perfection in every respect. Under unfavourable conditions the results might be quite as unsatisfactory as are sometimes the results in monochrome photography. To look for a nearer approach to perfection would be unreasonable in the present state of photographic science.

I hope to go more exhaustively into this branch of the subject at some future time, but believe that, in a general way, I may claim to have stated the case fairly. If the scientific specialist is inclined to think that I may have made out too good a case for composite heliochromy, the practical photographer will, on the other hand, be astonished to find that, in spite of all theoretical and practical difficulties, the image of familiar objects, as seen in the heliochromoscope, is as satisfying to the eye as the transient image on the ground glass of the camera which he has so often admired and dreamed of fixing.

In actual practice defects due to quite different causes have been far more troublesome and irritating to me than either of those described. Fortunately, however, they are not inherent in the process, and it was only necessary to discover their true cause in order to eliminate them. With certain developers, hydroquinone being one—the image of the blue-violet sensation commences to develop first, and goes on almost to completion long before the detail is all out in the image of the red sensation, even though the latter may appear relatively over-exposed after the development is fully carried out. Under such circumstances, the relation between the two images will vary with the time the plate is left in the developer, and it is difficult to ensure accuracy. This difficulty was substantially overcome by using the eikonogen developer, and seems to have entirely disappeared with rodinal development.

With some sensitive plates the image of the green sensation, formed principally in eoside of silver, develops more density than either of the other images, and introduces troublesome irregularities. Fortunately, some of the best makes of sensitive plates are free from this defect, and may be selected for this purpose.

For a long time, in spite of every precaution I knew how to take, my negatives developed considerable more density towards the edges of the plate than towards the middle. The consequence of this was that the top of the negative of the red sensation, and the bottom and outer sides of the negatives of the green and blue-violet sensations, would be so over-dense as to make the colours in those parts of the reproduction distinctly incorrect. I imagined this to be due to a defect in the sensitive plates, an effect of the more rapid drying of the emulsion at the edges in process of manufacture. In this I was happily mistaken. It proved to be due to access of air to the outer portions of the plate during the process of development, by constant rocking in a dish containing a rather small quantity of developer. The unevenness disappeared as if by magic when the plates were developed by deep immersion in the developer in a dipping bath. Probably the reason that this unequal action of the developer has not been noticed in monochrome photography is that the centre of the plate usually receives more light than the edges, and the action which is so injurious in the colour process is seldom more than sufficient to compensate for this unevenness of illumination.

In my earlier experiments, light objects against a dark ground frequently reproduced with a red or reddish halo, because of strong halation in the image of the red sensation, so that, even for objects that come very well in monochrome photography, I found that the plates should be "backed" for composite heliochromy.

The results which I show, taken in connexion with what I have said, will make it evident that the process has already been reduced to very successful practical operation in my hands, and that the conditions of success are such as may easily be realised by others when provided with the same apparatus properly adjusted.

The method of carrying out the process to the production of colour prints, although it will doubtless prove of great value for some purposes, cannot, by reason of its complications, difficulties, and cost, be successfully utilised by amateur and general photographers. As long ago as the year 1881, when I was the only successful producer of half-tone process blocks for the type press, and had considerably improved upon the old methods of composite heliochromy, without quite realising the true principle which I first published in 1888, I made the first photographic reproduction of a coloured subject by three impressions from process blocks. This three-colour print, a reproduction of a chromo-lithograph, was referred to in a leading article in the *Photographic News* of September 5, 1884, page 561. I have one of the prints with me now. The lines expressing the light and shade were run in different directions in the different blocks, in order to avoid the production of a disagreeable pattern—a plan which has quite recently been claimed and patented as a new invention in Germany, and adopted by Kurtz, of New York, and others. My Franklin Institutes lectures upon this subject, in 1890 and 1891, were also illustrated with examples in cemented gelatine colour prints, mounted as lantern slides and window transparencies. The latter are now in the United States National Museum at Washington. I have not followed up these developments of the process very industriously, because it has been my ambition to realise a simple and readily available method of photographic colour reproduction, perfect so far as it goes, before undertaking to fully develop the process in its more complicated form. The best fruit of my efforts in this direction is the heliochromoscope and its appurtenances, which I claim to be the first completely successful means for reproducing the natural colours by photography.

I believe that scientists who have been aware of the impossibility of escaping from the inherent photographic defects which I have described, have greatly over-estimated their importance, through quite overlooking the fact that they result in nothing more serious than an apparent exaggeration of natural defects of colour vision, for which we are already in the habit of making unconscious allowance.

While the not altogether unreasonable doubts of the true scientist have made him cautious and reticent in his attitude towards the claims made for composite heliochromy, some who write with an air of authority upon subjects quite beyond their comprehension have industriously discredited my efforts to substitute the application of true theories, definite methods, and scientific tests for false theories, wrong and indefinite methods, and unsuccessful guesswork. A well-known representative of the latter class recently went so far as to characterise my work as a mere "laying of stress upon words," "of the nature of throwing dust into the eyes of simple mortals." This is certainly a sufficiently bold and simple way of combating facts and arguments that are not comprehended. A sufficient reply to all such wilful or accidental misrepresentations, past or future, may be found, by those who are capable of understanding the subject, in the two papers which I have now had the honour to read before the Society of Arts, and in the references given and results shown.

Objection has been made to the use of the terms "heliochromy," "photochromy," and "colour photography," as applied to this process of

colour reproduction. It has been said that, because colours can be produced directly by the action of light upon certain sensitive surfaces, these terms should be restricted to processes of that character. It was to meet this objection that I named the process "composite heliochromy." If a better descriptive name can be suggested, I will readily adopt it. But I shall be greatly surprised if the public does not finally insist upon calling the production of chromograms after my method by the name of "colour photography," just as they now call the production of stereograms "stereoscopic photography." It is of comparatively little consequence what name is given to the direct processes, so long as they cannot be made to reproduce the colours of nature, and are therefore of no interest to the general public. It is the successful process that should have first choice of suitable names. The only recognised talking machine of to-day is the phonograph, although the name "talking machine" was applied to something far different—an arrangement of bellows and reeds, and pipes, and keys, in imitation of the human vocal apparatus—long before the phonograph was dreamed of. Perhaps the heliochromoscope would be more properly called a photochromoscope, a name which I like better, but have not adopted, because inventors of devices of a very different character have already been quarrelling about the right to use it.

In conclusion, a criticism of the heliochromoscope, from the painter's point of view, may be of interest. An artist friend, who leans towards the Impressionist school, on seeing the instrument for the first time, said the reproductions of nature offended him in the same way that ordinary photography did, by idealising nothing, and leaving nothing to the imagination; in short, the reproduction was "too absolute to be artistic."

F. E. Ives.

Abstract of Discussion.

Mr. J. Wilson Swan congratulated Mr. Ives on the marked progress he had made since he last showed his results in that room. He had told them plainly the limits of his ambition, that of attaining a practical method of producing what he thought was attainable in the direction of colour photography. Popularly, no doubt, photography in natural colours meant something different from what had been shown that evening; it meant a process by which not only light and shade, and the natural form, but also the colours of the objects, would be produced directly on the sensitive surface. Some sanguine people conceived that such a thing was not impossible, but many far-seeing and able men considered it to be quite unattainable, and these would certainly not be the discoverers. The path of progress and discovery was illuminated by the light of hope, and to search for any object hopelessly was not the way to find it. He believed that the feeling that colour photography was unattainable had restricted experiment, and, as without experiment very little progress could be made, it was not wonderful that colour photography, in this ideal sense, had not yet been realised. Within the last few days particulars had appeared in the newspapers to the effect that the long-desired result had been achieved in Paris, and that some few had been privileged to see it. He at once felt a strong impulse to go off to Paris and satisfy himself, but checked the impulse with the reflection that if this piece of news was true—as it was well known how deep an interest the President of the Photographic Society of Great Britain took in the subject, and as Paris was only about eight hours distant from London—it was almost certain that some examples of the alleged discovery would have been there that night. Since they were not, he feared that one more disappointment was going to crush this hope. In short, this discovery had been announced about as often as that of the "sea serpent;" and, probably, the chances of such reports turning out to be true were nearly equal. It struck him that the form of colour photography which had been described that evening had one advantage even over the more ideal process to which he had referred, viz., that it contained within itself the elements of multiplication and reproduction by means of negatives, a feature that characterised the photographic method originated by Fox Talbot, a most valuable feature, and one which he thought was hardly appreciated at its true value. He hoped that this would not be the last time they would see Mr. Ives at the Society of Arts. What had been shown and described that evening was, without doubt, the high-water mark of what had, so far, been obtained in colour photography; and one hardly knew which to admire the most, the logical clearness of Mr. Ives's ideas and the expression of them, the ingenuity of his devices, or the beauty of his results.

In reply to various remarks, Mr. Ives said the images which formed the chromogram had no colour themselves, they were only a register of colours, and might be compared to the wax cylinder in a phonograph, which contained no sounds though it registered them, and, on putting the instrument in operation, reproduced them. In the triple photograph there was a record of the colours, and when it was put into the heliochromoscope they were brought back to the eye. One image was called the red, not because it was red, which it was not, but because it represented the relative amount of action on the fundamental red sensation. It represented the effect of light coming from the object upon the fundamental red sensation. The same with the blue and the green. He had not attempted to go into the science of the subject that evening because he did so very carefully last year, when he explained what various colours of the spectrum excited each fundamental sensation. The sensation itself was of a perfectly simple colour. The screen to produce the effect of the red sensation in the negative must transmit sufficient not only of the red but of the orange-yellow and yellow-green rays, all of which had the power to excite that sensation. The exact colour of the screens in the camera depended on the colour sensitiveness of the photographic plate. If the latter were twice as sensitive to red as to orange, while, on the other hand, the fundamental red sensation was affected twice as much by the orange rays as by the red, it would evidently be necessary to use a screen which cut out some of the red rays, which would otherwise have a disproportionately strong effect. The plates actually used were many times more sensitive to orange than to red, and it was necessary in practice, in order that the red rays should have time to do their share of the work, that the colour screen should cut off a very large proportion of the orange rays. The screens were tested by photographing the solar spectrum, and it was assumed that they were right when the photograph of the spectrum showed a distribution of density which corresponded to a curve representing the power of the different rays to excite the respective fundamental sensations. The heliochromoscope and lantern screens, on the other hand, were, like the fundamental sensations themselves, of pure simple colours. The subject was very difficult to follow for any one who had not made a special study of it. As he stated in the paper, he had devised a camera with which the triple photograph could be made at one exposure of one sensitive plate. He had also explained that the tint of yellow-green on the edge of the water pitcher was due to a defect in the development, not to anything inherent in the process itself.

The Chairman said he believed he was one of the first to see the results of Mr. Ives's work last year, and he must say that what he had now brought forward showed a very decided advance, and was not only very interesting but of scientific value. One could not help seeing that Mr. Ives had worked on thoroughly scientific principles. It was not every one who would undertake to find out what the three fundamental colour sensations were, and where they were situated in the spectrum. A good many who had worked in this direction had not taken so much trouble, and some had selected colours which did not really excite the fundamental sensations. The three which Mr. Ives had chosen seemed to be very near the truth, as far as was at present known. The red sensation was stimulated by the red which lay near the limit of the solar spectrum, and when you got as far as the c line, where the red was pretty bright, there was a very small contamination of green with it, but so small that you might use it, without serious error, for over ninety per cent. of the colour sensation produced in the eye would be caused by the stimulation of the red-perceiving apparatus. The green was situated not in the yellow-green, but was a distinct green of itself; probably only one man in twenty-five had ever felt the true fundamental green sensation at all, because they must be colour-blind in order to do so; the real fundamental sensation was so much mixed up with white that we only felt the green largely diluted. The blue-violet was the one at the far end of the spectrum, somewhere about o, and was very fairly represented by the colour Mr. Ives had chosen. He was rather glad Mr. Swan had not gone to go to Paris to see the colour photographs which were reported, for had he done so he would not have been present to have made his remarks. From the accounts he (Captain Abney) had received he was very sceptical whether any real progress had been made in colour photography. What the Paris process did was to show interference colours. That was not true colour photography, and would only be achieved when actual pigments were produced. A photograph in which the same part looked red in one light and green in another was not colour photography. There were several very interesting points in the paper with regard to the modes of developing; for instance, the fact that the image exposed to the red would not develop with hydroquinone as rapidly as blue did. This he had long been familiar with, and there was a scientific explanation of it which ought to be known, but which would take too long to detail now. Again, he had always held that, in some sensitive plates, the image formed by the green rays was principally formed in the eoside of silver; it had often been combated, but he still held to it, and was glad to find that Mr. Ives's experience confirmed him. Another interesting fact was the method of applying the developer. Mr. Ives said that he first thought the fact that the plate developed more in density at one part than another was due to its not being evenly coated; but, directly he prevented the access of air to the outer portion during the process, the mischief vanished. That might teach a useful lesson to practical photographers. No one could have seen the heliochromoscope without being struck by the ingenuity of its construction, and the marvellous skill with which the reflecting surfaces were arranged. The little contrivances for getting rid of double images formed by reflection from the back and front of a plain glass mirror were admirable. Reflections from plain glass used for other work had bothered him so much that he had had to abandon such mirrors and use the surface of a prism, but Mr. Ives had got rid of the evil in another way, and made the two images coincide by using a very slightly prismatic glass. The little instrument was a masterpiece of ingenuity, and he hoped that when Mr. Ives came again next year he would have still further developed this very instructive process. The time was evidently coming when people would not be content with ordinary photographs as lecture illustrations of machinery or any

thing else, but would require all objects to be portrayed in their proper colours. He concluded by proposing a vote of thanks to Mr. Ives, which was carried unanimously.

ISOCHROMATIC PHOTOGRAPHY.

Before the South London Photographic Society, on May 15, Mr. E. J. Wall delivered a lecture on *Isochromatic Photography*. He said although the principle of isochromatic photography had been known for some years, it was not until Edwards introduced plates commercially that it received any attention in England. The sensitive salt used in the preparation of orthochromatic plates is stained with a dye, usually erythrosine, one of the eosine series. A great many amateurs think they cannot use the plates without a screen. It is seldom required; improperly used, as bad a result can be obtained in the opposite way. In the spring and autumn, when the grass and trees are more yellowish than in the summer, the value of colour-sensitive plates ought to be more appreciated. In the summer a great deal of white light is reflected from the foliage. Isochromatic plates show a great improvement in the rendering of distance, and finer detail in the shadows and water are obtained.

In snow scenes a better gradation of the whites is given. By the use of too deep a screen the sense of distance is destroyed. In sunset scenes the superiority of the plates is strikingly apparent. No yellow screen is required, and comparatively shorter exposures given than when using ordinary plates. A screen would make the shadows blacker. For clouds and seascapes isochromatic plates should only be used. For clouds, using a slow plate and stop *f*-16, an exposure of one-fourth to one-twentieth of a second will be sufficient. Thunder-clouds require one-fourth of a second, but for ordinary one-tenth is enough. Cloud negatives should be kept rather thin. The new developers, amidol or metol, are preferable to pyro for cloud work. Amateurs' snow pictures are mostly unsatisfactory. By using a colour-sensitive plate of medium rapidity and a second tint screen, and giving a comparatively long exposure, carrying out the old principle of exposing for the shadows, and then in developing get a rather thin negative, better snow pictures will be got than before.

Colour-sensitive plates are necessary in copying pictures. Sunlight is the best light to use for this purpose, next magnesium, and then gaslight, and, lastly, diffused daylight. For ordinary work gaslight is more convenient than magnesium. The lecturer used two Defries lamps, with the globes coloured with yellow varnish, and gave enormously long exposures. For pictures containing a good deal of red it was necessary to prepare plates specially for the purpose. Cyanine dye is the best sensitiser for red. To make plates that will keep, prepare your own cyanine. Oil-colour paintings require more exposure than water colours, pastels less, and illuminated addresses still less. For home portraiture the most rapid plates should be used. The only case in portraiture in which a screen, and that a very pale one, should be used is to render very pale-blue eyes.

The faults of isochromatic plates are the great tendency to too great density; but this can be dealt with in development. Ammonia is more likely to yield fog, and for this reason pyro-soda has been recommended as a developer. Pinholes.—These appear in greater numbers when ammonia is used as the accelerator than when soda or potash is substituted.

Screens of various makes were shown, but, if desired, photographers can prepare their own by dissolving one grain of brilliant aniline yellow in an ounce of amyl collodion, *i.e.*, pyroxyline dissolved in amyl acetate, and coating thin glass with it. By using two grains of the dye to the ounce, a screen increasing exposure three times will be obtained. Microscopic cover-glasses are useful in preparing screens, and two of them can be fastened together.

WATSON'S CAMERAS FOR THE SEASON.

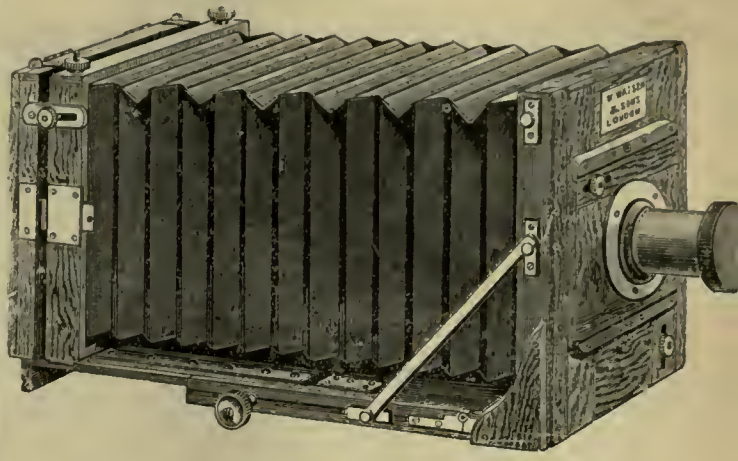
On visiting Messrs. Watson & Son's handsome and well-stocked establishment in High Holborn, we were shown several new and improved styles of cameras finished for the work of the season now before us. Among these, we were pleased to see an improvement that has recently been applied to the well-known "Acme," in virtue of which the lens, even one of the widest angle, can be raised or lowered to a greater extent than formerly without the folds of the bellows body being permitted to cut off the corners or any part of the plate.

We were gratified in being informed that a great many cameras, especially those of the half-plate size, are now being fitted up for stereoscopic work—a demand on the part of the public which attests the return from desuetude in which binocular photography has so long lain.

To prevent the possibility of light passing through the folds of the draw-slide, we were shown examples of those now made, in which the slide has been rabbeted out at the folding junctions so as to debar the passage of light; even if the textile fabric, which acts as the hinge, were to give way or be torn off in places, still would no light get to the plate.

To the "Studio" camera for 15 × 12 plates is now fitted an attachment with a repeating back, by which comparatively small negatives, such as cabinets and *cartes* can now be taken with facility, from which it follows that one in possession of a camera of this size and with this attachment does not really require a second one so long as his aspirations are confined within the 15 × 12 limit.

A peculiarity of the "Premier" camera, a class of camera which is much used abroad, consists in all the parts being made interchangeable. It is made in various sizes, from 5 × 4 up to 18 × 16. All sizes up to

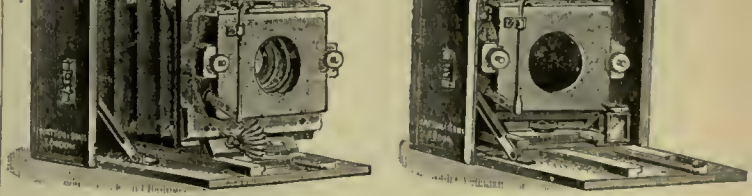


10 × 8 have movable central partitions and wide fronts, to use either for stereoscopic work or two pictures on the plate, with either one or a pair of lenses. The interchangeable idea is an excellent one for those who reside abroad and may desire to restore any damaged portion without being put to the necessity of sending the camera home for repairs.

We were given a description of two double cameras constructed expressly to order for the late eclipse expedition. The plates used in these were 15 × 18; the cameras were six feet in length and each one had a division to permit of the binocular principle being applied, for each exposure was duplicated, there being two lenses to each camera.

Although we have some time since spoken of the pretty little "Alpha" camera the following description of it as it now exists will interest the reader:—

It is made in box form, of sufficient size to contain when closed the bellows, front, the R.R. lens, shutter and finder. The front of the box falls down to form a base, and is held rigid and horizontal by a strut, which is fixed by being pressed home into a notch at its upper end; to close the camera, slightly lift the strut, and it will then fold in as the box is closed. The front of the camera is extended along the base, and there



is a scale with distances marked on it, by which the focus can be immediately set, but a ground glass screen is also supplied to use if desired. A socket is fixed in the side and base to attach to a tripod. The finder is so arranged that the view may be seen either by looking into or through it, according to the position in which the camera is held; there are two fittings to receive it—for vertical and horizontal pictures. The shutter is a specially small Thornton-Pickard Time and Instantaneous fitted with mechanical discharger. The whole apparatus is of highest quality, workmanship and finish, and is among the smallest complete apparatus yet introduced.

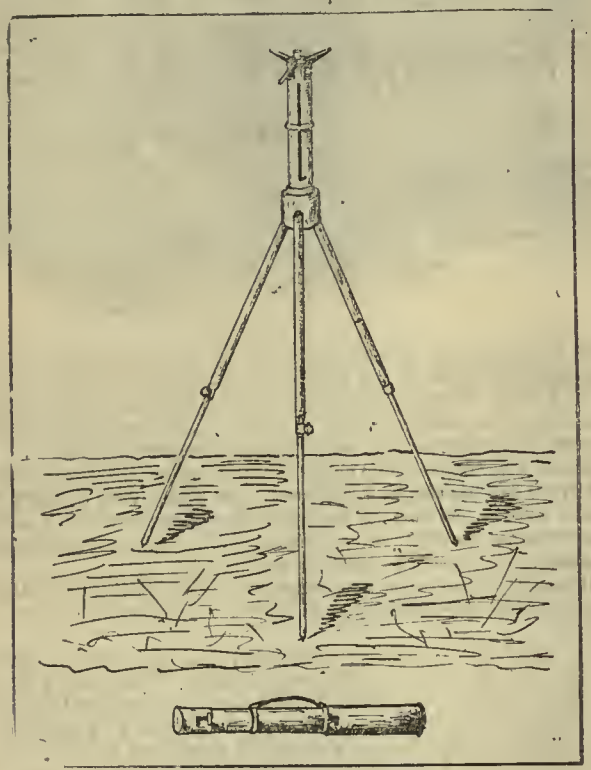
The lenses sold by this firm, at any rate those bearing their name, are all manufactured by themselves, in brass and aluminium. Although we cannot speak of their performances from al knowledge, yet from a

perusal of some Kew certificates which were shown us, we would consider them excellent. They are made in four forms, rapid, rectilinear, enryscope, portable or mid angle and wide angle.

Our Editorial Table.

The Simplex Camera Stand.

This stand, the invention of Mr. J. L. Benthall (13, Victoria-street, S.W.), comes better up to our idea of a quick-setting, portable stand than most of the class that we have seen. It is constructed of steel and aluminum, and is light conjoined with portability and rigidity. Its construction will be seen from the adjoining cut, in which is



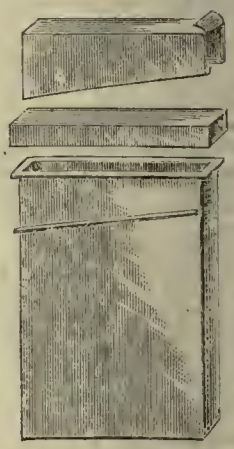
shown the stand packed for carrying and extended for use. On taking off the caps at either end the stand opens of its own accord by a species of telescopic movement. A half-turn bayonet joint ensures perfect rigidity. There are no loose parts. As the lower limbs of the tripod slide into those above, and as these can be pinched with thumbscrews, considerable range is thus allowed for pointing the camera in an upward or downward direction. Although primarily constructed and intended for small cameras of the hand class, we should have no hesitation in using it with one much larger, even to one of 10×8 dimensions, unless such were made abnormally heavy. Much mechanical ingenuity has been imported in its design and construction. An advantage, which many will appreciate, consists in the fact that by no possibility can any one guess as to the parcel being carried consisting of a camera stand, for its unconventional appearance might well relegate it to the domain of a portable ship's telescope.

Its height is four feet two inches, its diameter one and three-quarter inches, and its weight under fifty-six ounces.

Photographic Mosaics for 1893.

Edward L. Wilson, New York.

The chief feature by which this year's issue of a long-established annual is characterised is the very great number of pictorial illustrations—over eighty—it contains. A larger proportion of the text too than usual is contributed by the editor, whose first article, "The Work of the Past Year," extends over ninety-six pages, and forms a digest of what has been published during that time. Next follow practical articles contributed by about twenty or more of the editor's friends, in many cases men whose names are well known. The rest of the book is occupied by a series of six essays on topics relating to art, by the editor. *Mosaics*, with its 282 pages of text, including such a number of illustrations mainly in the art department forms an excellent book for study in the evening, or an agreeable pocket companion when one is on a journey. Dr. Wilson has acted wisely in changing its time of publication from Christmas to Midsummer.



The Primus Air-tight Box.

W. Butcher & Sons, Blackheath, S.E.

It is conceivable that a packet of plates, however seemingly well packed up, may yet be acted upon by the penetration of an impure atmosphere. To obviate this the Primus box is introduced. It is a japanned tin case capable of holding a packet of plates. After inserting this, the lid of the case, which is lined with indiarubber, is put on, and is kept pressed down firmly by a cover which slides on by wedge-shaped flanges on the sides of the box as shown by the cut. It will certainly serve the purpose intended.

Half Holidays with the Camera.

By Bernard Alfieri. London: W. B. Whittingham & Co., Limited, 91, Gracechurch-street, E.C.

This book chiefly consists of reprinted articles embodying the author's endeavour to give some indication of the character of the various localities touched on, mainly on the north side of the Thames, from a photographic standpoint; at the same time, and commendably so, he refrains from pointing out exact spots from which pictures may be obtained. From Burnham Beeches on the west to Southend on the east, the author constitutes himself a guide not only to the principal but to the less known points of interest. The book has several illustrations of familiar scenery, as well as a number of small maps, which should assist photographers desirous of arranging camera outings, to a very large class of whom it is calculated to be of great service.

Glycin-Hauff.

We have received from Messrs. Fuerst Brothers, of 17, Philpot-lane, E.C., a sample of the newest developing agent, Glycin-hauff. This differs in appearance from its congeners in being of a pale yellowish colour. We hope to try and report upon its properties in our next.

A Damp Sheet Detector.

From Mr. A. H. Baird, of 15, Lothian-street, Edinburgh, we have received samples of chemically treated paper for this purpose that should be welcome to tourists, travellers, &c. The directions for use say, lift a piece of the paper by a corner out of the box, and place it between the sheets, press the bedding gently down while you count five seconds, then examine the paper. If the sheets are slightly damp, the paper will be stained a dark red colour. If the sheets are well aired and dry, the paper will be hardly discoloured, if at all.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

MAY 25,—Mr. P. Everitt in the chair.

In reply to a question from the Chairman, Mr. J. CADETT said he was experimenting with the amyl-acetate lamp for standard light purposes.

"THE SPEED OF PLATES."

Mr. R. Child Bayley exhibited plates that had been exposed to light and exhibited different degrees of colouration, as bearing upon a remark of Mr. H. A. Lawrance on the same subject before another Society. Differences in colour between the plain bromide and bromo-iodide plates were noticed, which Mr. COWAN said would depend on the composition of the films. No suggestion was made as to how this method could be availed of for telling the sensitiveness of plates.

"REVERSAL."

Mr. J. E. Smith showed a negative made on a Paget plate two years old which had three seconds exposure with *f*-8, and was developed with pyro and ammonia, development being rather forced. The plate showed complete reversal.

The CHAIRMAN asked whether the rapidity of the plate might have increased by keeping, and, *apropos* coloured fog, also inquired whether ammonia-prepared plates were more subject to it than boiled plates?

Mr. W. E. DEBENHAM observed that red fog might be removed by treating the plate with bichloride of mercury.

"FLATNESS OF FIELD—SPHERICAL ABERRATION IN TELE-PHOTO LENSES."

In reply to a question as to whether it was possible to produce a lens having a round field which could be flattened at will without decreasing the aperture, Mr. DEBENHAM said a rectilinear lens might be made to have a round field by bringing the lenses together, and flattened by separating them.

Some discussion on tele-photo lenses took place, Mr. DEBENHAM remarking that it was an advantage to have an arrangement for adjusting the spherical aberration so as to perfectly correct the combination for degrees of enlargement.

Mr. T. BOLAS approved of Mr. W. K. Burton's arrangement, which was actuated by a milled head outside the mount.

HALATION AND BACKING.

Mr. J. S. Teape showed a plate that had been backed with caramel, exposures behind diamond-shaped openings of from twenty-five inches to sixty inches of magnesium at twelve inches distance being given. No halation was apparent. A quarter of an inch of magnesium would have sufficed for a normal exposure. He also showed a Sandell plate that had been backed, and had had the same exposure without showing reversal.

The CHAIRMAN remarked that at forty-five inches the plate showed halation.

Mr. TEAPE said that perhaps little pinholes had appeared on that part of the plate, or the coating was thinner there.

The CHAIRMAN doubted whether it was possible to find a printing paper which would render the scale of gradation which it was claimed the Sandell plate gave.

After other discussion the proceedings terminated.

Hackney Photographic Society.—May 23, Mr. J. O. Grant in the chair.—Mr. R. BECKETT said he had inquired about polychromy, but doubts were expressed about it. Members' work was shown by Messrs. Dean, Gosling, Roofe, Sodeau, and Wire. Mr. Grant showed an electric lamp which would work for eight hours, and can be used as an ordinary reading or dark room light. Mr. R. Beckett showed a Swift's hand-camera lens (45*s*.), anastigmatic, covering a quarter-plate sharply to corners, five and a half inches focus, full aperture *f*-8, with iris diaphragm. Mr. Gosling showed his half-plate hand camera, which, by adding a central division to, could be used for stereoscopic work. Mr. Hudson showed the "Meteor." Mr. Sodeau showed one he had had constructed capable of being used as an ordinary camera, and had all the movements. It was somewhat large. Mr. S. J. Beckett showed the camera he used when in Italy. He used a Thornton-Pickard shutter, had a focussing scale, and double dark slides. The shutter draws right out, and by reversing when reinserting he could tell when plate had been exposed, as one side was plain and the other polished. Mr. GRANT gave his experience of a Kodak, and thought as a rule they (or his, at any rate) were not quite light-tight. Mr. HUDSON objected to the use of indiarubber bands about shutters, and preferred pianoforte wire. Mr. GOSLING thought Mr. Sodeau's camera too complicated. Mr. HUDSON said he thought the weight could be reduced by substituting part of the box by use of bellows over a framework. Mr. HAWKINS objected to the Thornton-Pickard shutter, as it gave equal exposure to sky and foreground. The members then proceeded to summarise a hand camera, and were of opinion that they should have the power of extending time of exposure to any length, being able to use different stops, and focussing on glass. The CHAIRMAN said a beginner ought not to start with a hand camera.

Tooting Photographic Club.—May 25.—The new home of the Club, situated over Mr. Mellhuish's establishment in the High-street, was opened on this date. Mr. Anderson, the President, offered a welcome to the visitors. He congratulated the Club on its new home, and thanked the younger members for the trouble they had taken to get it in order. Messrs. Dollery and Irwin then took a flashlight photograph, and the plate was developed for the benefit of visitors. A large collection of slides were exhibited by means of the lantern.

Liverpool Amateur Photographic Association.—May 24.—Mr. S. HERBERT FRY gave a lecture on the *Sandell Plate*. He explained the mode of making the triple and double layers of sensitive emulsion, also the great advantage in the latitude of exposure, which, for ordinary purposes, was equal to ten times that of the ordinary single film, also the great freedom from halation, and a special feature being their great superiority for interior work where great contrasts are experienced. On Thursday evening, the 25th inst., the fifth ordinary monthly meeting of the thirtieth session was held in the Club rooms, Eberle-street, the President (Mr. A. J. Cleaver) in the chair. The following excursions were announced to take place:—Bebington, May 27; Bolton Woods, June 10; Windermere, June 17; Ingleton, June 24. Mr. L. E. MORGAN (Fuerst Bros., of London) gave a practical demonstration of the new developer, *Amidol*, developing a negative, bromide paper, and a lantern slide with excellent results, and he gave a very explicit account of the capabilities of this powerful agent. He also gave a short description and the uses of *Metol*, and small samples were distributed among the members.

Rotherham Photographic Society.—May 24.—First excursion of the season, the destination being Ingleton, popularly known as the land of waterfalls. Special railway arrangements had been made, and the day proved favourable. The party, including several friends, numbered thirty-seven.

West Kirby Photographic Society.—May 27, Excursion by wagonette to Burton.—This out-of-the-way little Cheshire village is at all times picturesque; but, with the roses in full bloom on every side, most of the houses newly whitewashed, the sun shining, and the trees in full leaf, it could not have been seen to greater advantage. The church, the cottages, and the woods afforded plenty of scope for artistic work. Two slabs of stone, the date 1663, with certain initials, situated in one of the woodland paths, and known as the "Quaker's Grave," makes a nice picture, and was not forgotten. Another view that looks well in a photograph is to be had, viz., the approach to the church by the stone pillars on the right hand as you come from the village. Years ago we saw this view in the collection of one of Liverpool's best amateurs, and were amused to think, out of twenty or thirty who photographed that day, he alone had secured it. So it is always, we miss the pretty, unobtrusive tit-bits, and return home laden with commonplace compositions. Perhaps repeated visits to really picturesque localities is the best cure for that indifference to originality so apparent in many amateurs. Next excursion is to Hilbre Island on June 17. As the bulk of the members will probably walk, or, rather, wade over to the island, or go on donkeys, it is quite possible a "snap-shot" man with a sense of the humorous might secure some good pictures.

MR. J. LIZARS has removed to more commodious and central premises, Nos. 101 and 107, Buchanan-street, Glasgow. The optical department is on the ground floor. On the first floor will be conducted the photographic and optical lantern departments, both of which have been arranged for their special requirements.

Correspondence.

THE CONCENTRIC LENS.

To the EDITOR.

SIR,—I have carefully read Mr. Stillman's letter of May 17, much of which better supports my contention than his; but the sentence, "On any given object I can focus as sharply with *f*-16 as with any smaller stop," is just what I contend is incorrect and misleading. Mr. Stillman apparently proves to his own satisfaction my incompetence because I cannot do this, forgetting that it is open to me to retort, that it is some evidence of incompetence when a professed expert cannot obtain better definition with a high-class lens at *f*-64 than he can with the full aperture. There is no need to confuse the issue by dragging into the Controversy the power of printing processes to render the definition.

I have a letter from Messrs. Ross before me, in which occurs this sentence, "For really sharp definition we do not recommend the Concentric being used with a larger aperture than *f*-22."

Mr. Stillman gives himself away entirely when he admits that in making negatives for enlargements he uses the smallest stop. Now, such negatives are generally of small size, not necessitating the stopping down of a ten-inch Concentric to obtain covering power, so what does he stop down for? Definition, of course, which is not sharp enough for enlargement at *f*-16. Ye gods! Delicacy of touch and eyesight, following the sentence, "I always 'mark,' *always* focus at *f*-16," or full aperture, and this, Mr. Editor, after calling Mr. Stillman's attention to your very able article on the "Focal Peculiarities of Wide-Angle Lenses," for the Concentric is a wide-angle lens.

Did any practical exponent of any art ever before refer to his less-experienced fellow workers as "duffers?" If Mr. Stillman has any faith in his contention, it should be as safe to use the Concentric at *f*-16 as at *f*-22, even for the duffers, for they at least have eyesight. My protest was not made on behalf of experts—they can take care of themselves—but for the guidance of earnest, if less experienced, workers who were in danger of being misled by Mr. Stillman.

Will Mr. Stillman send his lens to the authorities at Kew for report on the single point, "Does this lens define as sharply on any given object at *f*-16 as it does at *f*-64?" If he will do so I pay all expenses if the reply is adverse to my contention.—I am, yours, &c., F. H. BURTON.

Roundhay, near Leeds, May 27, 1893.

FOCUSSING THE CONCENTRIC.

To the EDITOR.

SIR,—I am not surprised that some users of the Concentric lens have found a difficulty in getting absolute definition with it at *f*-16, and as most men consider their inability to do a thing as proof presumptive of its being undoable, it is not surprising that the unsuccessful experimenters denounce the pretentions of those who assert that they have succeeded as mere swagger, or worse, for that is what the denial amounts to. And as I have asserted in the most unqualified terms that the lens is capable of doing perfectly defined work at *f*-16, I am ready to maintain it by the best of proofs, the work itself, done with the lens at that opening. But, at the same time, I will explain to the men who fail the probable reason of their failures. Any perfectly constructed lens will have a region inside which the definition is perfect, *as lenses go*, and *with the opening for which they are calculated.* I do not say that the definition is as perfect as it would be in a microscopic lens; it may or may not be. It is as perfect as the needs of photography require, or can profit by, or the eye distinguish on the ground glass. In the old form of lens, in which the field was a concave one, the centre of the field was the point at which the focus was most easily determinable, but the moving forward of the screen brought other portions of it into focus, so that, within a certain range, some portion of the screen always showed definite detail, *i.e.*, the maximum sharpness of which the lens was capable. A slight displacement of the screen did not therefore throw the picture out of the focus, and, as it was the custom to stop down for a flattening of the field, no harm was done by a little inexactitude. While, therefore, the operator found no injury from a slight margin in his focussing, or a trivial inaccuracy in the placing of the screen in the camera (and in one case I found that the screen of my camera was the one thirty-second of an inch out of place), so long as he had the old form of lens to deal with, in the new lens he had no range whatever, the whole field lying flat as the screen itself, and, like Wordsworth's cloud, "moving altogether if it move at all," so that, if the ground glass is coarsely ground and does not furnish a surface sufficiently fine to render the delicacy of detail of the image, or the position of the screen is a fraction of an inch ever so small out of the exact position of the focus of the lens, absolute accuracy in ocussing is a matter of luck, a[illegible] range in which it is possible to find a satisfactory sharpness being diminished in proportion to the largeness of opening given to the lens, the larger that opening the more precise must be the adjustment of the screen. It will be seen that the accuracy required, both in the racking out of the screen and in the construction of the camera, so that all chance of error should be avoided, is absolutely mathematical, the one-hundredth part of an inch being enough to diminish perceptibly the definition on any given plane.

Now, it rarely happens that the screen possesses a surface of the fineness of texture that is required for perfect focussing, and in my own case I have had to wax the centre of the ground glass; and it very often happens that there is in the construction of the camera a trivial inexactitude in the adjustment of the screen which would pass unnoticed in the use of the lens with a hollow field, but ruins the definition with the Concentric. In short, who uses the Concentric, works with a tool which must be employed with a mathematical exactitude, and those who do not find it mathematically exact must find the fault in their own operations. I have not always in my own work, found that I had hit the finest definition, but when I have taken the requisite pains, I have always found that the result proved that the definition at *f*-16 was as perfect as I can get with a smaller aperture, so far as my eyesight will serve me. Of course, when the least error is made in either of the ways I have indicated, the use of the smaller aperture will increase the sharpness of definition, *i.e.*, it diminishes the effect of the error. Ross & Co. advise that the focus should be obtained with the aperture *f*-22 and then, if it is desired to use the larger, that the lens should be opened out; but begging pardon for the liberty I take in differing from the constructors of the lens, this seems to me illogical, for if the focus is obtained with *f*-22 and the image at *f*-16 is sharp, it proves only that in the other case of focussing with *f*-16 directly, the difficulty is in the adjustment, not in the power of defining, for the lens cannot define the better for the manner of focussing—if the lens will define at *f*-16 it will do it whatever opening has been used in the focussing, and if it does not, the fault is in the operator or in the camera. That the planigraphic lenses, as we may call those made with the new glass, giving a flat field, have a shorter focus than the old form of spherigraphic lens, is certain, and the proof is in the using, as I have satisfied myself by careful comparison on the camera, and the new lens, while it gives its adjusted plane with equal sharpness, also gives the nearer or more remote planes with a closer approximation to perfect definition than the old one, but this is only an approximation, for mathematically, the lens can only give one plane perfectly, which it does with the aperture of *f*-16 and all assertions to the contrary are based on misapprehension or misapplication, but this faculty of giving greater depth of focus, increases the difficulty of accurately focussing, as it makes the error resulting from a slight displacement, so much the greater as the focus is shorter.

The head of the great photographic establishment of the Italian Government, Signor Gargiolli, who employs the Concentric for nearly all his work, and the Zeiss form for the rest, confirms my statement that the former gives perfect definition at *f*-16, with the additional charm over that given with the small stops of the latter, that it gives a representation more like the actual appearance to the eye. Being obliged by the nature of his work to exact the most precise definition, he is a better witness to the power of the Concentric than I am, for to most of my work, which is merely picturesque, it is of no importance whether it be of the most perfect definition or not.

It is impossible that the difference between the results reported by other experimenters and mine should depend on the accident of a better construction of the lens; for we know, in the first place, that there is no appreciable variation in the Ross lenses, and because between the four Concentrics which I have personally used, and am using, and those of Signor Gargiolli there is no difference whatever. It is a matter of prudence for the makers of the lens to advise the use of a small stop for focussing, simply because it is easier to find the focus when so used; but the recommendation to open out to the larger opening after focussing, implies that they are confident in the definition at the larger stop, which is the question at issue. I do not agree with the advice, nevertheless, for it seems to me that the adjustment of the focus must necessarily be more exact when done with the larger opening, as it is more difficult to hit the exactitude. I see no reason for deferring to vision, which is imperfect, to manipulation, which is careless, or to apparatus which is not exactly fitted for the purpose. And the fact, which I admit, that I do not myself always hit the absolute definition of which the lens is capable, only proves that I am not always careful, while the occasional occurrence of a definition which is ideally perfect proves that it is not the fault of the lens that I do not always get it.—I am, yours, &c., W. J. STILLMAN.

Rome, 27th May, 1893.

MOUNTING GELATINO CHLORIDE PRINTS.

To the EDITOR.

SIR,—I notice difficulties are met with in this operation. Let your correspondent get an old *linen* handerchief, free from fluff. Get some lady acquaintance to sew it roughly over a few pieces of thick blotting-paper, and you have a pad that will leave no fluff on prints and never stick. I have found it invaluable.—I am, yours, &c., OTHELLO.

May 29, 1893.

METOL.

To the EDITOR.

SIR,—Since I wrote last week I discovered too late to add to my article that for the very highest quality of result with metol you must use ammonia. This gives the most beautiful image I have ever seen from any developer, though it does not answer so well if the solution is to be used over and over again, owing to the volatile nature of the ammonia.

I make a solution of one ounce strong ammonia and two drachms bromide in ten ounces of water, using the fluid drachm of this in each two ounces of developer. Say, one ounce stock solution of metol, as given last week, one drachm ammonia solution, and seven drachms water, varying the proportions *pro re natâ*.—I am, yours, &c.,

May 29, 1893. W. B. BOLTON.

PHOTOGRAPHIC CONVENTION OF THE UNITED KINGDOM.

PLYMOUTH MEETING, JULY 3 to 8, 1893.

To the EDITOR.

SIR,—In connexion with this year's Convention to be held at Plymouth from July 3 to July 8, an exhibition of photographs, photographic apparatus and appliances, will take place at the Art Gallery, attached to the Athenæum Buildings.

The charges for wall space will be 3*d*. per square foot, with a minimum of 3*s*.; and those for table or floor space, 6*d*. per square foot, with a minimum of 5*s*.

Intending exhibitors will kindly apply for space, not later than June 24, to the Hon. Secretary, Mr. F. P. Cembrano, jun., 10, Cambridge-gardens, Richmond, Surrey; or to the Hon. Local Secretary, Mr. R. Hansford Worth, C.E., 42, George-street, Plymouth, stating the nature of their exhibit and space required.

All applications must be accompanied by a remittance for the amount of wall or table space desired.

Exhibits should be delivered, carriage paid, and addressed, "To the Hon. Secretary, the Photographic Convention, the Athenæum, Plymouth," not later than ten o'clock on the morning of Saturday, July 1.

The Executive, while exercising all reasonable care and supervision, will in no way accept any responsibility for any loss or damage to exhibits either in transit or during exhibition.

Exhibitors may have an attendant present to look after and explain their exhibits.—I am, yours, &c., F. P. CEMBRANO, JUN.,

May 26, 1893. *Hon. Secretary.*

SWITZERLAND.

To the EDITOR.

SIR,—If your correspondent "C. B." requires topographical information concerning Switzerland, he will find almost all that is needful in *Baedeker's Guide*.

With regard to plates passing through the Douane, I have only once had any trouble, viz., last July. Travelling by the P. L. and M., on reaching Vallorbes I was interrogated as to the contents of certain boxes, and, learning that they were sensitive plates, they charged me a small fee. I remonstrated, telling them that I had never had to pay before, but to no purpose. On returning, the Douaniers took no notice of the same boxes re-entering France at Pontarlier.

You are correct in saying that a passport is not needed in Switzerland, but I have frequently found more civility at the post-offices, both in that country and in Italy, by showing my name on my passport than otherwise. A passport can be obtained by application at the Foreign Office in London, where a paper, to be signed by applicant and countersigned by a magistrate, will be supplied, and, for a small fee, the passport will be granted. It lasts a life-time, and is always useful in case of any trouble.—I am, yours, &c., J. CARTER BROWNE, D.D.

Thurning Rectory, Oundle, May 29, 1893.

PHOTOGRAPHY AS A BUSINESS PAST AND PRESENT.

To the EDITOR.

SIR,—In reply to your article on the above important question, I should like to repeat what I have before suggested in a contemporary, that it is desirable that leading members of the profession should discuss this subject together and endeavour to formulate some course of action, with the object of endeavouring to dissuade the profession generally from practices at once unprofitable and undignified—I allude more particularly to that of indiscriminate gratuitous sittings which has so increased in recent years, and has induced, I think, in the public mind a very erroneous idea of the value of the professional photographer's services, which is greatly aggravated by the mighty army of amateurs practising the art for amusement with more or less success; and is carried, I hold, beyond its legitimate bounds when extended to other than bonâ-fide public people and professional sittings for the purpose of studies and publication.

Then again the *honour* which is so continually thrust upon us, with or without permission or payment, of having our work reproduced by a multitude of illustrated papers in various forms of process work, often the veriest smudges and barely recognizable, is a matter worthy of discussion.

These may not in themselves answer your question, but I think they are entitled to consideration, if only members can be brought together to discuss them, when others of greater importance would no doubt arise.—I am, yours, &c., WILLIAM GROVE.

63*a*, *Baker-street, Portman-square, W.*

Exchange Column.

*** *No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance. The full name of the advertiser must in all cases be given for publication, otherwise the Exchanges will not be inserted.*

Will exchange 158 numbers of *Photography*, from No. 15 up, for interior background or cheap hand camera.—Address, MOORE, Buckfastleigh.

Will exchange Merritt type-writer for half-plate camera.—Address, F. HOLWILL, Quay House, Bideford.

Wanted, an exchange of backgrounds (interior), 8×7, will send photograph with pleasure.—Address, A. E. STANLEY, Lansdown Studio, Stroud.

Will exchange Duchess half-plate camera and three double slides in good condition for good quarter-plate hand camera.—Address, WILLIAM HEMING, East Cliff Studio, Whitby, Yorks.

Exchange 11×11 square camera, three double dark slides by Dallmeyer for ten or fourteen-inch "Fernando" or "Globe" enameller, differences adjusted.—Address, M. E. MALLETT, 258, Brixton-hill, S.W.

I will exchange a quarter-plate camera, with rectilinear lens, and six double slides and tripod stand for half-plate camera and lens by a good maker. Difference adjusted in cash.—Address, F. SIMCO, Chemist, Wellingborough.

Answers to Correspondents.

*** *All matters intended for the text portion of this* JOURNAL, *including queries and Exchanges, must be addressed to* "THE EDITOR, THE BRITISH JOURNAL OF PHOTOGRAPHY," 2, *York-street, Covent Garden, London. Inattention to this ensures delay.*

** *Correspondents are informed that we cannot undertake to answer communications through the post.*

*** *Communications relating to Advertisements and general business affairs should be addressed to Messrs.* HENRY GREENWOOD & CO., 2 *York-street, Covent Garden, London.*

*** *It would be convenient if friends desiring advice respecting apparatus, failures in practice, or other information, would call at the Editorial Office either on Wednesdays from* 4 *to* 6, *or Thursdays from* 9 *to* 12 *noon, when some one of the Editorial staff will be present.*

CLIFFORD E. F. NASH.—Ground rice is meant.

BRISTOL BOY.—Nothing ever eventually came of phosphorescent emulsion proposed twelve years since.

W. COPE.—Consult an analytical chemist in your town, who will undertake a proper examination of the mounts for a fee.

J. PEACH.—In the absence of details of the method referred to, we cannot, of course, say anything as to its practical value.

S. THORNE.—On the whole, No. 1 is to be preferred on account of the non-repetition of pose in the fishermen. Both are good pictures however.

A. CLARKE.—Possibly the mottled appearances will not be apparent if the developing solution be slightly warmed. See articles on the subject in last volume.

ED. CLARKE.—Try ordinary negative varnish mixed up with lampblack.

OTHELLO.—If French chalk fails to prevent sticking, try beeswax dissolved in benzole.

MONTAGUE BARSTOW.—You are probably thinking of the Optimus drawing attachment to a lantern. See p. 753 of THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC for 1892.

A. SMITH.—The only way to recover silver from gelatine paper prints is from the fixing bath. For opalines, try the effect of giving a coating of dilute albumen to the glass. This will prevent the peeling off.

F. WILLS.—Granted that, according to your figures, the silver, the bromide, and the gelatine cost so very much less than the price at which the plates are sold, you have quite overlooked the glass. Does this cost nothing?

PRINTER.—The spottiness of the prints may possibly be due to the hyposulphite of soda. Be that as it may, hyposulphite that is damp and discoloured, and has an offensive smell, is quite unfit for photographic purposes, and should not be used.

MASON.—The appearance of the negative is caused by its being imperfectly washed before it was varnished. It is quite a mistake to suppose that any varnish is a perfect protection if the film contains hyposulphite of soda, and damp silver paper is placed upon it in the the printing frame.

W. SELLMAN.—The print has stood well so far, but it has been exposed only six months. If you call upon us, we can show you silver prints that have been exposed, without showing signs of fading, for eighteen years. We also possess the first platinum prints that were made, and can attest the undiminished brilliance of the same.

COLLODION.—A sixty-grain bath, that has been used for sensitising paper, is not suitable for the collodion process. In the first place it is far too strong for the purpose. In the next it is charged with organic matter which would be fatal. It might be possible to remove this, but it would not be worth the trouble when a new bath is so easily made.

DELTA.—If bulk in the apparatus is of no consequence it would be well to have a finder and a focusser in one. But if you can focus independently of the finder, it is only requisite that the image received by the working lens is correlative with that of the finder, so that when you look on the finder ground glass you know just what to expect in the negative.

R. R. E. says that, on sensitising some rough drawing paper, according to a formula given in the JOURNAL a few years back, it became covered with a number of fine spots, which began to show before the paper became dry. He asks how they are to be avoided?—The fault is, no doubt, in the paper, and, if so, can only be avoided by using another brand.

A. WALLER.—So far as can be judged from the appearance of the print, we are led to iufer that the lens was not sufficiently shielded from light during the exposure of the plate. From the direction of the cast shadows the sun must have been shining very much in the direction of the lens at the time. There is no remedy but to retake the negative. Probably more brilliant prints might be obtained from it on bromide paper than is possible on albumen.

HON. SEC.—If certain prizes are offered for "the best" photographs in any particular class, and those competing in that class are considered by the judges to be below their preconceived idea of excellence, they cannot, however, withhold bestowing a medal for the *best* of such inferior photographs unless there has been attached to the published conditions a statement that they are empowered to withhold medals at their discretion. They could, we believe, be brought to their senses by a court of law.

T. A. E.—1. The front lens of an ordinary portrait combination, worked with an aperture of *f*-8, will do quite well for taking a group of several persons, but with such an aperture crisp definition must not be expected. 2. With that aperture it will be as quick acting as a rapid combination with similar opening. Indeed, theoretically, it will be quicker. 3. The convex side of the single lens should be next the ground glass. 4. The chemical and visual foci will be coincident, so that no after-adjustment will be required.

MANCHESTER PHOTOGRAPHIC SOCIETY.—June 3, Liverpool (hand camera).

MR. NORRIS B. STEADMAN, formerly of 30A, Bold-street, has now removed to 129, Dale-street, Liverpool.

LEYTONSTONE CAMERA CLUB.—June 3, the Tower of London. Leader, Mr. G. H. Cricks. The Club will assemble at the gates at three o'clock.

OLDHAM PHOTOGRAPHIC SOCIETY.—June 3, Saturday, Chew Valley. Depart, Clegg station, ten minutes past two p.m., for Greenfield. Return fare, 8*d*. Leader, Mr. J. Greaves, jun.

RECEIVED.—The price list of Mr. C. H. Bradbrook, photographic printer and enlarger, of Chapel-street, Colchester; T. Aston & Son (Toning Powder); S. Sidey (Brilliantine). These and others in our next.

MR. SNOWDEN WARD has compiled *A Few Notes* for intending visitors to the World's Fair at Chicago, in which a great deal of information likely to be useful to photographers and others is condensed.

Dry Plates for May contains an article by Mr. J. Cadett on "Speed Determination," which gives in a clear and popular form an explanation of Messrs. Hurter & Driffield's system of measuring the speed of plates. We gather that *Dry Plates* is to reproduce Messrs. Hurter & Driffield's papers on the subject.

"OPTIMUS" 100-GUINEA COMPETITION, 1893.—Messrs. Perken, Son, & Rayment, of 99, Hatton-garden, announce a series of competitions the pictures to be taken with Optimus lenses. There are nine classes, open to both professional and amateur photographers. The competitions will not be closed until December 31, 1893. The prizes are to take the form of apparatus of great value. Full particulars and conditions of the competition can be obtained of Messrs. Perken, Son, & Rayment, 99, Hatton-garden.

EXHIBITION AT HAMBURG.—An International Photographic Exhibition will be held in the Gallery of Arts at Hamburg from October 1 to 31, 1893. The following foreign representatives have placed their services at the disposal of the Exhibition Committee for the purpose of inducing participation in the forthcoming Exhibition by their respective countrymen and by amateur photographic societies existing in the countries represented by them:—Belgium: Herr Eduard Ludwig Behrens, Consul-General. Brazil: Herr Wilhelm Pump, Vice-Consul. Chili: Herr Ad. Joh. Schwartz, Consul. Corea: Herr H. C. Eduard Meyer, Consul. Denmark: Herr Henrik Pontoppidau, Consul-General. France: M. le Comte Léopold Balny d'Avricourt, Consul-General. Great Britain: The Hon. Charles S. Dundas, Consul-General, and Mr. G. Ambrose Pogson, Vice-Consul. Greece: Herr Aug. William Gorrissen, Consul-General. Japan: Herr Martin Valentin Burchard, Consul. Mexico: Herr O. M. Vélez, Consul. Netherlands: Herr Richard von Schmidt-Pauli, Consul-General. Norway and Sweden: Herr Bernt Anker Bödtker, Consul-General. Persia: Herr Carl von Haase, Consul-General. Portugal: Le Commandeur Francisco van Zeller, Consul-General. Sandwich Islands: Herr Ed. F. Weber, Consul. Spain: Herr Tomás Ortuño, Consul-General. Switzerland: Herr Paul Edward Nölting, Consul. Turkey: Herr Rudolf Hardy, Consul-General. United States: Hon. W. R. Estes, Consul, and Mr. Charles H. Burke, Vice-Consul. Zanzibar: Herr Albrecht Percy O'Swald, Consul-General. Applications for programmes, forms of entry, and inquiries should be addressed to the above-named Consuls, or to Das Ausstellungs-Comitté des Amateur-Photographen-Verein, Hamburg, Schwanenwik 33.

PROFESSOR W. K. BURTON ON "DENSITY RATIOS."—*Photographic Scraps* for June contains a letter from Professor W. K. Burton, in which he refers to some experiments that have resulted in proving conclusively that the permissible latitude in exposure is even greater than he had supposed. He says: "It is possible to vary the exposure as one to forty, and yet to get negatives giving prints that are identical, or that are, at any rate, so nearly similar, that an experienced photographer cannot tell which is from the negative that has had the longest exposure. By this I mean that, if one second is the shortest exposure that will give a really good negative with a certain kind of plate, I can give a second plate of the same kind an exposure of forty seconds, and get a negative that has no appearance of being over-exposed, and that will give an excellent print. The negatives can generally be distinguished by the difference in colour of the image. In some cases I have succeeded with exposures varying as one to eighty. This is, moreover, using the same developer, namely, pyro, with carbonate of soda—my favourite developer now for some years—merely varying the proportions of the ingredients, and without recourse to intensification. By using entirely different developers, it would be possible to compensate for greater differences. Moreover, the subjects selected were ordinary landscapes. By selecting a special subject, mostly very deep shadow, with only a small proportion of high light, it would be possible again to compensate for greater differences in exposure. I send you herewith prints from two negatives, one of which received an exposure of three seconds (with an extremely small stop), whilst the other, exposed immediately afterwards, on a plate from the same box, using the same stop, received an exposure of one hundred and twenty seconds. The plates used were, I may mention, such as are sold as 'ordinary,' but are of very fair rapidity, even as plates of the present day go. There is no great secret in the method used. The first plate was developed with the least quantity of pyro that would give sufficient density, one grain to the ounce of developer, and a mere trace of bromide, one-fifth of a grain to the ounce, used to restrain a slight tendency to incipient fog. In the case of the second plate, the pyro was increased to eight grains to the ounce, and ten grains of bromide of potassium were added to each ounce of the developer. The development was complete in the case of the first plate in about five minutes. In the case of the second it took twenty minutes. How, it will be asked, is this statement compatible with the dogma that the density ratios cannot be altered by development? Even after allowing for the difference between 'density' and 'opacity' as used by Messrs. Hurter & Driffield, it is not compatible at all, and *it is, as a matter of fact, possible to vary the density ratios enormously in negatives by development.* To demonstrate this, it is only necessary to expose two plates on a landscape, giving normal exposure. One is developed so as to give what would be understood as a 'good' negative. That is to say that, amongst other things, it shows all, or nearly all, the shadow detail that is visible to the eye, and that the high lights are represented by a certain density. Now, it is quite easy to develop the second plate so that very little more than the high lights are visible at all, yet these high lights are much more dense than in the case of the first negative. It is evident here that neither the 'densities' nor the 'opacities' can bear the same ratio to each other in these two negatives. In fact, if two 'density curves' were drawn, they would cross each other." Illustrating the letter are reproductions from two prints of negatives that had received three and one hundred and twenty seconds exposure respectively. The difference in the nature of the results is difficult to detect.

With this week's JOURNAL *we present, as a supplement, a phototypic reproduction by the well-known firm of Thevoz & Co., of Geneva, of a study by Mr. William Brooks, of Reigate, the subject being a "Tower Warder," or, as he is more popularly termed, a Beefeater. The excellent qualities of Mr. Brooks's negative receive full justice from the process of Messrs. Thevoz, the effects of which are heightened by the grained surface of the paper upon which the impressions have been taken. We understand that photographs of the picturesquely garbed and historically interesting body to whom the custody of the Tower of London is committed are not very common, and our picture should therefore have additional value.*

VIEWING LANTERN SLIDES BY DAYLIGHT.

At a time when, as regards the prolongation of daylight, we are in the month which occupies the position of being the middle one of summer, the exhibition of slides by the lantern is somewhat impracticable unless such be extended far into the night, or, as an alternative, the exhibition take place in a place capable of being especially darkened. What, then, is to be done by way of gratifying oneself or one's friends desirous of inspecting the outcome of camera trips to choice scenery, ancient cities, picturesque villages, or fashionable watering-places? The obvious answer is, Arrange to show them by daylight. We are, of course, writing in the interest of the innumerable army of hand-camera snap-shottists, or of those wiser ones who, with whatever kind of camera they may have selected, take special care not to omit taking with them a stand as well as the camera, or those whose "be-all and end-all" is the production of transparencies for the delectation of family and friends.

No photographer is fully equipped who, in addition to his camera, is not also the possessor of a lantern for evenings and a table-stand for the parlour or drawing-room table for use during the daytime, "ere the evening lamps are lighted;" and, having just risen from taking part in a daylight entertainment, in which the last-mentioned of these has played a prominent part, we can the more strongly advocate its universal adoption.

The optical requirements for constructing a table-stand for the purpose in question are simple. It is only necessary to interpose a large magnifying-glass, of short focus compared with its diameter, between the eyes and the picture. We are, of course, assuming both eyes to be used.

But large lenses are both costly and clumsy, and the same end may be equally well attained by employing two portions from the margins of such a lens mounted one opposite each eye, taking care that the thickest portions are nearest each other. This serves the twofold purpose of magnifying the picture and sending the ray transmitted through it, so as to enter each eye under circumstances nearly approaching to parallelism, without which even the healthiest eye would be pained by the strain necessary to see, with both of them, anything brought so close to the eye.

The prisms with which even the very commonest stereoscopes are now fitted answer in an excellent manner for viewing with both eyes a lantern transparency; but they must be mounted in the reverse position to what they are in the stereoscope, that is, instead of having their thin ends next to each other, these ends must be to the outside.

Prisms of this nature, however, are open to the objection of being unable to give a great degree of magnification on account of the chromatic aberration necessarily present, eight inches being the focus beyond which it is unwise to go.

Here is a curious thing which we noticed in examining a coloured slide. Having painted it so as to give a moonlight effect, a house in the near background and a number of sub-tropical trees by which it was surrounded were painted of a tint between a pale blue and French grey, to keep up the idea of the front not being illuminated by a bright moon almost overhead, although slightly behind. The windows were scraped out and painted a warm yellow colour. On examining this through Adams' binocular pantascope, which is without doubt the best of this class of instrument on the market—at any rate, the best we have seen—these yellow windows were seen as if projecting some feet in front of the wall of the house. This is just what any one acquainted with the laws of chromatics would have expected. Had the windows been blue and the walls red, then would the contrary effect have been produced; the latter would now project, while the windows would retire. It is the application of the same law of chromatics that enables one—as we have long since pointed out and explained the reason—to see the large red flower, with its *entourage* of green leaves standing out in such stereoscopic-like relief when viewed by the large lens of the graphoscope. This is not the case when the large lens, usually biconvex and invariably uncorrected, is supplanted by an achromatic one, although, as a set-off against this, the latter is preferable for plain, uncoloured photographs.

When a pair of round achromatic lenses are employed in an instrument such as the binocular pantascope of Mr. Adams, it is advisable that they be of short focus—say, from five to six inches—while it is necessary that they be mounted so close together as to permit the eyes to be opposite a portion of the lens situated between the centre and the margin. As it is well that the diameter of these eyepieces should be large, it may be, as we have found it the case, impossible to set them sufficiently close together to enable the eyes to be at a distance outside the centre of the lens to see the picture with the requisite displacement for distinct binocular vision, and without that straining of which we have spoken. In this case, nothing remains but to grind away a small portion of the edge of one or both, in order that their centres may be brought nearer together, for, as just stated, it is the space outside of the centres—that is, between the centre and the outer margin—that forms the real eyepiece through which the picture must be viewed.

In order to conduce to comfort, it would be well that the instrument were, when in use, inclined downward at a slope

like the microscope instead of having to be directed against the sky. This position can be readily secured by hanging a mirror to the outside lower part of the ground-glass frame backing the slide under examination, and then inclining it so as to reflect the light from the sky. A white sheet of cardboard, laid flat upon the table, answers the like purpose.

SOME CAUSES OF DEPRESSION IN PROFESSIONAL PHOTOGRAPHY.

No one, we surmise, will question the opinion expressed last week by Mr. W. Grove—whose long experience in professional portraiture fully qualifies him to deal with the subject—that the prevailing system of giving indiscriminate free sittings has tended to cause in the public mind an erroneous idea of the value of the professional portraitist's services. From the way these sittings are now given, by some, on almost any pretence whatever, they must certainly greatly diminish what may be classed, if we may apply the term, the legitimate business of the portrait photographer.

When this system was first introduced—and that was in the early days of collodion—it was confined for a time, if we remember rightly, to scientific men and men of letters. Afterwards it extended to the clergy, the stage, and other persons of eminence, and, subsequently, to the ballet, &c. Still the portraits were taken expressly for publication, and that was looked to for the only source of profit. Now, however, gratuitous sittings are given by some photographers to such as members of County Councils, Local Boards, and the like, not with any idea that the portraits will ever be sold, but on the probable chance that the sitter may order duplicates for himself, or possibly an enlargement. This must very materially affect the acknowledged business of the portraitist. Here is another thing that has not conduced to the elevation of photography as a profession, namely, the practice of making "speculative enlargements," without permission, from customers' negatives, with the idea that they will eventually be purchased at one price or another. Further, competition is now so keen, that even first-class houses are frequently induced to depart from their usual tariff to secure a customer. This means a reduction in the profits, and at the same time a lowering of the status of the profession.

There is yet another point in connexion with this part of the subject that must be alluded to, as it materially injures local, photographers in the provinces. We refer to the practice, with some large houses in London and elsewhere, when it is known that a garden or shooting party, or other aristocratic gathering, is to take place at a country mansion, to obtain permission to send down an operator to take groups in the grounds, and sometimes some of the rooms in the house, free of charge, merely on the probability of selling copies to the visitors. Generally, especially if royalty is included in the group, a good sale is effected. This is hard upon the local photographers who would otherwise, as formerly, have been engaged to execute the work at his regular tariff, particularly as hitherto he has looked upon a few of these gatherings a year as a steady source of income. In such cases not only does the local artist lose directly in pocket, but sometimes he does so in prestige, because, as he has always had the work to do, the idea may prevail in the neighbourhood that it has not been done satisfactorily, or that it could be done better by people from town. This kind of thing also conduces to the impression amongst the public, as photographers are so anxious to take pictures gratuitously, and go to a considerable expense to do so, that their time and ability are of little value.

In his letter, Mr. Grove alluded to the influence of "the mighty army of amateurs." It may, we think, be concluded that, since the introduction of dry plates, amateurs have, directly or indirectly, materially affected the profession. The *bonâ fide* amateur, it is true, may have done but little direct injury to the business; but we are afraid he has unwittingly done so indirectly. In most families now one or more of its members are amateur photographers, and, as a rule, amateurs know the cheapest markets for everything they purchase; hence the lay public generally have become cognisant of the actual lowest cost of everything connected with photography. This, coupled with the free-sittings system and the low price at which some photographs are taken, has induced the idea, and we have often heard it expressed, that fair-price portraits, although they may be of the highest class, are nearly all profit. When the bare cost of the materials is known, artistic ability and skill in the production of the finished result is too frequently entirely ignored by many.

Supposing the lay public did not learn the cost of the materials employed in photography direct from the amateur, is it not given them in all the so-called "stores" price lists of groceries and other household commodities? In one now before us over fifty pages are devoted to photographic goods. Lenses by leading makers are quoted at prices below those in their own catalogues. Standard brands of dry plates are also quoted lower than in the manufacturers' list prices, and so with almost everything else. Prices are also given for developing, retouching, mounting, copying, enlarging, &c., at what most would consider ridiculously low prices. For example, the price for copying 12×10 is five shillings only, while the price for a 23×17 enlargement on bromide paper is a similar sum. With these prices before them, it is scarcely to be wondered at that the outside public sometimes think those charged for the high-class work issued by most good houses are exorbitant. But for amateurs, this state of things would not have existed. The question is, how is it to be remedied?

THE TREATMENT OF GELATINO-CHLORIDE PAPER.

The growing popularity of the various kinds of gelatine printing-out paper would seem to indicate that albumen, after many years of good service, has at last a good chance of being superseded; but, although it has had its undeniable faults and drawbacks, it is very certain that the change will be made by most of the older hands with much regret; for the gelatine papers, despite the beauty of the results attainable, and, perhaps also the additional chances of permanency, are undoubtedly surrounded by many little difficulties and objectionable features that were entirely absent with albumen.

These arise solely from the physical character of the gelatine film itself, not from the sensitive material; and long familiarity with the behaviour of chloride of silver in albumen perhaps renders it somewhat difficult to realise that the mere change of one organic vehicle for another can produce modifications that seem sometimes almost to arise from chemical causes. If, however, the beginner with gelatine paper will recognise at the outset how important is the difference in physical properties of the

new films, he will free himself at once from the chief portion of his troubles.

The differences between gelatine and albumen commence with the papers themselves before the printing operations are entered upon, inasmuch as gelatine, from its more marked hygroscopic nature, necessitates a greater degree of care than is required in the case of ready-sensitised albumen paper. This is not so much, perhaps, due to want of keeping properties, in a chemical sense, for the newer paper keeps far better under ordinary conditions than does the best ready-sensitised under the most favourable circumstances; but, in order to avoid actual physical damage to the paper, and also to ensure evenness of action in printing and toning, it is absolutely requisite to guard against the effects of damp.

In addition to the hygroscopic nature of the gelatine, it should also be borne in mind that the emulsion papers contain deliquescent salts, the result of the decompositions that occur in sensitising; and although these, together with free silver nitrate, are also present in albumen paper, their action is held in check by a considerable proportion of free acid. In the modern commercial gelatine papers the proportion of free silver is very considerably less than in the case of albumen, which reduces the necessity for the acid, and in some, at least, of the samples now on the market it is entirely absent. In fact, it is quite possible to make a keeping emulsion paper for printing-out purposes without either free silver or free acid, but rather with an alkaline reaction.

The first uncertainty that arises after precautions against damp have been duly seen to lies in the washing, before toning. With some of the papers, under certain circumstances, the preliminary washing may be dispensed with, or it may be resorted to as choice may decide. This appears to have given rise to an idea that the question of washing is of no importance, and that, if resorted to at all, the most perfunctory performance of the task will suffice. Nothing is further from the truth, for, though the operation may be dispensed with altogether, if it is performed it must be done thoroughly, or else nothing but irregularity will result. It should be borne in mind that, in the unwashed film, the soluble matters are evenly diffused throughout the whole of both emulsion and paper, and the dry print enters the bath in a condition to be uniformly acted upon over its whole surface. But if it be first of all soaked for a few seconds, or a minute or two, in water, especially if, as is likely to be the case, a number of prints are crowded together into the same dish, the only result can be that the soluble salts are partially and unevenly removed from the print, which is, accordingly, acted upon by the toning solution in an irregular and patchy manner.

But, even when the theoretical necessity for perfect washing, or none at all, is recognised, the tendency, with old albumen workers especially, is to shirk the task, or, at any rate, to under-do it, trusting to the same amount of washing as would suffice for albumen paper answering equally well with gelatine. But the gelatine film parts with its soluble constituents far more slowly, and consequently requires a proportionately longer washing. It is, indeed, remarkable how protracted a washing may be given without thoroughly eliminating the soluble salts, for the tendency is, unfortunately, almost invariably to crowd too many prints into the same dish. When the printed instructions to wash "in two or three changes of water" are followed, the quantity of water should be liberal, and the time of soaking in each fairly lengthy. Moreover—and this is perhaps the most important condition of all—the prints should be turned over singly at least once in each water, and the surface gently rubbed, to remove any film of chloride or carbonate that may be formed by the action of the hard water upon the soluble silver salts. Uniformity of tone in gelatine, as in albumen, paper is best promoted by a complete removal of all the free silver.

Many operators prefer—and it is specially recommended in some cases—to treat the prints with alum before toning. This, of course, adds one more complication; but, where it is resorted to, every precaution should be taken to prevent its leading to inferiority of result. The necessity for thorough washing is equally as great before using the alum as before toning; but it is even more important after removal from the alum. The latter is an acid salt, and nothing so quickly modifies or destroys the action of the toning bath as a trace of acidity. What, then, is more likely to conduce to irregularity of tone, or to destroy the toning power of the solution, than to remove the prints into the gold solution while they are partially and unevenly impregnated with alum?

Besides this, it is also to be kept in view that alum and hypo mutually decompose one another, and that therefore the introduction of a print impregnated with alum into the mixed toning and fixing bath is in the highest sense dangerous. It is true that in some of the formulæ for the mixed bath both alum and hypo play a part; but in that case their mutual reactions are complete, and have ceased before the process of toning commences, whereas with an imperfectly washed print the decomposition is set up the moment the print goes into the bath, and most probably precedes or takes the place of toning proper.

The importance of thorough washing cannot, in fact, be too strongly impressed upon those commencing to use emulsion papers, and therefore, in order to lessen as much as possible the trouble, we should not counsel the use of alum before toning unless it is absolutely necessary. If proper care be observed in regard to the temperature of the washing waters and of the toning bath, we have never found it difficult with any of the papers we have tried—and these include all or most of the commercial makes as well as numerous samples of private manufacture—to dispense with the preliminary alum bath; but, when the weather is warm, or the gelatine surface from any reason is inclined to be soft or "slimy," the alum solution is undoubtedly a very great boon, but, if adopted, it must be with the full knowledge of the necessity for thorough and complete washing and with the intention of carrying it out.

The utility of the alum bath is not only confined to such severe cases of softening as those that verge on the solution of the film; then it becomes an absolute necessity, practically. But, if a large batch of prints be examined carefully, they will seldom be found free from minute specks, which represent so many little flaws in the gelatine film. Even with the utmost care such will make their appearance, and with the least roughness or carelessness will develop into serious defects. Even in their mildest form they detract from the beauty of an otherwise perfect print, and are therefore to be avoided if possible. Here, again, the value of the alum bath is exemplified, for, when this is used, these little flaws, arising from the friction of minute dust specks in the various solutions, are less troublesome, if not altogether absent, owing to the less tender nature of the film.

It will be seen, then, that in the matter of the use of the preliminary alum bath it is a question of compromise, trouble on the one side being weighed against quality of result.

Action of Light upon Iodine Compounds.—Professor Meyer has definitely decided the question of the action of light upon pure hydriodic acid gas. Bulbs exposed during the summer months in the laboratory were filled in a few days with brilliant crystals of iodine. After ten days more than half the gas was decomposed, and at the end of summer practically the whole of the gas was dissociated.

Relative Strengths or Acidities of some Weak Acids.—Before the Chemical Society Dr. John Shields read a paper on this subject which throws some instructive light on such problems as often occur in photographic practice as to the amount of relative decomposition that takes place when certain substances are mixed in solution. He found hydrochloric acid to be the strongest; taking it as 100, acetic acid was only ·35; biboric acid, ·0057; carbonic acid, ·00001.

Photography of the Human Eye.—M. Albert Londe has recently published a very complete and highly interesting paper upon the photography of the eye of living subjects. It is well known that for many years past experiments in this direction have been made, but it remained for Herr Gerloff in 1891 to make a practical success. He has lately still further improved his methods. Before describing them, we may briefly allude to the investigations of earlier experimenters. For instance, in 1862, M. Noyes of New York, and Sinclair of Toronto, were the earliest to work in this path, but they found the insensitiveness of the plates of the period to be a bar to success. Then, in 1864, a method, which has since been rediscovered, was invented by Mr. Rosenburgh. He placed a thin piece of glass at the intersection of two tubes, one pointed at the eye and the other view by the operator. The solar light was directed down the first into the eye, a portion being wasted by the piece of glass and the rest entering the pupil. The image was then reflected by the glass plate, similarly diminished in brightness by the partial reflection, and then photographed at the end of the cross tube. Other inventors used a concave mirror like those employed by artists at the present day, the image being viewed from the central aperture of the mirror. In 1884 Mr. Rosenburgh's plan was modified by M. Dor, of Lyons, who experimented with the eyes of a chloroformed cat and a rabbit, and using the electric light with Trouvé's photophore. Cohn, in 1888, devised a plan for reducing the time wasted in focussing. Two identical rhomboidal prisms were placed in the path of the luminous rays, and so obtained two images, one for focussing, and the other being directed on the sensitive plate, screened by a special shutter. Later, Hope, in St. Petersburg, and Galezowski, in France, tried to solve the problem, but found the greatest difficulty in suppressing the reflections from the cornea. M. Bagnéris used an equilateral prism covering a portion only of the pupil, then with a short-focus lens, placed about two-and-thirty inches from the eye, directed a ray of light upon the prism. The rays refracted by the first face and reflected by the second left the third at a right angle and converged towards the corner, thus lighting the eye. The objective was then placed in front, and took an image through the uncovered part of the pupil. Using Perrin's artificial eye, he obtained images two inches in diameter. We now come to M. Gerloff's plan. To avoid reflections, he placed before the eye, previously treated with cocaine and atropine to destroy sensitiveness of the conjunction and to enlarge the pupil, a reservoir whose anterior face was formed of a plate of glass with parallel sides, the whole being filled with a physiological solution of chloride of sodium. The corneal reflections were thus eliminated. He used a zirconium or magnesium lamp, or the magnesium light. The reflector was a laryngoscopic mirror like that worn by the surgeon over his face, and the camera was placed behind the opening. His results were the best yet obtained, but it was a very delicate piece of work to employ it, and the images were faint. In his final efforts he resolved to eliminate certain objections. He would take the largest possible field of view, would not require the patient to keep his eye rigorously in one direction (which was found to be almost impossible), nor employ troublesome apparatus for eye or hand, would take the photograph very rapidly, and use no light likely to be injurious. He places the subject before a table or other support carrying the lamp. The light is thrown into the eye through a tube with a cross piece with mirror placed at the intersections. The mirror throws the image out of the right line into the cross tubes, in which the focussing is done on a piece of ground glass. To expose, the mirror is twisted, which then allows the light to pass into the main tube and on to the sensitive plate. He uses burning magnesium, and it is found to be not at all injurious to the eye, on account, it may be surmised, of the brilliance being spread over a large area, and so less intense on any particular spot than when the eye focusses it in the ordinary manner. It is not possible to enter into further details without a diagram, but we may be sure the new plan will excite a great amount of popular interest. It has been suggested to us that a modification of the microscopic immersion lens might be made for the purpose of avoiding reflections of the cornea, a piece of glass of about an average corneal curve on one side and plain or concave on the other might be placed in contact with the eye, rendered insensitive by cocaine, optical contact being ensured by some gelatinous non-irritating lubricant between eye and glass.

PHOTOGRAPHIC PROPERTIES OF THE SALTS OF CERIUM.

We referred some time since to the fact that Messrs. A. & L. Lumière had been experimenting with the salts of cerium for producing photographic images. In a note presented to the Académie des Sciences, and since published, they observe: It is well known that cerium yields two principal series of salts, the cerous and the ceric. The first are very stable, whilst the ceric compounds are reduced by feeble reducing agents; some intermediate compounds, and more especially organic salts, are even spontaneously reduced so soon as they are formed, so that so far it has been found impossible to isolate them. The easy reducibility of the ceric salts has led us to a study of the action of light upon them, and we have remarked that this action, followed by readiness of reduction, appears to us to form a basis for perfecting an interesting photographic process.

Among the mineral salts which have given us the best results we may mention ceric nitrate and sulphate, formed by dissolving ceric hydrate in nitric and sulphuric acids. Aqueous solutions of these salts were used to impregnate paper sized in the ordinary way or treated with gelatine, the ceric salt colouring it a deep yellow. After being dried in the dark, the paper was exposed to sunlight under a positive. In the transparent parts of the *cliché* the luminous rays reduced the ceric salt to the cerous state, and the paper is decolourised on those parts. This decolourisation enables one to watch the action of light, and to stop printing when necessary. The print should be treated with a suitable reagent that will differentiate the cerous salt from the unaltered ceric salt, and will thus fix the image. The process, it will be observed, is one for making positives from positives.

In an analogous process with manganic salts that we have already published, say Messrs. Lumière, we have utilised the oxidisable properties of the manganic salts to form with a great many bodies of the aromatic series insoluble colouring matters. In the same manner, if we treat cerium prints with these reagents, there is formed by oxidation, and fixed, coloured substances in those parts where the ceric salt has not been reduced by light. All that is then necessary is to eliminate by washing the excess of the reagent as well as the cerous salt to obtain definitely fixed prints.

It is important that the colouring matter should be insoluble, in order that it should not be removed in the washing.

We have discovered, in the course of our investigation of their photographic uses, and in making a comparative study of the action of the ferric, cobaltic, manganic, and ceric salts on a great number of bodies of the aromatic series, that the last-named are capable of setting up colour reactions much more numerous than the others. Among the more characteristic of these reactions, the following may be mentioned:—

In acid solution, the prints are coloured grey with phenol, green with salts of aniline, blue with naphthylamine, brown with amidobenzoic acid, red with parasulphanalic acid, &c. Treated with ammonia, the colouration changes, becoming, for example, violet with aniline, red with naphthylamine, &c.

Paper sensitised with the ceric salts is more sensitive to light than either ferric or manganic paper.

Messrs. Lumière conclude by saying that they are still pursuing the study of the photographic applications of cerium salts.

ON THINGS IN GENERAL.

Mr. Lewis Wright has done good service to lanternists in his article in the "Lantern Supplement" regarding the use of compressed coal gas for lantern use, and the possible presence of iron carbonyl. He has hit upon a very probable solution of some of the difficulties attendant upon the use of household gas in a compressed form. That this carbonyl is present is highly probable, but to assume that any liquid found in a compressed gas cylinder is necessarily to be put down to its existence would be a mistake. It would be very difficult to say what it could not be, in fact, for coal gas is a substance of almost infinite complexity. It contains, in addition to what are more generally understood as gaseous compounds, of greater or less illuminating value, a number of vapours of chemicals, liquid or solid, at ordinary temperature, as, for example, water, benzine, naphthaline, &c. When the whole body of gas is subjected to pressure, and cooled, a considerable amount of these bodies must be deposited. Further, when the gas passes out of the cylinder at all rapidly, deposition will occur through the cold produced. Hence, though Mr. Wright's suggestion is a very happy one, it cannot cover all probable causes, at any rate, of deposited liquid in the cylinder. But, regarding for a moment only the injury liable to be caused by the production of the carbonyl, it is evident that his proposal to coat the cylinder internally with something of the nature of a varnish, to prevent the action of the gas upon the steel, would, if effectually carried out, answer admirably; but better than varnish would be a metallic coating. The cylinder could be internally electro-plated with silver copper, or any suitable metal, or, if zinc or tin was thought better. they could be easily applied. Finally, however, I would say, seeing the absolute certainty of precipitation in the cylinders, and the possibility of further injury from some of the gases when coal gas is used, why use it all? Let hydrogen, clean, pure, and dry, be used; it can be made at a very low rate, and would carry none of the above-mentioned disadvantages.

We have, in the same journal, some of the usually interesting and practical mems from Mr. Baker, but he seems to have mixed things through not seeing a proof of his paper. In The British Journal of Photography he makes a correction which, being a purely clerical one, the Editor has already put right. But he is confusing to outsiders in his remarks about sulphuric ether. The density of ether has nothing whatever to do with any smell it may or may not possess, and, when he says ·720 s.g. is about the densest that should be used, I can only say that ·720 is the density at 15° C. of absolutely pure ether according to the best authorities, and so is the least dense obtainable.

The question of plate speeds has been occupying a good deal of attention of late, and much talk foreign to the matter in question has been indulged in. I can only say that those acquainted with Mr. Williams's work and abilities are aware that whatever thesis, derived from experiments, he advances may be looked upon as the carefully thought-out results of the work of an eminently skilful worker. Then, again, we all know Mr. Cowan's ability; but, when he says that, if Messrs. Hurter & Driffield's "original paper is carefully read, it will be found that they have been very careful to express what they really did mean." I must say that such, also, was my own belief; but it was very quickly settled by a letter in this Journal from the experimenters in question, in which they stated that they had not made certain assertions which ordinary minds thought they saw in the original paper. But we all have heard of the celebrated cynic's saying that "language was given to conceal thought." Professor W. K. Burton will have to take the same lesson to heart; he has recently shown that it is possible to vary the density ratios by development. Messrs. Hurter & Driffield's letter is in print, saying they never said the contrary. Like others who had read their original paper, I thought they had denied this possibility, but "language was given," &c.

It was very pleasing a week or two ago to meet an old friend again. True, it was about the period for a recurrence of his visit. I allude to our very old friend, Photography in Colours. He has been dressed up again, and the papers have gone into the usual, though milder, hysterics over the grand discovery. It is a little singular that, just at the time when his form is decidedly less shadowy, the excitement is less severe than when he might be said to be *vox et præterea nihil*.

With regard to the reduction of over-printed proofs on gelatine paper, Mr. Lindsay has, in a recent number, some interesting remarks. So far as albumen prints are concerned, there is no doubt the best and only suitable reducer is a five per cent. solution of cyanide of potassium. As to gelatine. I am less able to speak positively; I must try Mr. Lindsay's plan. But I shall not find it necessary to go to the trouble of dissolving common salt in hot water, and waiting for it to cool, for the simple reason that hot water will not dissolve chloride of sodium any more quickly, or in any larger quantity, than cold water. According to some authorities there is a slight difference, but it is fractional only.

Poor "Cypher!" who writes to know what he must do, for the rain has got to his negatives and stuck them to the paper—the Editor very properly tells him there is no remedy but to retake the views. I would add to that advice, say, when you get your views again, do not print from them till they are varnished. You will then be free from stains on your negatives from your paper at any time, and, if the rain does again attack them, you may, by dissolving off the varnish in spirit, have them as good as ever they were, unless the rain beats for a considerable time in this unwelcome proximity.

Free Lance.

ANGLE OF VIEW.

[London and Provincial Photographic Association.]

If we examine the picture formed by a photographic lens upon a screen of sufficient size, we shall find it is circular. This circle is the base of a cone of rays transmitted by the lens. Divide this cone in the direction of its axis. The section is triangular, and the angle at the apex is called the angle of view. Let us suppose the focussing screen is square, and that the circle of illumination touches each side. A plate under such conditions would be unexposed at the corners. Yet, to calculate the angle enclosed by such a plate, we have been directed by the rules hitherto accepted to take the diameter of this circle as a factor. It is an astonishing fact that these rules have the sanction of a number of writers, amongst whom may be mentioned Shadbolt, Grubb, J. H. Dallmeyer, Traill Taylor, Woodman, Emerson, and still more recently A. Haddon, the respected curator of this Society.

To cover a plate such as has been described, it is evident the circle of illumination must enclose the plate, and not the plate the circle of illumination. We must therefore measure the diameter of the circle by the diagonal instead of the side of the plate. The perpetuation of the mistake is probably due to the habit, common amongst writers, to take data at second-hand rather than think them out for themselves. There are, however, two noteworthy exceptions. Dr. Eder, in his *Ausführliches Handbuch der Photographie*, gives rules and tables for calculating the angle of view included by a lens, and for that included on a plate. For the latter he takes the diagonal as the basis. Professor W. K. Burton also estimates the angle of view by the diagonal of the plate, according to an article on the Concentric lens in *Photographic Work*, February 24, 1893.

Recently I criticised, before this Society, the rules laid down by Mr. Haddon for calculating the angle of view included on a plate. They were published in The British Journal Photographic Almanac for the current year, and may be taken as correctly representing the rules of the writers first mentioned. These rules take the longer side of the picture as the base of the triangle enclosing the angle of view. You may follow the rules and work the problem correctly, but the answer will always be at variance with the facts. Either the angle will be too wide or the focus of the lens too short, when you take the photograph. We may also have a series of plates such as 15×9, 15×10, 15×11, 15×12, yet, by these rules, all will include the same angle, with the same lens, under similar conditions; or, if we wish to include a given angle from the same station-point, we must use a lens in each case of identically the same focus. Further, no matter what position the lens may occupy on the front of the camera, the angle will remain the same. Rules giving such results are evidently wrong, and, as a more rational system, I would suggest the adoption of the method used in perspective.

The circle of illumination of a lens corresponds with the base of

the cone of visual rays. The lens is the eye and the picture plane is the photographic plate. These are corresponding terms in photography and perspective. The picture plane is vertical, and must not extend beyond the base of the cone of rays.

The angle of view in perspective is limited to sixty degrees to avoid that exaggerated appearance with which we are familiar in pictures taken with wide-angle lenses. But, for the purpose before us, this may be disregarded, since what is true of an angle of sixty degrees is also true of any other angle. In perspective, if the picture plane touches the edge of the base of the cone of rays at any point, it is said to include an angle of sixty degrees, and, similarly, we may speak of pictures including any other given angle.

On the picture plane there are two important lines, the base line and the horizontal line; the base line is that upon which the picture rests, and the horizontal line extends from right to left at the height of the eye. Upon this line is the centre of vision, or centre of the circle forming the base of the cone of rays. The axis of this cone is called the principal visual ray, and corresponds with the focus of the lens.

The artist may select any portion of the base of the cone of rays for his picture, and the photographer does a similar thing when he moves the cross fronts of the camera in arranging the subject on the focussing screen. What, then, are the conditions which determine the angle of view for any given picture? First, the distance of the spectator from the picture plane, which, in photography, we may call the focus of the lens. Second, the position of the centre of vision, which, as I have shown, will vary according to the position of the lens on the front of the camera. To ascertain the position of the centre of vision, we must draw a line perpendicular to the plate from the apex of the cone of rays. Where the line touches the plate is the centre of vision, and we must measure the distance thence to the farthest corner of the plate. We can now measure the angle of view by means of the table of natural tangents given by Mr. Haddon, the rule for which should be stated thus:—

To find the angle, divide the distance from the centre of vision to the farthest corner of plate by the focus of the lens. Find the nearest number to this in the table of tangents, and twice the arc opposite it is the angle required; or, if we know the angle of view, and wish to find the focus, find the tangent opposite the arc, which is half the angle of view. Divide the distance from the centre of vision to the farthest corner of plate by the tangent. The answer is the focus of the lens required.

Mr. Haddon was unfortunate in the selection of the title of his article, "Angle of View included on a given Plate by a given Lens." If the lens is not opposite the centre of the plate, the whole angle of view is not included. But the expression is permissible if we understand by it the angle under which the picture is taken. I mention this merely to draw attention to the fact which some may overlook, that the angle is different if the lens is moved by using either of the cross fronts. It must also be remembered that a lens can be used to cover a larger angle if the axial ray is not perpendicular to the plate, as pointed out by Mr. W. E. Debenham when this subject was last under discussion. But, as I have used the term angle of view in relation to the picture, and not to the lens, the rules I have given apply to the picture only. If it is required to calculate the angle covered by a lens under the abnormal conditions mentioned, the necessary modification must be made in the formula. P. Everitt.

NOTES ON STUDIO-BUILDING.*

This being the time of year when studio building is usually undertaken, and the matter having recently been discussed in the columns of this Journal, it occurred to me that, having worked in several different studios, and built two which answered their purpose fairly well, but which were capable of improvement, a few notes on their good and bad points might be useful as showing what to avoid, if not what to adopt. The chief matters to be taken account of are: *Size*, as regards length and width; *height* and pitch of roof; *aspect*, north, north-west, north-east; *amount of space glazed; kind of glass; nearness* or otherwise of neighbouring buildings, or possibility of their subsequent erection; *supports for glass; roof on shadow side; blinds and method of fixing; tie rods; ventilation.*

The first studio I worked in had clear glass in roof, and I fancy north-east aspect. We used to get the sun in, and I remember once placing a thermometer on top of camera and finding it registered 120° Fahr. The next had either Hartley's rolled or else plain glass in roof, with plain glass at side. Aspect, north by northwest. In the middle of summer the sun used to shine in during afternoon, restricting us to the use of one end of the room for the time being. The framework of roof was of T iron, and inside walls painted pale blue. Light was quick, and lighting good. Dimensions about 27 × 12 or thirteen feet, with room to back out at one end when taking large groups. The side light came down rather low, about two feet or two feet six inches from floor, with short curtains along the bottom portion. Ridge roof, light only from one side.

Another studio, dimensions about 30 × 15, also with ridge roof, had a narrow top light, with long sloping side; glass all "white cathedral," or similar sort. This is a good kind to use where the studio is overlooked, as it prevents sitters seeing outside objects clearly, and gives a feeling of seclusion and privacy—more apparent than real, however, as from a little distance off any one outside can distinguish objects inside, though not sufficiently to recognise individuals. To entirely prevent outsiders seeing what is taking place inside, ground glass is necessary.

This studio ran out end ways from the house on ground floor, and at opposite end were some fairly highly trees, so that, whichever end the sitter was placed at, the front top light was seriously cut off. Walls and roof on shadow side painted chocolate, lighting being slow, except when very bright clouds were about, and always hard. There were no cross ties, and I was able to use a head screen for bust portraits. The next studio was in London, glazed at top on both sides of ridge with Hartley's rolled glass. One side of roof generally kept covered by opaque blinds. No side light, but a window at one end, which could be uncovered if desired. With the exception of this window, there was no glass lower than about eight feet, and wall of next house ran up higher than studio. Lighting too much from top, and consequently hard; and, unless both sides of roof were uncovered (which gave flatness), light was very slow.

The next studio was at the seaside. Aspect something like north-west, sloping light, starting at about three feet nine inches from floor, and running right away above wall on shadow side, a small portion near the wall being ceiled. On the south side were other rooms, with their roof running up above to meet the studio roof. There was thus a considerable air space up under the ridge. The studio was cool, except in middle of summer, when the sun used to peep in. Glass was plain, and to keep out sun tissue paper was pasted over it, which, owing to the sitters having to be placed close to the window on account of narrowness of room, gave considerable glare, and caused very large high lights in the eyes. I found four large opaque blinds in use, running on wires horizontally, each one covering one quarter of the glass. As the room was only about 20 × 10 ft. on the floor, and narrower still five or six feet above, the sort of lighting it was possible to get with sun shining in may be readily imagined. Several smaller black muslin blinds were substituted for the four large thick blue ones (also running horizontally), which subdued the glare and enabled me to modify the lighting according to requirements. In winter time the tissue paper cut off too much light, so it was dispensed with, and when summer came round again mineral paper was used instead, with good results. The supports for the sloping light were of wood, and occasionally the wet found its way through. Ventilation was effected by lifting up hinged portions of the framework, with the disadvantage that in wet weather the rain drove in.

With reference to dimensions, 30 × 15 feet is a useful size, and, if there is a room opening out of studio in which accessories not in every-day use can be kept, the width will be enough for most purposes; eighteen feet would, however, be better. The tendency nowadays is towards large work, necessitating large cameras and stands, which require to be kept handy and yet out of the way when not in actual use. I should have made my present studio eighteen feet, but was limited by width of ground. Thirty feet is long enough for most work; but, if background carriers with projecting feet are employed, and some at each end of room, thirty-five feet would be more convenient.

Height.

Up to eaves mine is eight feet, but nine feet would have been better, and, if studio is to be eighteen feet wide, height to eaves should certainly not be less than nine feet, assuming a ridge roof to be chosen. Height of ridge from floor is about fourteen feet, but rather more would have been an improvement, with the eaves at eight feet, and, with the eaves at nine feet and the width at eighteen feet, the height to ridge should be as much as eighteen feet. The steeper the roof the more easily will the snow slip off, and the cooler will the place be in summer.

Support for Glass.

I can speak strongly in favour of T iron. I have had it in use for seven years, and have never had any wet come in. Glass was painted over at edges before puttying in, and I believe the rabbet of iron also. The first two summers were very hot ones, and after the second

* Mr. Cole's article has been in type for a considerable time, but had to be held over through pressure of other matter.

it was found that a little of the paint and putty was the worse for wear. It was repainted and puttied where necessary, and went for five summers without anything being done to it, then had another puttying and painting, being apparently as good as when first put up. The framework for side light is of wood, with a wooden plate. If building again, I should have this also of iron, with an iron plate, which would obstruct less light at the eaves, and be less inclined to twist or warp. For another studio I built, which there was a possibility of wanting to remove, wooden rafters were used with patent zinc tubing to avoid fixing glass in with putty. The zincs were supposed not to require any other rafters, and were supplied extra strong for the purpose, but they were of no use as supports. By fixing them on wooden rafters they answered all right, except for the bottom panes next to gutter, which were always slipping and breaking till I had some iron stops made and screwed on to plate. T iron has this disadvantage over wood, that, when it is required to attach anything in the way of supports for blinds and curtains, there is nothing to fix them on to; therefore, at intervals along the framework, before the glass is put in, the iron should be drilled, and a few small pieces of iron screwed on inside, to which wooden rails can be fixed. On these rails any fittings can be easily attached. If an iron plate instead of a wooden one at the eaves is adopted, this should also be drilled, and a strip of wood bolted to it for fixing side blinds or cords to. It must be remembered that in frosty weather the roof gets very cold during the night, and condenses any moisture there may be in the studio. This moisture runs down towards eaves, and any projections, such as tie-rod connections, are liable to arrest the water and cause it to drip off on to the floor or furniture. All such projections should, therefore, be bevelled off on under side, so as to lead the wet *on* to the roof instead of away from it.

I saw in London not long ago a studio in which the roof and sides were in one continuous curve, bent glass and curved T-iron frame, work being employed. This gave a free, unobstructed light, and the moisture was led right away to bottom of the side light. The proprietor spoke highly of it.

Aspect.

North-west is undesirable unless high buildings happen to trap the afternoon sunshine. North by north-east is more suitable than due north, as tendency now is for people to come later in the day than formerly. As there is always the possibility of early sitters, it is advisable to have the means of screening the morning sun as well as that of the afternoon. I have zinc screens, about two feet wide, attached by brackets to the roof, running up each end and along the ridge. These are screwed up in the spring and taken down in the autumn. Zinc is better than wood. I was once nearly killed by a wooden screen being blown down piecemeal through the glass roof. About ten large panes were smashed. One board came through just where the operator had been varnishing some negatives.

Amount of Space to be Glazed.

Best to have enough, it can always be screened off when not wanted, and there are occasions when all possible light is required.

The distance from floor at which side lights should start is a matter for consideration. My own begins at about three feet six inches from floor, and in a wide room this might do, but in a narrow one the glass might come down lower. Talking to a photographer the other day whose side light begins at about the same height as mine, we both agreed that, if building again, we would make it lower. Short curtains running on wire can be used to screen the bottom portion. When young children are taken standing on the floor, it is difficult to get sufficient light on the legs unless the side light is low.

Kind of Glass to Use.

In the roof I have used Hartley's rolled, and like it very well. It certainly cuts off more light than clear glass, but it diffuses what passes through, which compensates for any cut off. There is a good deal of colour in some samples, which are therefore to be avoided. If building again, however, I should be inclined to try ground glass. Hartley's is pretty strong, and although the street urchins are fond of making a target of the roof, and several panes have been cracked in the course of a few years, it has not been found necessary to replace any.

In the side I have "white cathedral," which gives a pleasant illumination, but does not diffuse the light so well as "ground." Working in a studio on ground floor, having clear glass in side, the window looking out on to a grass plot, with a one-storied building about twenty feet away, the lighting was found to be hard, and was much improved by fixing up ground glass inside the clear for about two-thirds of the distance up the sides towards eaves. If the side light is quite unobstructed and likely to remain permanently so, and studio not overlooked, then, provided the outlook is pleasing or interesting, a certain amount of glass in the side might be left clear—it affords occupation to sitters or their friends to look at while waiting, and where several negatives have to be taken this is an advantage. For lighting, however, I prefer *ground* or *figured glass* up to level of head of standing figure, and above that *clear* or "white cathedral." As figured glass is expensive and not strong enough for outside use, I should be inclined to glaze the whole of side with "white cathedral" or similar kind, and then have an inside casing of figured about two-thirds the way up to eaves, this to be so fixed that it could be removed or slid along for occasional cleaning. Clear glass could be left at intervals for outlook if preferred.

Blinds.

Whether these should run vertically on spring rollers or horizontally on strained wires depends on individual fancy, and on the way the tie rods are fixed. I have some of each kind. The chief, in fact only, objection to those running on wires is that they have to be moved with a long stick, which invariably causes sitters to look up at the skylight, and they then begin to realise that the light is strong, and perhaps find their eyes dazzled. Those running vertically, moved by a string, do not seem to have this drawback. With those running horizontally more graduated lighting can be obtained.

Tie Rods.

These are generally necessary evils. They are apt to be in the way of blinds, &c., and, unless eaves are high and the ties arched upwards, they prevent anything in the way of head screens being conveniently used. Screens such as recommended by Mr. Whaley in a recent "Annual" cannot be used if the tie rods are low. The places for these should be well thought out beforehand, so that, instead of being in the way, they may be made use of for hanging a swing or hammock from at a suitable distance from background.

When I built one of my studios, not having had much to do with actual building operations, I wanted, as far as possible, to dispense with ties. Builder thought he could manage with two up in the roof only, not braced to the sides, with the result that, as soon as men began putting the slates on, the walls began to spread out, and we had a narrow shave of having to build twice instead of once. They were got back nearly into the original position, but not quite, and the wooden framework of side light remained somewhat twisted. Fortunately there was no glass in, or it would have been smashed. We then had to put ties in where we could, with the result that those attached to the sides did not correspond for position with those in the roof, and rather interfered with the working of blinds.

In the matter of choosing a builder, it will be found cheapest in the end to go to the best, preferably a local one, who can be fetched back to make good anything that may not have been done just as it should have been. Coming as a stranger into the town, I thought it would be better to employ a man I had some acquaintance with (a non-resident) rather than take my chance of getting hold of a good one amongst strangers. I made a bad spec. My friend (?) used poor mortar, did not put any damp courses to the new work, put up a gutter to small too carry off the water properly, and fixed it up badly. This side being close to neighbouring property, the gutter had to be kept back flush with wall, so he just bedded it on top of wall with ordinary mortar, consequently it overflowed inside as well as out.

I had to call in another builder, who raised the wall to form a parapet, and put down a proper lead gutter. The parapet is a great convenience, as, when we want to get on roof to fix stove-pipe, put on a new slate, fix up the zinc sun screens, or mop the glass, we can walk along without having to ask permission to take a ladder on to adjoining property.

Materials for Walls.

If on own property, or such as there is a long lease on, it is best to have brick—at any rate, if building is at all exposed to the sun's rays—and, if one cares to afford the luxury of a tiled roof, the room will be all the cooler for it in summer. If sheltered from the sun, wood and iron will do, provided there is good convenience for keeping it warm and dry in winter; if exposed to sun, an iron building is decidedly hot in summer.

Ventilation.

I had arranged with the builder just mentioned to have good-sized ventilators in the gable ends, but he forgot, and persuaded me to rest content with a couple of air bricks. Result: operator and sitters baked.

Next spring air bricks were replaced by a good swinging ventilator at each end, and the studio has since been no hotter than the generality of such buildings.

Warming.

Hot water from a Loughborough boiler heats all the rooms on ground floor, studio itself being warmed by a tortoise stove. Hot water saves a vast amount of mess and dirt, besides being more economical, and, provided the stoker is intelligent, leaves little to be desired. If, however, the stoker has a fancy for getting the pipes nice and hot on a mild day, and letting the fire out when the weather is chilly, the surplus heat cannot so quickly be got rid of by opening windows and doors, nor the room quickly warmed, if cold, as when a stove in the studio is the source of heat. If a stove is used, the fewer bends in the pipe the better. I used formerly to have the pipe go straight up through the roof, and the stove always drew well, never requiring sweeping all the winter through, a slight tapping on the pipe being sufficient to shake the soot down. Having moved it to a fresh place, necessitating a bend or two in the pipe, the moisture, which gets into it during the night in damp, foggy weather, cakes the soot, and necessitates frequent sweeping.

Thanks to the ventilators at each end near the top, any smoke that may be puffed out when fire is first lit can be readily got rid of. However full of smoke the room may be, by opening the various doors and ventilators it can be all blown out in about five minutes, and a clear negative taken. It is a great convenience to have a good supply of gas near the stove from which a Bunsen can be supplied to light up fire quickly when required. For small rooms, or branch places not open perhaps every day in the week, the new hot-water apparatus heated by paraffin should answer well if means are adopted to lead away the products of combustion into the outside air.

Under any circumstances it is advisable to have stoves shut off from the printing department. Unfortunately, in my case, the only access to the Loughborough boiler is through the printing room, and the number of black spots due to coke dust that we get on our vignettes during the winter months is somewhat alarming. Doubtless, where it is necessary to heat rooms on different floors, a high-pressure boiler will do it most satisfactorily, but of this I have no experience. Some insurance companies, I believe, decline to insure studios heated with water at high pressure.

W. Coles.

PRACTICAL REMARKS ON PHOTOGRAPHING DIFFICULT INTERIORS.

II.

In a previous article I referred to a few of the different kinds of interiors an operator is sometimes called upon to deal with, and instanced a few of the chief points necessary in dealing with well-lighted subjects, where it was possible to bring into one's aid diffused light.

There are very many other cases, however, where the light is so poor as to require extremely long exposures—ranging from hours to days, even when using plates of the most exalted sensitiveness, instances of which will be found in warehouses under dark arches, such as are only lighted by large windows or doors at one end, and where the interior runs a long way back from the light. This class of subject is generally to be met with in large cities, where the arches under the railway lines are utilised for warehouse purposes, such as bonded stores, and many other similar businesses. I have known cases where, an exposure of twenty-four hours proving insufficient, a further exposure of from two p.m. on Saturday until ten a.m. Monday yielded a satisfactory negative, using a stop equal to *f*-22. One item of paramount importance, when giving such long exposures, is the utmost certainty of the camera and all its fittings being absolutely light-tight; and a further cause of failure, which I have never seen pointed out or referred to by writers, is the necessity for the plates being the full size of the cells. I have known cases where plates, being cut too small in their breadth, although right as to their length, gave no end of bother even to find the cause of failure; when such happens, the light plays round the back of the plate, and proves disastrous, the appearance of the plate being as if badly fogged. Another frequent cause of failure is using a lens too wide of angle for the camera, or dimensions of plate being used, whereby the sides of the camera reflect light on to the front of the sensitive plate. Wide-angle lenses, however, are a necessity for this kind of work, but they should be carefully selected, to suit the size of plate being used.

I sometimes feel platemakers have a deal to answer for in the careless manner they cut their plates to sizes, and when any one experiences, as I have done, the annoyance of a plate being just so small as to allow of one side of it being pushed forward of the rebate in the slide by the pressure springs, he will know to his cost how necessary it is to examine carefully every cell before leaving the dark room. This is especially the case when using large-sized plates, such as 12 × 10 and upwards. When a plate is cut too small, it is just about a hundred to one the withdrawal of the shutter of the slide will cause a scratch line straight across the face of the plate, and, worst of all, when the shutter of the slide is fully drawn, the pressure springs of the slide will push forward the plate, and prevent the door of the cell being reclosed. A more exasperating trouble cannot fall to the lot of any one. But these troubles are not only confined to interior work, they happen at all times; still, after having exposed a plate upon a difficult subject for, say, forty-eight hours, it is doubly annoying to have to go all over the routine again.

It is highly important that the plates fit the cells thoroughly. With camera and slides all being in perfect order, an operator has the utmost confidence that, even with the most prolonged exposure, his plate will develop up free from veil or fog. A very necessary precaution, however, is the backing of every plate with a coating of asphalt dissolved in benzole, as described by me in a former article on photographing stained-glass windows. This should never be omitted where very long exposures are being made, and any extra trouble expended in preparing the plates is more than compensated for by the results attained.

Later on I hope to refer to the development of such long exposures. In very dark interiors, such as I have just referred to, it is almost impossible to over-expose a plate when properly backed with a preventive against halation.

I am a firm believer in utilising daylight for all exposures when at all practicable. There are many instances, however, where artificial lighting may be employed in combination with daylight. This I hope to refer to later on. Daylight, with plenty of time, however, will be sure to make its presence felt on the sensitive plate, and, as a rule, yield the most truthful representations.

In some cases isochromatic plates are a distinct advantage, but they should be used with considerable forethought, according to the nature of the subject.

In dealing with large engine shops, where the entire structure has to be included, prolonged exposures will generally be found necessary, and a time selected when the works are quite free of smoke and dust. I have known cases where some parts of the machinery required, under similar conditions of plates, stops, &c., an exposure of only twelve minutes, whilst the entire workshop was not overdone when exposed from early morn till dark, the cause being that the portion of machinery was situated somewhat near to a large window. When operating on machinery a considerable amount of preparation is necessary. This includes the colouring of the various parts, and toning down unduly bright portions. As a rule, however, in every well-appointed engine shop the makers and workmen are quite alive to the necessity of such, and generally arrange for this being done before sending for the photographer. Badly situated windows must also be dealt with, and one of the best means of doing so is by hanging outside the windows large tarpaulins; this should never be neglected, and, although to any one unaccustomed to this kind of photography it may appear a lot of heavy work to arrange for such, still, in engine shops and other similar cases, the workmen are quite accustomed to face far heavier preparations than the mere handling of a few waggon covers, or the placing of such in suitable positions. I never yet met a case where the utmost willingness was not shown to assist in and carry out every necessary preparation. Engine work, as I have said, differs very much from all other branches of photography, and, before a young operator undertakes the responsibility of such, he would do well to put in some experience with one accustomed to this special class of work. On doing this he will at the outset feel that he is, as the Yankee says, dealing with the "big in everything;" he will soon, however, come to learn that what previously appeared an almost insurmountable obstacle was easily removed by a few willing hands, which are always to be found ever ready to help, and this will soon engender confidence. It is seldom, however, especially in the case of photographing machinery, that negatives can be obtained sufficiently clean or free from adverse surroundings as will permit of their being printed from without a considerable amount of preparation. This to a very great extent means the necessity of blocking out such parts as could not be dealt with in the preliminary arrangement before taking the negative.

In striking contrast to large engine works will be found such subjects as interiors on board ship. Of course there are large and small ships; but, even in the case of the new Cunarder *Campania*, there are very many interesting parts so cribbed and cramped up for space as makes it a matter of extreme difficulty to overtake. Of course, the magnificent dining saloon, capable of seating about 450 passengers, is one of the big things, and so are many of the other points of interest on board, including the funnels, which are over twenty-one feet in diameter, and large enough to permit an express train to pass through as it were a

tunnel, are things that require a pretty big plate and wide-angle lens to do them justice, but the cramped and cribbed subjects on board are the alley ways, state rooms, pantries, &c. To photograph such was a matter of no little difficulty. So, also, was the library; although one of the features of the ship, and a magnificent room it truly is, still it gave me no end of bother to get a good result. This delicious retreat is built somewhat in the shape of a horseshoe, and the semicircular bookcase, entirely filled with a most careful selection of books, corresponds in shape exactly to the curve of the structure, every portion of which, at short distances apart, has little windows entirely round its sides. These windows throw a beautifully soft light into the room, but for photographic purposes—oh, what a horror!—every light is reflected back from the glass window in the bookcase. Screen off the windows, away goes the light. After much thought, however, I hit upon a plan which worked admirably, and, although I did not succeed in getting all the bookcase into the view, still, by cutting off the light all round one half the circle of the structure, and by blocking out the windows, I was able to get rid, to a very great extent, of the objectionable flaws in the bookcase. An exposure of exactly one and a half hours yielded a good negative. The magnificent dining-room gave little or no trouble, and makes a very fine interior, and doubtless, before long, the market will be flooded with all sizes of pictures of this enormous saloon. I obtained a fine negative in one hour and a quarter's exposure.

As I have said, it is the confined places, such as the pantries, bathrooms, and "a warm corner for two" that taxes to the utmost the energies of an operator. The plan I found best was to invariably use a fast plate, well backed with tar, and to expose, say, on such small, confined situations a plate of large size, with a small lens in the camera of good covering power, well stopped down, of course giving very long exposures. By this means I got a good range of view of the pantries, and many others of the confined places on board. At no time did I resort to the use of the magnificent installation of electric lighting, of which there are nearly fourteen hundred lamps on board. I found daylight quite sufficient. Of course there are very many interesting places on board that are not possible of being photographed; but, for the coming season, the rage will be *Campania*, and I dread to think how often that kind-hearted genial gentleman, the steward, and that hard-headed level Scotchman, Mr. Paton, the head engineer, will have to suffer the infliction of having their pictures drawn. Were the Company to tax hand cameras, and hand the proceeds to the Photographers' Benevolent Association, I think, before the close of the Chicago Exhibition, they would have a real good thing.

T. N. Armstrong.

"PREVENTIVES OF HALATION."

A few remarks on the above subject will not, I hope, be considered untimely, bearing in mind a statement that Professor Burton and another gentleman in Japan had found in picrate of ammonium a sure preventive of halation. I have not been able to find much detail, but presumably picric acid was dissolved in water (its solubility is barely one in ninety), the solution carefully neutralised with ammonia, a plate immersed therein, dried, and exposed, with, as stated, the best results. I confess to failure so far; working as above, there is a total absence of halation, simply because the plate, no matter how much alkali be used, is quite insensitive, and this even when using a solution so weak as 1 in 2400; however, a trial was made of other dyes for the same purpose (also of the picrate salt used differently) with better results. The idea was, of course, to interpose between subject and plate a tinted film, which would prevent excessive action in the high-lighted portions of the plate, while allowing full exposures for the shadows. The most convenient method of following out this idea was to make the solution in spirits of wine, and then mix with enamel collodion, coating a plate with this, and drying (which it does quickly) prior to exposure; *e.g.*, dissolve a grain of picric acid in fifteen minims or so of rectified spirits of wine, neutralise with ammonia—though I don't think this is essential—add two or three parts, say, thirty to forty-five minims, of ether, and then make up to half an ounce with enamel collodion.

In the case of any other dye, as green, rose aniline, or rosine, the solution would be simply made in spirits of wine, and then diluted or mixed with collodion as stated above. Four plates were coated with collodion thus prepared, and received comparatively brief exposures upon a subject suitable for the purpose. It was found possible to develop the eosine-coated plate with an ordinary pyro and sulphite developer; also, with rather more alkali, the *green*-tinted plate. The rose and yellow-tinted plates remained quite insensible to the blandishments of the pyro, &c., and an immersion of nearly half an hour failed to produce appreciable effect; they were therefore removed, rinsed in water, placed in a bath of methylated spirit, and, after wiping off the superfluous spirit, were once more submitted to the action of the developer, with the result that the pictures developed up quickly, these two being the most satisfactory as regards colour and density, while, with reference to *halation*, the *yellow*-tinted plate was first, closely followed by that tinted with rose aniline. I am inclined to think that, combined with a good "backing," the use of a canary-tinted collodion applied to the sensitive surface of a plate will be found an advantage, not very great perhaps, but every little helps. The trouble of coating is very slight; the plates are dry very quickly, and a preliminary bath of methylated spirit is not a serious business.

I imagine the selection of picrate of ammonia to be merely an incident, probably a convenient solution to use—I handle it every day for the treatment of malarial fevers, &c.—and that picric acid, well diluted, answers the purpose just as well. With eosine, a drop or two of ammonia solution is an improvement. Finally, the degrees and attenuation of the solutions used may be mentioned:—

Picric acid	1	part in	4,000
Green dye	1	„	1,000
Eosine	1	„	200
Rose aniline	1	„	10,000

the collodion being prepared by dissolving one part of pyroxyline in a mixture of eight parts of spirits of wine and twenty-four parts of ether.

J. Pike.

PHOTOGRAPHY AT GREENWICH OBSERVATORY.

The annual visitation of the Board of Visitors of the Royal Observatory at Greenwich was made on Saturday last, June 3. The Board consists of the President of the Royal Society (Lord Kelvin), the President of the Royal Astronomical Society (Captain Abney), six Fellows of each Society, the Savilian and Plumian Professors of Astronomy at Oxford and Cambridge, and the Hydrographer of the Navy. In addition to the Board a large number of other visitors were present. On this day—and it is the only day in the year when such is the case—work at Greenwich is entirely suspended, so that visitors have then an opportunity of examining the various instruments, which it would be impossible at other periods of the year to obtain. The annual report of the Astronomer Royal to the Board of Visitors is also presented this day, and from it we here give one or two short extracts:—

Catalogue and Chart.

"With the Astrographic equatorial 722 plates, with a total of 1812 exposures, have been taken on 161 nights in the year ending May 10, and of these 116 have been rejected, viz., 57 from photographic defects, 6 from mechanical injury, 12 from mistakes in setting, 6 from the plate being wrongly placed in the carrier, 7 from failure in clock driving, and 28 from interference by cloud. The following statement shows the progress made with the photographic mapping of the heavens in the year 1892, May 11, to 1893, May 10:—

	No. of Photos. taken.	Successful Plates.
Astrographic Chart (exposure 40m)	200	183
Plates for Catalogue (exposures 6m, 3m, and 20s)	367	288
Number of fields photographed for the chart		172
Number of fields photographed for the catalogue		271
Total number of fields photographed since the commencement of the work for the chart		176
Total number of fields photographed since the commencement of the work for the catalogue		299

It has been made a practice to take a trail on each night on a catalogue plate as a check on orientation, and during the past year 127 plates with trails have been thus secured."

Among the negatives shown were several illustrative of the effect of prolonged exposures, the latter as compared with comparatively short exposures enormously multiplying the number of stars photographed.

Miscellaneous Photographs.

The following miscellaneous photographs (included in the total number of 722 given above) have also been taken:—

Nova Aurigæ, 49; for zero of scales and orientation, 36; North Pole (for adjustments of equatorial), 11; Pleiades, with various exposures, 19; Victoria comparison stars (for determination of scale value), 12; lunar

eclipse, 1892, May 11, 4; comet Holmes, 2; moon, 3; Saturn, 5; conjunction of Saturn and γ Virginis, 16; trails of equatorial stars, 3.

Four of the plates of the Pleiades have been taken with the group in four different positions on the plate for determination of the optical distortion of the telescope.

Some experimental plates of Jupiter, Saturn, double stars and lunar craters have also been taken with the image enlarged about fourteen times by a secondary magnifier, consisting of a triple commented concave lens of one and three-eighths of an inch in diameter and three inches focus, supplied by Mr. T. R. Dallmeyer. The results are very promising.

The Photo-heliograph.

The telescope and camera of the Dallmeyer photo-heliograph were again removed on September 9, 1892, from the wooden dome, where the new buildings obscured the horizon, to the first floor of the new museum, where they were remounted on stand No. 3, which was simply placed on the floor and found sufficiently steady. From this position it was possible to photograph the sun during about two hours each day. The instrument and stand No. 3 (the proper stand No. 4 having been lent for use in the eclipse expeditions) were taken back to the wooden dome on April 7, 1893, the sun being then visible over the roof of the intervening building.

In the year ending May 10, 1893, photographs of the sun have been taken with this instrument on 180 days, and of these 410 have been selected for preservation, besides twenty-two photographs with double images of the sun for determination of zero of position.

The photographic telescope presented by Sir Henry Thompson, which has been mounted on the Lassell equatorial, has been in regular use as a photo-heliograph since January, 1893, and photographs of the sun have been obtained with it on eighty-nine days, of which 158 have been selected for preservation. In all, with one photo-heliograph or the other, a record of the state of the solar surface has been secured on 220 days during the year. A new enlarging lens by Messrs. Ross & Co., which appears to be very free from distortion, was fitted to the Thompson photo-heliograph on December 13, and has been used regularly since for the eight-inch photographs of the sun.

For the year 1892 Greenwich photographs have been selected for measurement on 197 days, and photographs from India and Mauritius (filling up the gaps in the series) on 165 days, making a total of 362 days out of 366 on which photographs are available."

For photographs of sun spots an exposure of $\frac{1}{5000}$ of a second is given.

Magnetic Observations.

The following remarks as the value of photography in magnetic observations will be read with interest.

"The photographic registration of the variations of magnetic declination, horizontal force and vertical force, and of earth currents, with the accompanying eye observations of absolute declination, horizontal force and dip, are maintained as in former years. The period has been one of great magnetic activity, and at such times we can appreciate the advantage of the newer photographic processes, as compared with those of earlier days, in the clearness and delicacy of the registration of the many rapid magnetic movements that occur during magnetic storms. There is also greater general certainty in the photographic work, the loss of register due to photographic failure being now a very rare circumstance."

Recent Sunshine.

Photographers may like to know what the Greenwich authorities have to say over the recent remarkable summer weather:

"The sunshine registered in the months of March and April has been phenomenal. For March it was 155·1 hours, and for April 231·0 hours; the greatest numbers for these months in the sixteen years 1877–1892 being 141h·0 (1880, March) and 196h·3 (1892, April). The greatest values for *any* month in the sixteen years preceding are 277h·1 (1887, July), 267h 1 (1877, June), and 237h·8 (1882, May); and, if we consider the *ratios* of sunshine to the total time the sun was above horizon, or to the total time, less one and a half hours each day, during which the sun is too low to give a record on the paper, we find that April, 1893, was the sunniest month yet recorded."

	Ratio to Total No. of Hours.	Ratio to Total, less 1½ hours daily.
1877, June	0·540	0·594
1882, May	0·493	0·546
1887, July	0·558	0·615
1893, April	0·557	0·624

A NEW SOCIETY—THE NORTHERN PHOTOGRAPHIC AND SCIENTIFIC ASSOCIATION.

When a number of amateur photographers and scientists residing in the more northern suburbs of London decided upon the formation of a society which should prove of greater scope than photography alone could provide, the pleasant and now largely populated village of Wood Green was universally selected as the site of its headquarters. Wood Green in itself has many amateur photographers and others devoted to scientific pursuits, and these have during the past few weeks being doing advance work in the formation of a society which should embrace not alone photography but other sciences more or less cognate to it. Wood Green, from having a short time ago been an outlying and very small suburb of London, has now become a species of centre, having suburbs of its own, the preponderance of its male inhabitants being engaged in London in business during the day. It is in contiguity with Noel Park, Hornsey West Green, New Southgate, and similar populous districts.

The inaugural meeting, which assumed the form of a *conversazione*, took place in the Public Hall, Canning-crescent, Wood Green, on Wednesday evening last week. The Hall was crowded, many ladies being present. On the tables around the Hall numerous microscopes, showing objects with plain and polarised light, were arranged, together with curios from China, Japan, India, Africa, and the South Sea Islands, lent by medical men and others of the neighbourhood. The walls were decorated with photographs, both of a pictorial and a scientific character. A twelve-foot screen at one end, and a lantern in the middle of the Hall, left no room for doubt as to what one part of the entertainment was to consist of, and which eventually was found to be a display of a selection from Mr. F. P. Cembrano's choicest slides.

Mr. J. G. Robins, the President of the Association, occupied the chair, and in course of his remarks spoke of the future of the Society that had just come into existence. Two preliminary meetings had been already held, and that night it was to be launched out to take its chance among the many others of different kinds that already existed. This Society was a scientific as well as a photographic one, and the person who took a practical interest in it found himself perforce dabbling in chemistry, and several other sciences. The promoters of this Society were a few gentlemen who were scientists, and who thought that a very good society could be formed in the district. The audience could judge for themselves as to the success of the inaugural meeting. The aim of the Society was to unite photography and other sciences together, which was plainly demonstrated that evening by a glance round the hall. The speaker then went on to enumerate the various collections they had lent them that evening, speaking in very kind terms of the gentlemen who had so befriended them, and expressing the gratitude the Society felt towards them for their kindness. He also spoke in eulogistic terms of the Secretary, Mr. A. S. Murrow, of the hard work that had devolved upon him in that capacity, and of the efficient manner that he had performed his various duties. The Society was indebted to Mr. Murrow for the handsome screen they saw before them, which was in every respect one of the best that it was possible to get. Mr. Murrow had made them a present of it, and his kindness had been greatly esteemed. With regard to the lantern and photographic slides that would be exhibited by Mr. P. D. Coghill a little later on, the Society owed its thanks to Mr. Cembrano, of Richmond, who had sent, for this occasion, the finest photographic slides it was possible to obtain. Those present would soon have an opportunity of judging for themselves as to the accuracy of his remarks when the slides were projected on the screen. The speaker then went on to announce that the next meeting of the Society would take place that night three weeks, on which occasion a lecture would be given by Mr. C. Coulter on *Chemistry on Dry Plates*. After supplementing several additional fixtures, the speaker concluded his remarks by urging all his hearers who took an interest in any scientific pursuit of any description, to give in their names to the Secretary, who would cordially welcome them on behalf of the Society.

The Treasurer, Mr. F. K. Beagley, said that the Association was not being run as a paying concern, and all that was required of it was that it should pay its own way. In view of this the subscription was not a heavy one, namely, ten shillings a year; and this was very reasonable considering the programme that was in store for them.

The exhibition of Mr. Cembrano's slides, each of which was greeted with encomiums, was followed by a similar exhibition of microscopic projections on the screen. Music, including madrigals, formed an attractive feature in the proceedings, and as some of the members and their lady friends are professional musicians, this element was ably conducted.

The committee of management deserve unqualified thanks for the able manner in which everything was carried through.

The membership is very numerous, and the Association has our best wishes for its success.

PHOTOGRAPHIC SALON, 1893.

The following are the particulars of the Exhibition of Pictorial Photography, to be held at the Dudley Gallery, Piccadily, from October 9 to November 11, 1893.

1. An Exhibition of photographic pictures, to be called the Photographic Salon, will be held at the Dudley Gallery, Piccadilly, London, W., from October 9 to November 11, 1893.

2. Careful consideration will be given to all pictures entered for exhibition, and a selection of works of pictorial merit only made by a Committee.

3. Foreign as well as English photography will be represented.

4. The aim of the organizers of this, the first Photographic Salon, is to inaugurate a series of Exhibitions (which it is hoped may be annual ones) bringing before the public the best productions of photography solely from the pictorial point of view.

5. No awards are offered, and no charges made to exhibitors.

6. The usual charge of 1*s.* will be made to the public for admission. Exhibitors will be entitled to a season ticket

7. Arrangements will be made for the sale of pictures, if desired, and a commission of fifteen per cent. will be charged on sales effected. Particulars as to price and sale will be printed in the catalogue.

8. Each picture must be separately framed, and each frame must bear on the back name of exhibitor, number and title of picture, and price if offered for sale, corresponding to the particulars on the entry form. This information must also, for catalogue purposes, be repeated on a label attached by a string, and made to hang over the front of the frame.

9. The form announcing intention to send picture should be forwarded as soon as possible, and not later than Friday, September 1. The entry form must be sent with, or previous to, exhibits, and received not later than Wednesday, September 27th, addressed to the Secretary, Photographic Salon, 215, Shaftesbury-avenue, W.C.

10. Pictures sent in packing cases, &c., must be delivered, carriage paid, at 215, Shaftesbury Avenue, W.C., not later than Wednesday, September 27. Frames delivered by hand must be left at the Dudley Gallery, Piccadilly, on Saturday, September 30, and removed, after the Exhibition, from the same place on Monday, November 13.

11. The Committee will unpack, repack, and deliver to carriers all exhibits sent in cases, but will not be responsible for damage. Every care will be taken of exhibits. To avoid damage, frames should have no projecting nails.

12. Intending exhibitors are desired to fill up the forms of advice and entry, and to forward the same to the "Secretary of the Organizing Committee, Photographic Salon, 1893," 215, Shaftesbury Avenue, London, W.C., in accordance with the instructions noted thereon.

NATIONAL ASSOCIATION OF PROFESSIONAL PHOTOGRAPHERS.

May 26,—Council Meeting—the President, Mr. Thomas Fall (London), in the chair.

Present: Messrs. Birtles (Warrington), Warwick Brooks, Hon. Secretary (Manchester), Crosby, Hon. Treasurer (Rotherham), Eddison (Barnsley), Higginson (Bowdon), Whitlock (Birmingham), Yates (Sheffield); also as a member of N.A.P.P., T. N. Longton (Sheffield), and D. J. O'Neill, Secretary.

Telegrams and letters of apology were received from Messrs. Bromwich (Bridgnorth), Gill (Colchester), McIver (Leeds), Slingsby (Lincoln), Whaley (Doncaster).

Secretary's report was read, and the business transacted may be summarised as follows:—Annual report and statement of accounts, also list of the new Council elected at the annual meeting had been forwarded to the (146) members.

Next annual meeting will be held February, 1894, Birmingham. A dinner to be arranged for the members and friends on that occasion, details of which will be duly announced.

Members of Council and members of the Association had paid over to Guarantee Fund for working the Association, 35*l.*

New members elected by vote of Council, Mr. Lyd. Sawyer (Newcastle-on-Tyne), Mr. A. Hollis (Barrow-in-Furness).

Several members not having yet paid their 1893 subscriptions (10*s.* 6*d.*), Council requested that same may be forwarded to Secretary, D. J. O'Neill, 47, Charlotte-road, Birmingham, as speedily as possible.

Secretary continues to receive communications of various kinds from all parts of the world, evidencing the fact that the N.A.P.P. was now fully recognised as the official representative of the profession.

The Photographic Convention of the United Kingdom will be held at Plymouth, July 3, 1893.

Mr. Coles (Watford) had kindly sent a list of proposed members to Secretary.

The various uses to which the Association might be applied for the benefit of the profession had been frequently referred to in the photographic press.

The establishment of a Photographic Club and Institute was heartily approved by the Council, and it was noted that the President, Mr. T. Fall, had been requested to act as a member of the Provisional Committee of the Club.

Respecting the very important case of the most unjust prosecution of Mr. Cowley, the Secretary gave full particulars of the correspondence on the subject between influential members of the N.A.P.P. It was felt that, while every member of the Association heartily sympathised with Mr. Cowley, the Association was not in a financial position to take up his case and to institute legal proceedings on his account, especially as he *was not a member of the Association*. Council recognised gratefully the active part taken by the President, Mr. T. Fall, in this matter, and he detailed the action which he (Mr. Fall) was taking for the benefit of Mr. Cowley on his own responsibility, and without in any way compromising the Association or its friends.

A desire was expressed that the members should send in to Secretary suggestions and designs for the proposed "Certificate of Membership," which it was agreed at the annual meeting should be issued to members.

Referring to suggestion from Mr. W. P. Marsh (Bognor, Sussex) as to traders and manufacturers supplying members on special advantageous terms, Council was of opinion that the present members (146) of the Association now warranted their demanding such advantageous terms for the Association. The President kindly undertook to procure data as to the terms on which makers and traders would be willing to comply with this very reasonable request of the Council.

Mr. R. Slingsby (Lincoln) having brought forward the subject of *certificates* of skill and capacity to be issued to assistants, the President dwelt at length on the very unpractical character of the certificates now issued by the London Polytechnic Institution, which were merely good for a limited *chemical* knowledge.

Council expressed strong wishes that some system should be adopted to bring really capable and duly qualified assistants within reach of the professional photographer.

Secretary was instructed to communicate with Secretary of Polytechnic Institution, with a view to some arrangement that before such certificates were issued, students should be examined by some representative, capable, and experienced photographer.

In reference to the comments of Mr. Battersby (Manchester) on the sale of methylated spirit, Council considered that there was now no practical difficulty in the way of photographers procuring same. The President stated he should be happy to assist all members in this matter, and to give them the advantage of his knowledge and experience on the subject.

The President reported his intention to visit the Chicago Exhibition Photographic Conference as requested by the Council.

Mr. Eddison (Barnsley) brought forward the subject of the present unjust mode of dealing with photographers by the fire insurance companies, as regards compensation for loss of negatives. He spoke from painful and personal experience in the matter, and stated that instead of the person insured recovering the amount which he was insured for, the insurance company only paid on a "proved average of the actual sales from negatives in stock over a given period," making the amount refunded about one-fourth of that on which the insurer had been paying all along. The Secretary was instructed to communicate with Mr. Eddison and his assessors, Messrs. East & Haslam, Leeds, with a view to procure some alteration in this most unjust mode of procedure.

The next Council meeting will be held at Anderton's Hotel, Fleet-street, at the time of the opening of the Pall Mall Photographic Exhibition, London. All professional photographers will be gladly welcomed by the Council.

Our Editorial Table.

GLYCIN-HAUFF.

Fuerst Bros., 17, Philpot-lane.

Last week we acknowledged receipt of a sample of the newest developing agent, and since then we have had an opportunity of putting it to a trial. Its salient qualities are thus indicated in the makers' instructions. "Glycin-Hauff, with potash, forms a developer giving, without the addition of bromide, absolutely clear and transparent negatives of an agreeably grey colour. It is not a rapid developer, but works slowly, with great harmony and softness. An advantage not to be under-estimated of this developer also consists in its great keeping quality, which will not alter if the solution is sufficiently concentrated and in well-closed bottles. The concentrated developer is made up as follows:—350 grains of sodium sulphite crystal are dissolved in one ounce of water, 150 grains of glycin are then added and heated to boiling point, and one and a half ounces of potash carbonate are added (begin adding the potash in small quanti-

ties, on account of the carbonic acid gas). When cold, this concentrated developer—forming a thin, pasty solution—may be kept as stock. For use, shake the solution first, and dilute the required quantity twelve times for ordinary purposes. For use when development is to be left to itself, the stock solution is diluted fifty times."

In our own experiments, we made up for use the following solution:—

Sodium sulphite	40 grains.
Glycin	20 „
Potassium carbonate	80 „
Water	4 ounces.

Using this solution as the working developer, we found that, although its action was comparatively slow, with rightly exposed plates it yielded a charming quality of image, having perfect softness and harmony, with a richness of colour of the deposit which should make glycin eminently useful for transparency work. It works very cleanly, and has great power over detail, so that, with those who incline to slow development, it should be a favourite.

The A B C Toning Powder.

Aston & Sons, 95, Spencer-street, Birmingham.

To the drachm of hypo dissolved in two and a half ounces of water, twelve grains of the toning powder are added to make a combined toning and fixing bath. The combination yields excellent tones on gelatine paper. It will, doubtless, be a convenience to many to have the toning powder in this handy form.

A New Hand Camera—the "Queen."

The "Queen" is well worthy of notice, for two reasons: first, it is the invention of a lady photographer who has shown that she possesses an inventive faculty hitherto believed, in this direction, to have been confined to the sterner sex; and, secondly, and more particularly, that her "Queen," although selling retail at only 15*s.* 6*d.*, is a really effective magazine camera, containing one dozen of plates in its interior, each in a sheath. It has an achromatic lens, which covers a quarter-plate sharply. It is light (small doubt of that when a lady is the inventor), weighing only three pounds when charged. The general principle is this: The plates are stacked behind, and pressed forward by a spiral spring to the checks at the focal plane, like those in the well-known Swinden & Earp camera. Upon pressing a button concealed under the carrying handle, a part of the stage containing one sheath only is depressed, which causes the sheath and plate to fall forward on to a spring-board, from which it slides into a receptacle at the back, into which the plates store themselves very neatly one on the other. The instantaneous shutter, which is always set, is simple in the extreme, but it answers the purpose, and, like the other acting parts of the camera, cannot get out of order. It is made by N. Crouch & Co., 122, Newington-butts, S.E.

Brilliantine.

S. Sidey, Richmond-road, Dalston, N.E.

Brilliantine is a solution which, when diluted with water, is intended for removing pyro and other stains from negatives, and clearing up their shadows. This, from a single trial, we have found it to accomplish.

Wynnes' Exposure Meter.

An exposure meter, differing from those already known, is brought under our notice by Mr. G. F. Wynne, of Wrexham, who has organized a "company" in order to its being brought efficiently before the world, and who, claiming the infallibility of its indications, has adopted this qualifying term as the name of the meter.

The Infallible Exposure Meter is a miniature slide rule which, being only a little over three inches in length, can easily be stowed away in the vest pocket. In the right-hand column are the stops, ranging from *f*-4 to *f*-256. The third column, which, like the first, is on the solid rule, represents the speed of plates, graduated from a very low degree of slowness to an almost inconceivable rapidity. The centre column is engraved on the brass slide, and ranges from 64 seconds downwards to the 128th of a second. The meter is accompanied by full directions for use. We believe that this little instrument will prove very useful, especially when used with an actinometer, the use of which is described, but which has not yet come to hand. Mr. Wynne truly says that the greatest difficulty a beginner in photography experiences is in rightly estimating the correct exposure to be given under the varying conditions of subject, stop, speed of plate, and light value, and he believes that this exposure meter will prove an "infallible" guide to such. It sells at a very low price. We may return to this subject after receiving the actinometer referred to.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

JUNE 1,—Mr. W. D. Welford in the chair.

The CHAIRMAN exhibited an album of gelatine-chloride prints, toned with his bicarbonate of soda toning bath, mentioned at a previous meeting of the Association. He also said that, during a recent trip to Belgium, he had exposed sixty plates in a hand camera, and had only lost four of them.

Some discussion arose over a statement in one of the photographic journals that ninety per cent. of the light was stopped by the glass roof of a studio.

Mr. W. F. DEBENHAM thought twenty per cent. a better proportion.

Mr. P. EVERITT observed that as much as fifty per cent. might be obstructed when the glass was not apparently in a dirty condition.

Mr. R. BECKETT exhibited a negative plate, having a positive partly formed upon it, which he thought might be caused by repeatedly looking at the image during development. He promised to confirm the observation by developing an unexposed plate, and allowing the light to show on it, and continuing development.

It was suggested that he should cover up one half of an exposed plate during development, a suggestion which Mr. Beckett said he would adopt.

Mr. P. EVERITT read a paper on *Angle of View* [see page 357]. A discussion followed.

Hackney Photographic Society.—May 30, Mr. E. J. Wall presiding.—Referring to amidol, Mr. VINING said, although the negatives were pretty-looking, they were not good printers; they suited landscape work better than portraiture. Mr. R. BECKETT suggested that he should reduce the exposure and extend the development. He used it every day: that day he had developed twenty-five negatives in thirty minutes; could get any amount of density and excellent gradation. Mr. Wire showed prints from an amidol-developed negative taken by flashlight; they had sufficient contrast. The CHAIRMAN said it was always best to add amidol *dry*, otherwise the density-given power is soon lost. Two grains of amidol and a quarter of a grain of bromide to the ounce works well. It is specially good for old plates, but he did not believe in the latitude in exposure generally claimed for it. The negatives are not so non-actinic as pyro. Metol is nearer pyro. More control can be had over metol than any other developer excepting pyro. It must be dissolved in the order given in the printed formula. There are two kinds of metol—one an oxalate, the other a sulphate; the latter gives most density. A discussion then took place on cloud negatives. Mr. G. Hankins uses a hand camera, small stop, and rapid exposure. A black glass mirror with an isochromatic plate *f*-32, one-twentieth to one-quarter of a second, cuts off much of the too energetic blue rays by polarisation. If the sky is a brilliant blue, the light yellow screen is an advantage. Mr. E. J. Wall generally takes a silver print and cuts out at the sky line as a mask. Mr. S. J. BECKETT said clouds reflected in still water gave better results than the originals. Mr. W. L. Barker smoked the plain side of the negative with a wax taper. Mr. W. A. Hensler fully exposes and under-develops. Mr. E. J. Wall spoke highly of Place's shutter, a roller shutter giving less exposure to the sky. In a batch of views recently taken only three per cent. were without clouds. To develop, he uses one-eighth of a grain of pyro to normal of ammonia and bromide. Mr. W. F. Gosling suns down his skies, when dead white, darker at top than at horizon. Dr. Roland Smith always reduces the sky with ferrid-cyanide of potassium and hypo; however dense it may be, the clouds can always be got out. Mr. S. J. Beckett retards development by bromide applied locally with a brush. At the close of the meeting the presentation of a silver breakfast service was made to the Hon. Treasurer, Mr. J. O. Grant, in recognition of his valuable services to the Society.

East London Natural History and Microscopical Society.—The members of the above Society, according to their established custom, had their annual outing and "social" on Derby Day, May 31, to Epping Forest. Commencing from Theydon Bois the route selected was through the less frequented northern portion of the Forest near Epping, towards Copped Hall, and then southwards to High Beach. Early in the afternoon the party was increased by a contingent from the Hackney Photographic Society. The weather was all that could be desired, and some very interesting "finds" delighted the naturalists, and by the photographic section a good many exposures were made. The *rendezvous* for the "social" was the "George Hotel," George-lane, Woodford, where at seven p.m. the President of the former Society, Mr. W. Smart, and other members of the Executive and friends, met those who had borne the burden and heat of the day. After ample justice had been done to an excellent and much-appreciated tea, to which about thirty sat down, a most pleasant evening was spent. Mr. A. Dean, the Secretary of the Natural History and Microscopical Society, and who is also Curator and Assistant Secretary of the Photographic Society, performed several *morceaux* on the violin, Mr. Drew presiding at the piano. Messrs. Harding, Sparrow, Carrick, Dr. Gerard Smith, Love, and T. Wishart Philips enlivened the evening with many good songs, Mr. Slight giving an excellent recitation. Mr. Smart took an early opportunity of proposing the health of Mr. Dean, whose inception it is to hold these agreeable gatherings, and whose happy idea it was to combine the Photographic Society in the outing, which tended so much to the pleasure of the day and the success of the evening. In his remarks he referred to the charm of revelling in Nature's beauties, the variety of its teeming life, the necessary, but still mysterious, dying of all, filling the mind with awe, reverence, and humility. The smallest weed, the most insignificant insect, hold a secret no man has yet revealed. Mr. DEAN, in reply, hoped that next year there might be a larger attendance, and that the same good feeling and good comradeship would prevail.

Putney Photographic Society.—May 27, Second Summer Outing.—Although the weather looked very gloomy at starting, a good muster of members assembled, and, under the leadership of Mr. Faulkner, member of Council, proceeded to Hayes, on the South-Eastern Railway, for Hayes and Keston Commons. The weather having brightened, full advantage was taken of the very pretty scenery abounding on these beautiful commons, more particularly round the lakes at Keston. Good accommodation was provided at the "Fox Inn." Next Outing, June 10, to Burnham Beeches. Mr. William Martin, jun., will act as leader.

FORTHCOMING EXHIBITIONS.

1893.	
July 3-8	Photographic Convention of the United Kingdom, Plymouth. Hon. Secretary, F. P. Cembrano, jnn. 10, Cambridge-gardens, Richmond, Surrey, S.W.
August	Welsh National Eisteddfod. The General Secretary Pontypridd.
Sept. 25-Nov. 15 ...	Photographic Society of Great Britain, 5A, Pall Mall East, S.W. Assistant Secretary, R. Child-Bayley, 50, Great Russell-street, W.C.
October 1-31	Hamburg. Das Anastellungs Committé des Amateur Photographen Verein, Schwanenwik, 33, Hamburg.
,, 9-Nov. ...	Photographic Salon, Dudley Gallery, Piccadilly, W. Hon. Secretary of Organizing Committee, A. Maskell, 215, Shaftesbury-avenue, W.C.
December	Madras. The Hon. Secretary Amateur Photographic Society, Madras.

Correspondence.

☛ *Correspondents should never write on both sides of the paper. No notice is taken of communications unless the names and addresses of the writers are given.*

THE CONCENTRIC LENS.

To the EDITOR.

SIR,—I have given a direct challenge to Mr. Stillman's main contention in his letters on this lens, and specified an authority who can decide the point at issue fairly between us.

Surely it is plain to Mr. Stillman that his own results are no more conclusive to me than mine would be to him. Of what avail for me to send you a softly defined negative taken with *f*-16 and a sharply defined one with *f*-32? Would it convince any one of anything except my own self-conceit?

I trust Mr. Stillman will agree to send one of his lenses to Kew; but if he declines to do so, I will send mine. I am determined to have a reliable opinion on the point, as it will be instructive as well as conclusive.

I am greatly tempted to make some vigorous comments on Mr. Stillman's last letter, but will defer doing so for the present. What we want now is proof. Mr. Stillman says the Concentric defines as sharply at *f*-16 as it does at *f*-64. I say it does not, and will prove the truth of my contention, or retire with many expressions of regret for having driven Mr. Stillman into poetry to prove that all optical science is sheer nonsense.—I am, yours, &c.,

F. H. BURTON.

Roundhay, near Leeds, June 6, 1893.

LARGE CAMERAS FOR PHOTOGRAPHIC SOCIETIES.

To the EDITOR.

SIR,—The following letter, referring to a remark of mine in last "Jottings" as to the purchase of large cameras by photographic societies for the use of members, has been forwarded to me. In order that many more societies may profit by the admirable example of the South London, I would suggest that Mr. Oakden's interesting letter be published.—I am, yours, &c.,

COSMOS.

June 6, 1893.

"SIR,—Referring to your paragraph in THE BRITISH JOURNAL OF PHOTOGRAPHY relating to the purchase of a 12 × 10 camera by the Manchester Society and which leads to the inference that the idea is a new one, I desire to point out that three years ago such a camera was purchased by the South London Photographic Society in a somewhat similar manner. Since that time a wide-angle lens has been added to the outfit. Small fees for the loan of the apparatus have been charged to members, and these have now nearly repaid the original outlay.

"On the purchase being announced in print, our example was followed at once by two or three other Societies.

"A lantern for loan by our members has also been bought in a similar way.

"Some gentlemen have joined us simply to obtain the use of the camera,' &c.

—Yours faithfully, CHAS. H. OAKDEN, *Hon. Secretary.*

"*South London Photographic Society*, 51, *Melbourne-grove, East Dulwich, S.E., June* 1, 1893."

RAPID PLATES AND HALATION.

To the EDITOR.

SIR,—In the course of his paper, *Selections*, which he read before the Holborn Camera Club, Mr. E. Dunmore made some remarks on the subject of "Halation" that are so strongly at variance with my experience of the subject, and may possibly conflict with that of others, that I should

be obliged if you would allow me to say a few words in reference to it. He says, "With highly sensitive films, no precaution that I know of will altogether prevent, or even mitigate it [halation], if the subject is highly reflective, or possessing strong and abrupt contrasts." It is, as a rule, only in such subjects as these that halation is to be apprehended and provided against. I should have thought—and theory seems to me to indicate that such is the case—that the coarse particles of a very rapid film would, in themselves, interpose a natural barrier to the lateral spreading action, although they might not have the same effect with regard to the back reflections.

But, waiving this point, my experience of very rapid plates, backed with a mixture of caramel, gum, and burnt sienna—possibly as good a backing mixture you can have—is, that even in difficult interiors, requiring long exposure, the halation of the image is virtually inappreciable. Many of the most rapid plates contain iodide, of which fact Mr. Dunmore seems unaware, and which may account for my experience differing from his. Some years ago I ascertained, by experiment, that the iodide contained in some plates of inferior and extreme rapidity did not greatly differ in quantity.

Much, of course, depends on the amount of silver contained in the film of rapid bromide; but, apart from this, I do not think it a safe doctrine to put forth that very rapid plates, with a suitable backing, are unmanageable for strongly contrasted interiors, although slow bromo-iodide plates may be preferable, as being more calculated in themselves to subdue halation.—I am, yours, &c., J. STRINGER.

London, June 2, 1893.

COINS AS WEIGHTS AND MEASURES.

To the EDITOR.

SIR,—I am sure photographers ought to be very thankful to you for telling them, as you did in your last number, how admirably some of the current coins of the realm can be substituted for the usual weights and measures. It is not every one of us who knew that a sovereign could be used for a quarter of an ounce, half-a-crown for the half-ounce, and so on, and now that we have the information I fear that, in the present state of trade, there are very few of us who are able to put it to practical account, I, for one, at any rate, find it impossible to keep sovereigns and half-crowns long enough to use them as weights—even when I get them, which is rare now that, as Mr. W. Grove points out, my brother professionals are giving sittings for nothing. Could you not supplement your interesting paragraph by telling us how the sovereigns, &c., are come by—help us all, in fact, to make a living out of the profession you so worthily support? If you can assist us in doing that, I am sure there isn't a man among us who wouldn't be content with light coins, that wouldn't do for weights at all.—I am, yours, &c., HARD-UP PRO.

June 3, 1893.

CHEAP RAILWAY FARES FOR PHOTOGRAPHERS.

[THE following communication from Mr. James Railton, of Messrs. Swan & Leach, referring to cheap railway fares for photographers, has been forwarded to us as the result of a conversation with that gentleman on the subject. The fact that parties of photographers can obtain reductions on their fares deserves, as Mr. Railton hints, to be more widely known.—ED.]

To the EDITOR.

SIR,—Referring to my call at your office this morning, *re* railway fares, &c., for photographers, with regard to their being placed upon the same footing as members of angling societies, I made it my business to bring the matter before the Superintendent of the Great Northern Railway this morning, and he informed me, in course of conversation, that such a thing could not be; it would open too large a field altogether, and people would avail themselves of such a reduction by at once becoming members of photographic societies (which would greatly interfere with ordinary traffic) who would not become members of angling societies. The next time I have the pleasure of seeing you, I would explain the matter more fully, when I am sure you would agree with me that the idea is not one which can be carried through.

The reduction made for members of photographic societies we feel sure is not *generally* known, that is, of course, when they are travelling together on their field days, and personally I shall be very glad to make any arrangements for proposed parties.

As promised, I enclose a copy of the letter I wrote to all the secretaries of the photographic societies upon the enclosed list [24, Ed.]. We have not even received so much as an acknowledgment.—Yours faithfully,

Swan & Leach, Ltd., JAMES RAILTON.

3, *Charing-cross, London, S.W., June* 2, 1893.

DEAR SIR,—We beg to offer you our services in connexion with the arrangements for any excursions or field days which your Society may have during the ensuing season.

On any of the systems of the Railway Companies (or their connexions) mentioned above, we are able to offer you tickets in advance of the reduced tariffs granted to photographic societies, according to numbers.

We are also able to make arrangements for catering, and consequently could quote you a price per head, including cost of return ticket and meals, so that each individual member of your society could know at once the total expense to which he would be put, and at the same time the trouble of making the arrangements would be taken off your hands, and submitted to you when complete for your acceptance or otherwise.

For your guidance we make no charge whatever to you for our services, as we act in the matter solely as the authorised representatives of the Railway Companies concerned.—Yours faithfully,

SWAN & LEACH, LTD.,
JAMES RAILTON, *Managing Director.*

3, *Charing-cross, London, S.W., January* 25, 1893."

Exchange Column.

*** *No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance. The full name of the advertiser must in all cases be given for publication, otherwise the Exchanges will not be inserted.*

Will exchange 3¼×3¼ camera, four double dark slides complete, for half-plate camera.—Address, H. MOREL, Newcastle-chambers, Market-place, Nottingham.

Wanted, detective lens, hand camera, or offers, for Robinson's patent secret camera and plates complete. Address, F. COUCH, 11, Waterloo-crescent, Dover.

Will exchange Grubb's 3A portrait lens in fine condition (list price 6l.) for 12×10 rapid rectilinear by good maker.—Address, F. WILLIAMS, 25, Winton-street, Millow, Cumberland.

Will give a Marion's whole-plate, short-focus view lens for Kershaw or similar shutter, time and instantaneous, for three-inch hood.—Address, A. J. ROBINSON, 4, Windsor-place, Mumbles, Swansea.

Will exchange six volumes, unbound, of Cassell's *Illustrated History of England*, and about fifty odd numbers of THE BRITISH JOURNAL OF PHOTOGRAPHY for a half-plate camera and lens.—Address, H. TUBE, Byfield-villa, Rothes-road, Dorking.

Will exchange *Amateur Photographer*, July, 1891, to date complete, and *Boys' Own Paper*, vols. xiii. and xiv., for Griffith's guinea hand camera or Optimus rapid rectilinear quarter-plate.—Address, W. DOWNING, 22, Pepys-road, New Cross, S.E.

Will exchange 9×7 solid mahogany-box camera, single slide, rising and cross front, also five-inch gas bar burnisher, for hand camera, 10×8 slides, or quarter-plate camera set.—Address, CHARLES E. HEATH, 4, Cambridge-terrace, Brockley-road, Forest Hill, S.E.

Wanted, half-plate modern camera, and three double slides, in good condition, in exchange for three or four dipping baths (various sizes up to 18×14), and about 300 copies of THE BRITISH JOURNAL OF PHOTOGRAPHY.—Address, A. W. DURRELL, 44, Birkbeck-place, West Dulwich.

Wanted to exchange Marion "Excelsior" whole-plate studio camera, will take also cabinets and *cartes*, in perfect condition, for modern out-door whole-plate camera, with three double slides; difference adjusted in cash.—Address, J. T. SIMONS, 46, Elizabeth-street, off Trafford-road, Salford.

Answers to Correspondents.

*** *All matters intended for the text portion of this* JOURNAL, *including queries and Exchanges, must be addressed to* "THE EDITOR, THE BRITISH JOURNAL OF PHOTOGRAPHY," 2, *York-street, Covent Garden, London. Inattention to this ensures delay.*

*** *Correspondents are informed that we cannot undertake to answer communications through the post.*

*** *Communications relating to Advertisements and general business affairs should be addressed to Messrs.* HENRY GREENWOOD & CO., 2 *York-street, Covent Garden, London.*

*** *It would be convenient if friends desiring advice respecting apparatus, failures in practice, or other information, would call at the Editorial Office either on Wednesdays from* 4 *to* 6, *or Thursdays from* 9 *to* 12 *noon, when some one of the Editorial staff will be present.*

PHOTOGRAPHS REGISTERED:—

W. Crow Gordon, Nairn.—*Photograph of Rev. Currie Martin, of Nairn.*

James Burgoyne, Birmingham.—*Photograph of the Australian Cricketers.*

William James Wilson Munro, Annan.—*Photograph of otter hunters after kill.*

Guy & Co., Limited, Cork.—*Three Photographs of Blarney Mills, County Cork.*

John Charles Burrow, Camborne.—*Sixteen photographs of miners, and miners at work.*

Sydney W. Anstee, Luton.—*Three photographs of bridge over the River Lea at Luton.*

Sydney Victor White, Reading.—*Photograph of Alderman William White, of Birmingham.*

Philip Newman, Devizes.—*Photographs of H.R.H. the Prince of Wales reviewing his own Yeomanry Regiment upon Roundway Hill, Devizes, and upon the occasion of the Wiltshire Yeomanry Centenary.*

W. GIRLING.—Thanks for yours and enclosure.

BINOCULAR.—Screw the lenses on the front, so as each to be in the centre of its half of the plate.

PRINTER.—By boiling the water, and using when cold, the deposit on the prints will probably not recur.

K.—Any good lens of the euryscope class will serve your purpose. The one you specially mention belongs, we believe, to that class.

ALFRED BOEHM (Burton-crescent).—The agent for Gunther Wagner's transparent colours is Mr. C. A. Rudowsky, 3, Guildhall-chambers, E.C.

G. B.—The lenses of Lerebours et Secretan are generally considered good. We do not know the present commercial value of one suitable for whole-plates.

P. NEWMAN.—Registration enables you to proceed for infringement of copyright. The latter lasts for the owner's lifetime, and seven years after his death.

C. J. EMENY.—In the advertisement pages of the JOURNAL and ALMANAC, you will find every type of camera dealt with, some of which you will no doubt find suited to your purposes.

C. Y. O.—Unless you have a copyright in the picture, you cannot prevent its being sold at any price the pirate chooses. It is certainly annoying, after having paid a high price for the negative.

GRAMME.—Weights and measures on the metric system can be obtained from any of the dealers in chemical appliances; or any of the photographic dealers would supply them to order if they do not stock them.

W. HEMING.—If the prints, after being removed from the toning bath, are first subjected to a good dash of water, and are then transferred to fresh water, the toning action will not be continued. This, at any rate, is our experience.

R. MYERS.—Bichromate of soda is not so good as the bichromate of potash for sensitising carbon tissue. It has been recommended for the purpose, but it is found not to answer so well, as it has a tendency to render the tissue quickly insoluble.

NOVICE.—There is no necessity to boil the starch for mounting purposes. In fact, it is not so good if boiled. The want of adhesion in your case is, that the starch was not rightly mixed. Get a little instruction in the matter from the domestic department.

MADAME TALBOT WILSON writes: "May I ask if you could give me a list of the places in Rome, Florence, Venice, and other towns in Italy and Germany, where an amateur could develop negatives?"—Perhaps some of our readers can supply the information desired.

OXON.—Something must be radically wrong. Five grains of chloride of gold for each sheet of paper is out of all reason. As you are sure that none of the gold is reduced spontaneously, we can only suspect that the salt being employed does not contain the proper proportion of metal.

T. CRAVEN.—In copying oil paintings or water-colour drawings with plates orthochromatised with erythrosine, a yellow screen should be employed to obtain the best effects. Its depth ought to be chosen according to the character of the work. It is well to be provided with two or three screens of different depths. They are not expensive in small sizes.

W. A. C.—It was very unwise to send the money for second-hand goods without knowing something about the advertiser. As more than a week has elapsed and the apparatus has not arrived, and you can get no reply to your letters, the matter certainly looks very suspicious. Therefore lose no time in communicating with the superintendent of police for the district, giving full particulars of the affair.

C. TYLER.—The only way to obtain more detail in the darker parts of the interior of the church is by giving a longer exposure. Although twenty-five minutes may seem a long time to you, an hour and a half would not have been a bit too long, under the same conditions as to stop and plate, to get full detail in the deepest shadows. The light circle in the centre of the picture is a flare-spot as surmised.

T. BENJAMIN.—Unless you can prove that the negatives were badly packed, we think you have no remedy against the enlargers. As a rule, they state on their prospectuses that they do not hold themselves responsible for breakages in transit. The remedy, if any, would be against the carrying agents. But the claim should have been made at the time. After so long a period they will, no doubt, repudiate it altogether.

F. G. HILLHOUSE.—1. While the rates of wages for operators in the United States may be higher than those here, it is the case that competition for the best positions is as keen, if not keener. 2. There is no such journal there. 3. If you decided to start business there, we should suggest your going to a small town, and growing with it; but whether you would do better there than here hinges so largely upon personal qualifications that we cannot hazard any opinion on the question.

A. CAMPBELL says: "I have made up some collodion for enamelling, using equal parts of methylated ether and alcohol; but it does not answer. The film it produces seems all right, but the fault is, it will not strip freely from the glass—it sticks in places and spoils the prints, as those enclosed."—There appears to be nothing the matter with the collodion. The cause of the prints sticking is that the plate was not sufficiently treated with the French chalk—it was not rubbed sufficiently on the glass.

H. A.—We should say that the pawnbroker will have to give up the lens, even if the thief is not caught and convicted. As only twenty-one shillings was asked for on an instrument costing over twenty pounds, and bearing a well-known maker's name, the pawnbroker might well have assumed that it was come by honestly. That, we imagine, would be the view taken by the magistrate before whom he might be summoned. As the lens is a valuable one, it may be well, in the first instance, to consult a solicitor.

PYRO (Leeds).—It is impossible for any one to give the exposure "for an enlargement on bromide paper from a quarter-plate negative with a lens working at *f*·8 with daylight." It will depend upon the sensitiveness of the paper, the density of the negative, the light at the time, and the degree of amplification. The best way to ascertain what is required is, when all is in position, to make trial exposures on two or three small pieces of paper, and then develop them. With a few experiments of this kind, proper exposures can soon be arrived at.

C. FRITH.—Your announcement was only received after the preceding portion of the JOURNAL had been sent to press, but we insert here a synopsis. The Harringay Society will, owing to an increase of members, hereafter meet at 8, Station-road, Finsbury Park. They will open with a *conversazione* at the Public Hall, Finsbury Park (entrance, 14, Stroud Green-road), on Thursday, the 15th inst. Tickets of admission, 6*d.*, to be had of local chemists. Secretaries of Societies would greatly oblige by sending their reports so as to reach us *before* Wednesdays.

P. A. G. asks: "Whose place is it to keep a studio in repair, the tenant or the landlord? The tenant built the studio, removable at any time, some years ago in the garden, and the premises are held on a yearly tenancy. The landlord has always done the repairs to the house, and makes no demur to doing so still, but refuses to repair the studio. Can he be compelled to?"—We should think, certainly not. It is the tenant's property, and put upon the premises by him for his own use, and to be taken away whenever he removes. We consider it is as unreasonable to expect the landlord to keep the studio, under these circumstances, in repair as it would be to expect him to repair the furniture in the house when it requiresit.

H. T. writes: "A short time ago I bought a benzoline cask to store waste silver washings, The cask being full, I tried to precipitate the silver with common salt. Finding that it would not separate, tried sheet copper. That not having the desired effect, I have come to the conclusion that the benzoline retained in the wood of casks stops the precipitation. Could you say if it is so, and suggest a remedy? In both trials the washings have been given a longer time than usual to settle, but it has had no apparent effect, except to slightly coat the copper. Have used paraffin casks before, and have had no trouble with them."—The cask is not the cause of the silver not subsiding. The silver in the washings from some papers, particularly ready-sensitised, is more troublesome to precipitate than from others. In these cases hydrochloric acid is a better precipitant than salt. Try the effect of adding an ounce or two of nitric acid, and then give a vigorous stirring for a few minutes. After this treatment the chloride of silver usually subsides quickly.

PHOTOGRAPHIC CLUB.—June 14, Members' Open Night.

MANCHESTER PHOTOGRAPHIC SOCIETY.—June 10, Alton (ramble).

THE Birmingham Photographic Company, Limited, have removed to Criterion Works, Great Charles-street, Birmingham.

WE thank Mr. James Paton, Greenock, for an interesting photograph of a flash of lightning, obtained on the evening of the 20th ult. It was taken across the Clyde.

CHANGE OF ADDRESS.—The address of Mr. Fred H. Davies, Secretary of the Talbot Photographic Album Club, Birmingham, will in future be 265, Coventry-road, Birmingham.

LEYTONSTONE CAMERA CLUB.—June 10, "Up the River" to Battersea Park; leader, Mr. A. E. Bailey. The Club will proceed by the first boat after forty-five minutes past two p.m., from Old Swan Pier, London Bridge.

NEWCASTLE-ON-TYNE AND NORTHERN COUNTIES' PHOTOGRAPHIC ASSOCIATION.—Out-door meeting to Ripon and Fountain's Abbey on Thursday, June 15. Train leaves Newcastle at thirty-five minutes past seven a.m. Mr. H. G. Ridgway, leader.

WE are sorry to see from the daily papers that Messrs. Iliffe & Sturmey, the proprietors of our contemporary *Photography*, have had two cases of libel decided against them last week in respect of another of their publications, the *Bicycling News*. It is evident that some cyclists, to borrow our friend's language, have a less tough epidermis than others, hence these actions, which it is to be hoped will not be imported into photographic journalism, some of which body occasionally sail abnormally close to the wind.

LES PROCÉDÉS MODERNES D'ILLUSTRATION.—Messrs. Thévoz & Co., of Geneva, are issuing a small monthly publication, illustrated, dealing with modern photo-mechanical methods of illustration. The first number contains a brief article on "ancient methods," wood-engraving, lithography, and copper plate.

CROYDON CAMERA CLUB.—Wednesday, June 14, Excursion, conducted by Mr. H. Maurice Page; leaves West Croydon at thirty-two minutes past nine a.m. (*viâ* Clapham) for Weybridge. Saturday, June 24, Excursion, conducted by Mr. Maclean; leaves East Croydon at three minutes past two p.m. for Edenbridge.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.—June 10, Saturday Outing, London Colney; first train from St. Pancras after half past two. 22, Demoustration by W. D. Welford, *Welford's Toning Bath for Chloride Paper*. 24, Saturday Outing, Chingford, for the Forest. 29, Annual Meeting; election of officers.

OLDHAM PHOTOGRAPHIC SOCIETY.—June 10, Saturday, Rossett. Depart, Central, fifty-two minutes past eight a.m., for Rossett *viâ* Chester. Return fare, about 4*s.*; leader, Mr. W. Thompson. June 13, Tuesday, Belle Vue. Depart, Clegg-street, twenty-seven minutes past one p.m. Return fare, 1*s.* 2*d.*; leader, Mr. Tom Heywood.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—June 13, Ordinary Meeting, to be held at 50, Great Russell-street, at 8 p.m. A paper will be read by Mr. William Taylor (of Leicester) on *The Construction of Interchangeable Lens-screw Fittings;* and Dr. C. P. Goerz (of Berlin) will read a paper upon, and exhibit, *A New Anastigmatic Lens.*

LENS FLANGES.—It is already known that Mr. William Taylor, of Leicester, is to read a paper on this subject before the Photographic Society on Tuesday next. In this he will describe the method in use in the Slate-street Works for the accurate making of lens screw fittings. This he will do in the hope of improving the general condition of screw making, and all those interested in such mechanical work certainly ought to be present on that evening.

WRITING upon the recent conviction of a Chelmsford woman for cruelty to a child, the *East Anglian Daily Times* has the following remarks on the value of photography in this and similar cases:—"The second point is the link in the chain of evidence which bound all the others together, and made escape impossible. It was open to the defence to suggest perjury or exaggeration against any number of people; but, as Mr. Commissioner Kerr pertinently observed, the sun does not tell lies, and the happy thought of Mr. Kidd, in photographing the poor creature just as she had left her tormentor, removed all doubt from the minds of the jury, who gave their verdict without leaving the box. This is a hint which may be commended both to the police and the Society's officers. Nothing would make the lame excuses for cruelty—which some people accept so easily—utterly futile more than an invariable practice of photographing the victims at the earliest possible moment."

IN course of some correspondence of a somewhat chaffing nature that was indulged in between Messrs. Alfred Maskell and Cimabue Brown, jun., in this JOURNAL in the early part of last year, a statement was made by the latter gentleman in which was voiced a belief that the author of a certain article reflecting on the Camera Club was a well-known optician, who, although unmentioned by name, considered that his identity was unmistakable. As we have since then learned and believe that he had nothing to do with the matter, we can only express our regret that any statement which was calculated to give pain or annoyance to that gentleman should have appeared in our columns. While we allow the utmost freedom of expression to our correspondents, and not unfrequently have to tone down the force of their language, still may statements be allowed to pass which on intermediate inquiry would have caused to be eliminated. This is one such case for which we apologise to the person aggrieved.

RICHMOND CAMERA CLUB.—Summer programme, 1893:—Informal Meetings, third Monday in month: June 19, July 17, August 21, September 18. On these evenings members are requested to bring prints from negatives taken during the Club excursions. Excursion: Saturday, June 10, Uxbridge, twenty minutes past two train from Paddington; leader, Mr. Andressen. Saturday, July 1, Eynesford, forty minutes past two train from Holborn Viaduct, or forty-five minutes past two from Victoria; leader, Mr. Williams. Monday, August 7 (Bank Holiday), Oxted (for Limpsfield), forty-five minutes past ten a.m. train from Clapham Junction; leader, Mr. Williams. Saturday, September 2, Godstone (book to Caterham), trains from Charing Cross, five minutes past two; Cannon-street, seventeen minutes past two; London Bridge, ten minutes past two. N.B.—Those wishing to attend this excursion should inform Mr. C. H. Davis, 97 Church-road, Richmond, not later than August 28, so that a conveyance from Caterham Station may be arranged for.

WATER IN DEVELOPMENT.

IN the process of development, the employment of ready-mixed solutions is customary. In pyrogallic acid, or whatever developing agent is used, we have an energetic reducing agent, *i.e.*, one which is susceptible of oxidation. Air dissolved in the water here comes into play as an oxidising agent; any iron present will tend to strongly colour the solution. The water, therefore, in this case, should be boiled and filtered before use. In the alkaline solution almost invariably used in connexion with the reducing agent, the impurities are not so important, as the changes undergone on standing would be but slight. Alkaline reducing agents absorb oxygen much more readily than when in the neutral or acid state, hence the two liquids are mixed only at the time of using them, and a few drops of acid are added to the pyro stock solution to correct any alkalinity on the part of the water. Waste from paper mills or chemical factories discharging into the stream from which the water supply is taken may prove very serious at this point. Hyposulphite of soda is used as an antichlor in bleaching, and even a trace of this substance in the developer leads to disastrous results. Of the numerous chemicals which may be discharged into the streams, the supply is, of course, infinite, many of them exerting a very deleterious action on the development. Then there is the ever-present little microbe, a large number of them harmless, some harmful. Most of the plates used are coated with gelatine, and the introduction of numberless germs tends to set up decomposition, which eventually destroys the picture entirely.

This may seem an exaggeration; but, as a matter of fact, the existence and recognition of these bacteria is to-day determined by mixing a small portion of the water with nutrient gelatine, pouring it upon a glass plate and allowing the germs to develop, after which they are counted and examined. Their solvent action upon the gelatine is very marked, and many cases of frilling are undoubtedly started in this way.

In the Croton water supplied to this city, the number of these minute organisms frequently runs up into the thousands and tens of thousands for every cubic centimetre of water examined. Decomposition by these means is, of course, enormously accelerated by moisture, but then many of our negatives are stored away in places by no means absolutely dry. Upon the continent of Europe the subject of water is still more important. There, almost all of the drinking water of the larger towns and cities is unfit for use, and it is stated of the Seine water that it is capable of bringing out a feeble image upon an exposed plate without the addition of any chemical whatever. Organic matter in suspension and solution is a powerful reducing agent, and, if present, adds another complication to the delicate interaction and reduction characteristic of the development process. This may come either from decaying vegetable matter or through direct sewerage contamination.

In the fixing of the plate many amateurs use a solution of hypo which has been made up some time previously. Now, hypo solution is intensely delicate to all acids, which cause its decomposition with the separation of a white cloud of sulphur. Any quantity of free acid would, of course, seriously affect the strength of this solution, but that is something hardly likely to occur.

—*Anthony's Bulletin.*

THE FORTHCOMING CONVENTION AT PLYMOUTH.

WE have received a list of the papers that are expected to be read at the Plymouth Convention. These are as follows:—

Recent Developers, by E. J. Wall.

Multiple Films, by S. H. Fry.

Artistic Expression with the Hand Camera, by J. Guardia.

Lantern Slide Making, by C. L. Mitchell, M.D.

Some Slides from the Marine Biological Laboratory, by J. T. Cunningham, M.A.

The Special Properties of the Zeiss Anastigmatic Lenses, by Dr. Paul Rudolph.

Photography in Relation to Medical Record Demonstration, by A. Pringle.

Some Points in Connexion with Development, by C. H. Bothamley.

On the Power of Compensating in Development for Variation in Exposure, by Professor W. K. Burton.

There will be several excursions as under:—

July 4.—Steamer excursion to the Yealm and the River Tamar. Invitation excursion of the local committee, the Devon and Cornwall Camera Club, the Devonport Camera Club, and friends, to the members of the Photographic Convention. Excursion to Tavistock.

July 6.—Excursions to Launceston, Totnes, down the Dart, Looe, and the Cheeswing.

July 7.—Excursions to Lydford, Bickleigh Vale, Dockyard and Keyham, Cattewater.

July 8.—Excursions to Princetown, Ivybridge, Virtuous Lady Mine.

THE BRITISH
JOURNAL OF PHOTOGRAPHY.

No. 1728. Vol. XL.—JUNE 16, 1893.

TELE-PHOTO LENSES PAST AND PRESENT.

Another New One.

Some seed we threw in the ground nineteen years ago, after lying seemingly dormant for so long a period, is at last springing up in various directions. It will be remembered that at that time we pointed out how by the combination of a positive lens and a negative one, the latter of shorter focus than the other and separated some distance from it, a telescopic view of a distant object could be thrown upon the focussing screen of the camera, and we expressed a hope that practical opticians would take up the matter. We foresaw the great usefulness of such a lens, for we had by its agency obtained enormously magnified photographs of subjects in Highgate, the camera being in Wood-green, the distance between the two places being approximately three miles, and we had, as published at the time, obtained a sharp, direct photograph of the sun three inches in diameter, this latter being in our estimation no way inferior in definition to some we had about the same time seen produced in Kew Observatory by a large telescope. We spoke of it to one optician, who gravely told us he believed it could not be done, or, if it could, people would not be inclined to find any use in it.

The late Mr. Thos. Grubb, F.R.S., to whom we had explained it when we met him at the residence of Mr. George Shadbolt, entertained a different opinion of the idea. Fortified by the encouragement of this eminent optician, we ventured to publish an account of what had been done, but it was one of those things ushered into the world before its time. As every one knows, the tele-photo lens is now one of our recognised institutions, and forms the subject of several patents in various countries. One of these, the latest of which we are aware, is that of Mr. A. B. Parvin, of Philadelphia, whose specification is now before us, and will be found given *in extenso* in another page of this issue. The date of this patent is February 28, 1893, and it is presumable that Mr. Parvin has made himself well acquainted with all that has been published in this direction up to that date, and yet in his patent he appears to ignore totally the previously existing tele-photo lenses, so well known on this side of the ocean.

Every one now is aware that a tele-photo lens consists of a positive lens, or combination of lenses, placed at one end of a tube, at the other end of which is mounted a negative or dispersing lens, and that a greater or less degree of magnifying power is obtained by a very slight diminution or increase of the distances between these two lenses. Mr. Parvin does not appear to recognise this as an advantage, for in nine out of his eleven claims he prominently specifies a solid or non-extensible tube as the mount of his lens, a feature to which every optician is likely to make him gladly welcome, seeing that by its adoption he deprives himself of an important feature of the tele-photo lens system. It is much as if one were to patent a camera, a special feature in which was that, being solid from front to back, it was incapable of any extension save that given by its maker.

Looking a little closer into Mr. Parvin's specification, we find that, while the front lens of his combination is similar to those which characterised all lenses of this class that had been brought under public notice prior to the advent of 1892—that is, of the kind employed as the front lens of portrait objectives, viz., crossed, plano-convex, meniscus, achromatised, of course—his back or divergent lens differs in its external form from anything he believes to have been formerly employed. Many years before we had heard of this gentleman interesting himself in this department of optics we had published the fact of an opera-glass of the better class having been successfully employed in tele-photo work.

As he makes a special claim that the two surfaces of his negative lens (the eyepiece in a binocular or Galilean telescope—an opera or field-glass, in fact) must be of different radii of curvature, he may perhaps scarcely thank us for informing him that in numerous negative lenses of this instrument the radii are not similar. In the first one we ever adapted for this purpose, now over twenty years since, the curvature of the surface next to the front was of a much shorter radius than its opposite side. This, being formed of only a single piece of glass, and therefore non-achromatic *per se*, was supplanted by a plano-concave triple, as published in these pages nineteen years since; nay, anterior to that time binocular glasses were made, at any rate sold, in London in which the negative lenses or eyepieces were not double concave, or plano-concave, but the very form insisted on by Mr. Parvin in his patent, viz., convexo-concave or concave-meniscus, the convex side to the outside, as illustrated in the new patent.

We think it unwise in Mr. Parvin to make a special claim for several items in his specification, an infringement of which, if brought into court, would ensure the destruction of his patent. For example, his first claim is for "a photographic objective, comprising a tube provided with a convergent front lens and a divergent rear lens," as if this were not the characteristic of every tele-photo lens hitherto made; or, as in his fifth claim which is for "a photographic objective, provided with a divergent rear lens, having faces or surfaces of different radii;" or, further, in his sixth claim, which is the application of Waterhouse diaphragms to the tele-photo lens, as if this had in any sense been a novelty at the beginning of the present year.

The leading characteristic of the Parvin lens is the substitution of a simple lens of the concave or short-sight spectacle glass class, and of the meniscus form, for the achromatic lenses or combination of lenses hitherto employed for the purpose; and, further, in the employment of a mount, composed of a tube solid from end to end. Now, we say, unhesitatingly, that both of these features are bad, the latter because of the impossibility of effecting any variation in the size of the image, and the former because of the equal impossibility of getting a plate covered with an approximation to marginal sharpness, unless with a stop ridiculously small. Spectacle glasses, we all know, can, in skilful hands, produce photographs, but photographs of quite a different nature from those obtained by properly achromatised lenses; and in such a delicate matter as the production of a direct or tele-photo large view it is absolutely necessary that more than ordinary care should be imported into the achromatising of all the lenses of the objective. Mr. Parvin's lens may, probably does, answer when the magnification does not exceed that obtainable by the use of a moderately long-focus landscape lens, but when tried in contrast, as we have done, with Dallmeyer's tele-photo lens, in which the divergent back is a carefully corrected achromatic combination, then are its deficiencies rendered apparent.

In regard to such points as we have mentioned, Mr. Parvin's patent runs not the very slightest risk of being infringed by any optician in this country, for reasons we have already given. But, if he wishes it to have any force here, we would, in his interests, recommend him to materially cut down his claims. However, we sympathise with his desires to place in the hands of the public a cheap, if not quite an efficient, substitute for the necessarily more expensive lenses of this class now in use.

We close by expressing a hope that our opticians will devise means for supplying negative lenses which may be adapted to the rectilinears already in possession of so many of our workers, but who may feel disinclined to purchase an entire tele-photo outfit.

OUT-DOOR GROUPS.

The writer of the letter, "Young Amateur" (page 384), shows that we have still left unsaid what might be of interest to amateurs, for it is evident that the skilled professional does not need any hints in this particular department. We may reply to his query at once. The fault of his group is that the figures have been in full sunlight when the negative was taken, and no possible dressing in printing or otherwise will enable him to produce a really satisfactory print. Sticklers for artistic propriety are very hard upon studio illumination, and there is no doubt that much lighting of an eminently inartistic character is produced in so-called "artistic effects;" but, at the same time, it must be pointed out that the same thing may be seen in any collection of oil-painting portraits—the seeker need go no further than the present Academy to find examples of the kind. In photography, however, harsh justice is meted out by the painter-artists, and we must do the best we can; that best must exclude direct sunlight illumination. It need not be pointed out that for snap-shot pictures such lighting is a *sine-quâ-non*, at least for the quickest exposures; hence it is evident that snap-shots should not be attempted unless the group or individual is in the shade, or is taken on a day when the sun is not shining. As the latter, however, cannot be commanded at will, all workers should, naturally, lay themselves out for arranging their groups in the shade—either some tall building or under the umbrageous spreading of some large tree. There are objections to the latter, in that, pretty as a nicely posed group appears to the eye when so placed, trees, with the exposure proper for figures, will leave the tree background very black indeed. Taking, then, our figures with some mansion or old wall as a ground (and it often happens that there are steps and porticoes under such circumstances that greatly facilitate pretty grouping), there will be found two difficulties to encounter. Firstly, it frequently happens that, if the group be large, one end is shaded by neighbouring trees, and so comes out much darker than the other. Secondly, the very condition that sends the group behind a building too often necessitates the camera to be placed with the sun shining into it.

This difficulty is very common. If the building be unusually lofty, the instrument may be erected in its shadow; if not so high, then no good results may be expected until the lens be screened until the direct rays are excluded. Such an arrangement, of course, precludes the whole of the building being included with the group; but, to parody a well-known quotation, "the group is the thing," and the building must take its chance. When it must be included, all that can be done by way of precaution is to exclude as much sky as possible by the sunshade, and print in skies to the prints. We cannot lay too much stress upon these recommendations, we have seen so many good pictures ruined from this cause alone; indeed, when portrait lenses have been employed, the skylight alone, without any direct sun falling on the interior of the blackened tube, is quite enough to produce fog unless the lens be shaded.

Regarding the group being darker at one end than the other, we have seen the evil remedied by a kind of preferential intensification. The negative has been wholly intensified with mercury, and then reduced by rubbing the strongest side with a pledget of cotton-wool saturated with weak hypo. This is a method of reducing density that has not received the attention it deserves, for, as we have pointed out before, there are many mercury-intensified negatives in existence as good and apparently as permanent as those made the required density at the first operation; but, as this is matter of argument, we do not lay stress upon it.

With regard to groups, we would refer to the experience of a well-known Oriental explorer, which we related a few weeks ago. He used the ordinary cap for uncovering the lens, and down dropped his savage sitter in a collapse from fright. Now, though we do not liken the probable subjects sitting to those who read these lines to savages, they will yet be subject to the same mental shock when they see the lens uncapped; whether the result be to produce laughter or movement on the part of some members of the group, the result is equally unsatisfactory. Hence we would say, a group should, if possible, never be attempted except with a pneumatic shutter, working in or outside the lens. Besides the advantages alluded to, there is also the vast convenience in using such a shutter of looking straight at the group (not at an individual member), and so seizing the most propitious moment for working the exposure unseen and unknown. We have seen, for instance, a wedding group taken which was quite a failure, because one of the gentlemen, not observing the cap being removed, was in too affectionate proximity to a fair neighbour. With a shutter which enabled the operator to see the group while exposing, of course this would not have happened. We would conclude our observations by quoting the advice of a professional friend; we cannot, however, say we have followed it. He says every photographer who goes in

for groups should have single, not double, slides. There is so much hubbub and confusion, especially in wedding groups, that there is too much danger of double exposures with double slides.

THE TREATMENT OF GELATINO-CHLORIDE PAPER.*

In very many instances no trouble at all will be experienced in connexion with the softening of the gelatine film, though, where the water is naturally soft or free from lime and other salts, the necessity for the alum bath or some substitute will be especially felt. Alum is, as we have shown, objectionable on the score of its acidity; but, as many of the other sulphates possess the property of slightly hardening the film, it is possible to apply a perhaps milder remedy. In the very early days of gelatine plates, for instance, Epsom salts (or sulphate of magnesia) were added to the washing water to prevent "frilling" where any tendency in that direction existed. The same salt answers equally well in connexion with gelatine paper and is free from the objection of acidity, as also are the corresponding salts of potash and soda.

Where soft water is available it is for various reasons preferable to hard for washing the prints previous to toning in spite of its softening action on the gelatine, which can be overcome by the use of sulphate of magnesia. When the water contains considerable quantities of soluble chlorides and carbonates, these act upon the free silver contained in the gelatine film, and except in the case of the combined toning and fixing bath are liable to form a coating of silver chloride upon the surface of the print, which, besides giving a false idea of the progress of the toning, leads also to irregularity in the action of the solution.

Where the water supply is very hard, it is for this reason very desirable, when rain water cannot be obtained, to perform the first washing of the prints with distilled water. It is not necessary that a large quantity be used if the prints are left to soak for some time until the greater portion of the silver has been dissolved out; they may then be finally rinsed in two or three changes of ordinary water without danger of the formation of the film of chloride of silver.

Many operators attach importance to the thorough elimination of all free silver from the prints before toning, and, to ensure this result, use a bath of chloride of sodium. There is every reason to believe that the complete removal of the soluble silver salts conduces to regularity of tone and freedom from the defect known as "mealiness;" but, where the salt bath is used, it should only be after the bulk of the silver has been removed by washing in water as free as possible from either chlorides or carbonates. If a print direct from the printing frame be immersed directly in a bath of salt water, its surface will be covered with a layer of chloride of silver so dense as to completely obscure the tone, and render it quite impossible to judge the progress of the action, at the same time acting as a protective coating and preventing the free working of the toning bath.

In order to bring the prints into as perfect a condition as possible for toning, and to keep them as free as possible from surface deposit, it is well to apply gentle friction to each individual print. In the case of small pictures this is readily done with the fingers in turning them over, or they may be rubbed gently together in pairs, face to face; but with large prints it is better and safer to lay them singly upon a sheet of glass and pass a soft sponge, a tuft of cotton-wool, well wetted, or a broad camel's-hair brush, carefully over the surface.

The exercise of a little care in the minor details—even in so comparatively unimportant a matter as washing—will tend very greatly to improve the quality of the result, as well, perhaps, as the ultimate permanence of the prints, but particularly will it aid in securing uniformity of tone, not only in the same, but in successive batches of prints. Nothing is so likely to bring about an opposite result as imperfect or careless washing, for prints containing variable quantities of soluble matter are not only in themselves in an unfit condition for evenness of action, but they introduce into the toning bath substances which modify or perhaps entirely destroy its action.

The washing after toning should be performed with equal care, although it need not be carried to the same length as the previous washing. On removal from the gold solution, each print should be freely exposed to the action of a considerable volume of water, either from a tap or in a vessel of large dimensions, so as to at once arrest the toning action. If a large number of prints are removed in quick succession from the toning bath into a dish of water in which they have little room for the free circulation of the liquid, the toning action is certain to continue irregularly, with the inevitable result of patchiness.

Where a tendency to softness of surface is exhibited, it is not well to use the alum bath too soon—that is to say, before fixing; or very soon after, before the hyposulphites have been removed. As is well known, alum decomposes the hyposulphites, and should not therefore be allowed to touch the prints until the soluble salts have been, as far as possible, removed. In such cases it is far preferable to add a little sulphate of magnesia to the washing water, which should, of course, be kept at as low a temperature as can conveniently be managed. After a thorough washing in this manner, the alum may be used with perfect safety.

In no case, except where prints are to be mounted in contact with glass, should the alum bath be omitted. One of the strongest objections raised against gelatino-chloride prints is the difficulty of handling them in mounting, on account of the sticky character of the surface. But this is wholly due to neglect of the alum bath, which, if freely used, renders the gelatine surface as easy to manage as the ordinary albumen print. Indeed, a properly alumed gelatine print may be treated in precisely the same way as albumenised paper, even to drying it by heat.

Those who have been accustomed to albumenised paper are very apt to be misled with gelatine paper into over-printing, owing to the comparatively slight reduction that takes place in toning and fixing. Where this occurs a convenient reducing agent is handy, and nothing seems more efficient for the purpose than ferricyanide of potassium and hypo used very weak. When a print is seen after fixing to be only slightly over-done, it may be removed directly from the hypo into a dish of very weak ferricyanide solution containing only sufficient of the salt to very slightly colour it, allowing it to remain until the necessary reduction has been effected. Where greater reduction is needful, the print should be preferably slightly washed after removal from the fixing bath, and then immersed in a dish of similar solution of ferricyanide to which a few drops of hypo solution have been added. The energy of the solution depends upon the former salt, which should not be used too strong or excessive action will take place. The reduction should be gradual, as it is then not only under more perfect control, but is more likely to be uniform.

* Concluded from page 355.

The same means may be adopted in cases where from any cause the tone of the print is irregular. It very often occurs that from misjudgment a print after fixing turns out to be under-toned, the half-tones having reached the cool grey stage while the shadows are still more or less red. In such cases the use of the ferricyanide will very often satisfactorily modify the tone, removing the warmer colour of the unaltered silver, but leaving the gold-toned image intact. Of course, for successful treatment in this manner, the print must be of sufficient depth to bear a slight amount of reduction, though the effect then produced is far less than might be expected, so far at least as toned image is concerned. In most cases the action more closely resembles a continuance of the toning than reduction or removal of a portion of the image as it really is.

The Royal Wedding.—It will be remembered that, last year, when the wedding of the late Duke of Clarence was announced, there was a great run on the portraits of the Royal couple. An equal demand is now being made for the portraits of the Duke of York and the Princess May. The sale of those of the Princess appears, it is said, to be in no way diminishing by the enormous number that were disposed of last year.

A New Lens.—The new double anastigmat lens, described and shown at the Photographic Society of Great Britain on Tuesday evening by its inventor, Dr. Goerz, of Berlin, appears, if we may judge from specimens then exhibited, to be a step decidedly in advance. From its large aperture it is entitled to rank as an aplanat; it is free from astigmatism, and even with a large aperture it has a field that is quite flat. These valuable properties will ensure for it a cordial welcome when it comes to be introduced commercially in this country. It is only by a comparison of its work with that of other lenses formed of the Jena glass that its great advantages can be fully appreciated. Some details as to its nature will be found in the report of the meeting on another page.

The Eclipse Photographs.—The members of the Royal Astronomical Society have now had the opportunity of seeing some of the most interesting of the photographs of the late eclipse. At the meeting last week, with the President, Captain Abney, C.E., in the chair, Dr. A. A. Common, F.R.S., read the preliminary report of the Eclipse Committee, and some of the photographs obtained were described by Professor Thorpe and other members of the expeditions to West Africa and Brazil. At the same meeting some wonderful photographs of the Milky Way, and also of the comets Smith and Holmes, were exhibited on the screen by Mr. Barnard of the now famous Lick Observatory. What would astronomical science do nowadays without photography and the lantern?

The National Association of Professional Photographers.—It appears not a little surprising that this Society receives such scant support from the profession in whose interest it was formed. From the report given in our last issue it seems, although it has now been established some two or three years, it numbers less than a hundred and fifty members. It is obvious that, with this limited roll, with a half-guinea subscription, it cannot achieve much of what it was established to do. There is no question that a society of this description, if properly supported, might be of great service in protecting and furthering the interests of the profession generally. Why, then, is it so little supported? Is it because there is less unanimity among professional photographers than there is with almost every other profession and trade, or is it that the majority of photographers are too lethargic? It is noteworthy that the Association appears to receive more support from photographers in the provinces than it does from those in the metropolis.

Light in the Studio.—A question was raised recently at one of the Societies as to the proportion of light obstructed by the glass of the studio. An equally interesting question is the amount of actinism that is filtered out of the light by some glass, and the dirt that is frequently upon it. It is true that this is not such an important matter now with dry plates as it was in the days of collodion, but still it is worth consideration. Some kinds of glass are very prone to turn yellow with prolonged exposure to light, particularly some of the whiter sorts that are often selected for glazing a studio. We have seen several examples that, after a few years' exposure, had become quite of a yellow tint, and cut off a considerable amount of actinism, as proved by their retarding action when laid on sensitive paper. The dirt that accumulates on the glass in the roof of the studio—particularly in large towns—is of a highly non-actinic nature; especially is this the case with that on the inside, when coal fires are used. From these causes the exposures, in some studios, have to be materially prolonged beyond what would otherwise be the case.

The Award Troubles at Chicago.—The trouble with regard to the awards at the "World's Fair" is at an end. This has been brought about by a compromise that has been accepted, with one or two exceptions, by all the foreign commissions. The compromise is practically a surrender. The awards are now to be made by a jury, instead of upon the report of a single expert—the point of contention—as would have been the case but for the vigorous protests of the foreign commissioners, by the threatened, indeed the actual, withdrawal of the exhibits of something like a score of countries from competition. So far, we may hope the awards will be satisfactory, or, at least, as satisfactory as at most competitions. This gratifying result has been obtained mainly through the instrumentality of the Secretary of the British Commissioners, Sir H. Trueman Wood, whose opinion of Mr. Thacher's system, it is said, is still unaltered; but the notice given on the subject was ample, and the acceptance of the American system was practically completed when the exhibits were sent. We have before mentioned that British interests were in good keeping in Sir H. Trueman Wood's hands. But, there, no one ever doubted that.

STUDIO-BUILDING.*

IV.

Before proceeding to the act of glazing, it would be well to refer to ventilators, a point upon which no branch of the subject gives rise to so great a variety of opinion. The popular idea of ventilation is that, as heated air ascends, if a hole be made near the ceiling of a room, the hot air will go out; and a further elaboration of that idea is that, for this egress to take place, it is first necessary to make another hole near the floor for the cold air to come in. It too often happens under such circumstances that the air will come in at the top and go out at the bottom, the ventilation of a building depending upon such a variety of conditions, both internal and external, as to defy the production of any uniform scheme for self-acting ventilation. When mechanical contrivances are adopted to enforce the egress of air, it simply becomes a matter of paying the required cost and using judgment in selecting an apparatus that is likely to perform in a satisfactory manner. It would make this already long series of articles too long by far to enter into any details on ventilating questions, and, as few photographers would be likely to go to the cost of providing mechanical contrivances, I would briefly say that my own experience has been that, practically, the greatest comfort is brought about by having as many windows as possible at the sides of the studio capable of being opened at will, and as many openiogs in the roof also, not forgetting that a close watch is required to be kept upon the latter against probable showers of rain. During hot weather as many windows and doors will be kept open as conveniently can be. When the studio is overlooked, lattice-work can be placed outside the windows. One set of windows in my present studio is provided with obscured glass and lattice-work, the former opening outside, and the

* Concluded from page 294.

latter fixed internally, the laths being inserted at a suitable slant towards the sitter.

All that now remains to be dealt with is the painters', glazier's, and decorators' work, and the designing and arranging suitable blinds.

The glazier is usually a man of dogmatic turn, who "knows his own business," and resents interference. Painful experience has taught me that he is very far from being infallible, and, as touching the question whether he knows his business, it would be interesting to learn in how many studios in the kingdom he has displayed, or made use of, that knowledge so as to glaze a wood-sashed roof watertight. There are three main points in which his work may be overlooked First, the window bars should have by preference three coats of paint before being glazed (it goes without saying that the wood should be dry; no skill in glazing can counteract the evil effects of green timber). I have seen many, perhaps through the impatience of the owner, glazed when the wood has only had one coat of "priming;" this kind of work is almost certain to leak eventually. Second (this hint was given to me by a glazier who did know his business) it is greatly conducive to the production of a watertight joint to give a coat of paint along the margin for about half an inch on each face of the glass where the putty is applied. The facility of adherence, or "growing-to," as they quaintly express it, between putty and glass is increased to a very remarkable extent, and, when this is done, the bars painted as described on a dry day, and good putty is used, the studio-builder need not have much fear as to future tightness of his roof, provided it be not disturbed or shaken while the putty is setting. Third, let there be contracted for, and care taken that the agreement is carried out, that putty of best quality, and free from water as an adulterant, is employed. This is very important, as water-weighted putty very soon becomes leaky.

This part of the subject may now be dismissed by saying that the roof should be periodically inspected, decayed putty removed and replaced by new, and the whole repainted every year or two. Unfortunately, the best period of the year to do this is the busiest time—early autumn, when the wood is dry and before heavy dews have begun to form, as in the latter case work has to be deferred till the sun dries the roof, and the painters' presence occurs at a time when they are more than the usual nuisance.

With regard to the decoration of the interior of a studio, the proverb, "De gustibus non est disputandum," so strongly applies, that I should not think of laying down any rigid laws. It is often held that the unglazed walls of the studio aid, or should aid, in the general illumination of the sitter, by means of the light reflected from them on to the more shadowed portions of the figure. My present views are that, if the shadows are lightened, when needed, by specially applied reflectors of whatever material or fabric is preferred, there is greater control over the illumination of the sitter, and then the decoration can be done on its own merits. For a long while blue was considered the proper colour for painting the interior of a studio; but, fortunately, the plan has been mainly banished to the more elementary kinds of studios and workers. Still, remembering that the question of taste comes in, I would say, if the paper chosen for the walls be dark, and not striking or garish in pattern—bright yellowish or reddish hues being avoided—the sitters' eyes will experience a degree of comfort quite impossible when lighter and gayer patterns are chosen.

The *blinds* come last under consideration, but they are by no means least in importance. Indeed, it is by judicious arrangement of them in designing the studio, and by artistic arrangement of them in use, that the whole character of the work is influenced. It is here where the artist can show himself, and upon his control and power of control over them will depend, to a considerable extent, the reputation of the professional photographer. Blinds are mainly worked on two broad principles—curtainwise and roller-blindwise. Much depends on the construction of the studio and the various aspects under which the sitter may be arranged. Each has its advocates, and it is usually the case that a photographer, discussing the subject, is ardent in praise of the plan he himself adopts. For myself, I am not prejudiced, as I work both plans; but I have a very emphatic preference for the curtain over the blind style. I have tried roller-blinds and spring-blinds—the latter working up, and down, and sideways—and they have many advantages; but some time or other the cords will go wrong, and, as a matter of course, we all know such disaster always happens at a most critical moment. I will first describe the curtain-blinds I use. Many artists use strong metal rods for suspending them; others use wires. I have tried both, and I most strongly advise the use of the latter. They are cheaper, easier to erect, and they can be always rendered taut by the turn of a screw. My mode of fixing is to attach firmly into opposite walls, or other supports, a specially strong screw-hook for each end of the wire. The latter is, at one end, firmly twisted into a loop, and slipped on one screw-hook; the other end is attached to a swivel screw, constructed on a similar principle to those in use for tightening each length of wire in wire fences. The swivel end rests on the second hook, and a few turns will make thirty or forty feet of wire as tight as a piano string. These wires are laid in pairs along the lower part of the under side of the glass roof, and at a certain height they are made to run horizontally, as there is no object in screening the whole of a lofty roof. Curtains are suspended along these pairs of wires by means of curtain hooks, firmly stitched at intervals along each of the long sides of the material, and then hooked to rings, placed beforehand, on the wires. At first I used to attach the rings direct to the curtains, and thread them on to the wire, but, when they had to be taken down for repair or during decoration, the labour of re-erecting was greater than any one could imagine who had no experience with them. It should be understood that each length of curtain is divided into three separate independent pieces, so that the light can be brought almost anywhere, as a broad or narrow pencil, this being also facilitated by allowing plenty of length in each curtain, so that their combined length, if stretched to their fullest, would be much more than the lengths of the wires they are suspended from.

Lighter screens will also be needed for softening and subduing the light, or for killing the direct rays of the sun when early or late they cross the field of view. I have tried almost everything, but have derived the greatest comfort from the material called "tracing cloth." It is close-grained, robs the light very little, and can be kept quite clean by a simple duster. The kind glazed on both sides should be asked for, and I can promise those unfamiliar with the fabric who care to try it that they will be very pleased with its performance. It is infinitely preferable to the more common plan of whitening the glass during summer-time when the light is strong, for it robs the light of less of its actinic effect, and can be instantly brought into play or folded out of sight according to the exigencies of light. These blinds with me are attached to rollers, and work from the ridge downwards almost close to the glass. To avoid swagging they are each supported by three wires stretched in the direction of thei length from ridge to eaves.

I now take leave of my readers, trusting that what I have written may be of benefit to some. I shall be pleased if any one who wishes for further information would ask me, through the columns of the JOURNAL anything that may tend to further elucidation of what may be insufficiently described in my remarks.

G. WATMOUGH WEBSTER, F.C.S.

AMERICAN NOTES AND NEWS.

A Dark Room for Chicago.—The Cramer Dry Plate Company are enterprising. They have secured the sole right to erect a dark room on the World's Fair grounds in which photographers may change their plates, and they probably have had to pay a large sum for the concession. This, however, is not all; the dark room is to be under the charge of a competent attendant, and this spirited Company are to make no charge to the visitors who choose to avail themselves of its shelter for changing their plates. This is a good stroke of policy, as it is certain to be appreciated, and will eventually richly repay Mr. Cramer and his colleagues. This generosity deserves to be noted. An American visitor to this country not many months ago complained to us that he had been charged seven shillings and sixpence by a dealer in one of the main streets of London for the use of a dark room in which to change his plates, these plates having been supplied from the same establishment. We could only reply that the principal of the business was doubtless ignorant of this act, as it was

evidently so contrary to his interests to amerce a customer in such a charge. The money demanded was paid, but all dealings there terminated.

The "Beacon's" Non-appreciation.—The *Photo-Beacon* is somewhat strongly down on Dr. P. H. Emerson on account of the paper he lately contributed to the Photographic Society of Great Britain. Under the heading "Recantation Recanted," it tries to hold the author up to ridicule, characterising the paper as too silly to be laughed at and as the most absurd matter that ever appeared in a photographic journal. We, on the contrary, think that there is much that is really good in the paper alluded to.

An "Infantometer."—Such is the title given by the foregoing journal to an extract from an article by C W. Canfield, in the *Photographic Times*. This gentleman claims that composite photography was foreshadowed in 1853 by Mr. Mascher, of Philadelphia (where so many things in photography have been discovered), whose circular regarding stereoscopic Daguerreotypes contains the following:—"I have taken a gentleman's picture on one plate, and a lady's on the other, and by placing them in the stereoscope they were blended together, producing the most astonishing effect. The resulting picture is not a true picture of the one or the other, yet possesses the most prominent features of each, making a picture wonderfully like one of their children. From this it is suggested that those true lovers who wish to see what sort of appearance their children, should they be so blessed, will have, have merely to have either a stereograph of this nature, or by preference a true composite photograph taken, and by the union of the lady and gentleman will be obtained a likeness of the desired baby—in fact an 'infantometer.'" We ask with Charles Dudley Warner, Who, after this, dare say that Americans are mentally commonplace and unimaginative?

What the Button-pressers Lose.—The *New York Tribune* says that the enjoyment derived from pressing the button and hiring some one else to "do the rest" is of brief duration, and attended with much expense. The feeling of triumphant success which attends the production of a finished and mounted print by one's own hand is wholly lacking, and with this lacking the chief charm of amateur photography is lost, and there is nothing which can take its place. The artistic treatment of an artistic subject affords a field for work into which few may venture and hope for success unless they are fully determined to master all the details of the work. This is absolutely true, but it does not apply to any reader of the *British Journal of Photography*, as our readers "do the rest" themselves. Indeed, we have a rather firm persuasion that mere button pressers are ignorant of the existence of photographic literature.

A NEW DEVELOPER FOR GELATINE DRY PLATES.

Abstract.

1. A developer containing a soluble salt of silver incorporated with gelatine and suitable reducing agents, whereby in the progress of the development the image is built up electrolytically from the silver contained in the developer itself.

2. Preventing the veiling of the image, or fog during development, by the addition to the developing solution of an easily reducible compound of silver; permitting the development of under-timed plates to be prolonged at will, until all detail impressed by the action of light upon the film is brought out and the desired density obtained.

3. A method of intensification before fixing, enabling a negative worked up to the practicable limit of development by any of the formulæ in use to be further developed until sufficiently dense.

Introduction.

During the winter of 1892, an investigation of the chemical action of the different developing agents employed with gelatine dry plates was conducted jointly by Mr. W. Dinwiddie, of the U.S. Geological Survey, and the writer. In the progress of the experimental work it was noted that, while all soluble salts of silver were rapidly reduced and precipitated by the addition of a solution of ferrous sulphate, hydroquinone, or any other developing agent, yet, if the silver salts were first emulsified or combined with gelatine, no precipitation occurred even by the prolonged action of concentrated solutions.* Further, that suitable developing agents incorporated with the emulsified silver salt constituted a developer of unusual power for gelatine dry plates, specially applicable for instantaneous and under-exposures.

An application for U.S. patent was made for this discovery, and is now pending.

Description.

The accepted theory of the action of the developer upon gelatine dry plates is, that the latent image formed by the action of light upon the film becomes visible through the reduction of the photo-bromide of silver to dark-coloured reduction compounds and finely divided metallic silver by the chemical action of the developing agent, and that the image is further strengthened by a weak electrolytic action induced, whereby the image is built up from the bromide of silver, unaltered by light, remaining in the film.

With a developer containing silver, this electrolytic action may be increased and greatly prolonged, the image gaining additional intensity from the silver derived from the developer.

The veiling of the image, or fog, produced by excessive strength of the developing agent, or by its prolonged action, is thought to result from a reduction of the unaltered silver bromide disseminated in the film. This fogging may be prevented by the addition to the developer of a small amount—less than a half per cent.—of an easily reducible salt of silver. The silver salt in the developer is more easily reduced by the developing agent than the unaltered silver bromide in the film, and protects the latter from reduction and prevents fogging as perfectly as the coating of zinc given to iron in the galvanising process protects the metal from oxidation. This protective action of the silver in the developer is increased by bromide of potassium, which restrains the reduction of the silver bromide by the formation of a difficultly reducible compound, without interfering with the action of the argentic developer. Resultant from this is the power of prolonging development indefinitely without danger of fogging.

This developer may be prepared in two forms, as an emulsion, composed of the double sulphite of silver and soda, combined with gelatine, suitable for incorporation with any of the developers in use, or as a single solution ready for use, containing in proper proportions the argentic emulsion, developing agents, and alkali.

In either form it is an opaque olive-coloured emulsion, miscible in all proportions with water.

The silver salts employed are the different double sulphites of silver and soda. These enter into combination with gelatine, with the formation of stable compounds, capable of existing in a chemically passive condition in the presence of the strongest reducing or developing agents.

It should not be understood that this developer brings out much more detail than can be obtained by the exercise of skill with pyro. What is actually accomplished is a relatively uniform increase in density all over the plate, and a strengthening of the delicate detail in the low lights and shadows.

The ultimate object of development is not the negative, but a print obtained from it; and, by the employment of argentic emulsions, detail visible only as delicate tracery in the film may be built up in silver until it becomes printable.

Measured by practical results, the time of exposure of all well-lighted subjects may be reduced to from one-fifth to one-tenth normal (*e*-5 to *e*-10).

This is equivalent to an advance of two or three numbers in the sensitometer number of the plates used. With Carbutt's orthochromatic plates, Sen. No. 23, well-developed instantaneous views were obtained in bright sunlight with the exposure given by a Prosch shutter and full opening of lens; also in many successful experiments where the normal exposure was carefully determined by Watkins' meter; the exposures actually given were in well-lighted views one-tenth normal, increased to *e*-4 where detail was desired in the shadows.

Small diaphragms can be used in instantaneous views in strong light where there are not deep shadows. With quick plates, a lens of ordinary rapidity (f-d=8), and a shutter speed of one-fiftieth or one-hundredth of a second; a diaphragm of f-16 will afford, by prolonging

* This restraining action of gelatine and other organic substances, such as sugar, starch, glucose, and gum arabic, has been remarked by Abney and Carey Lea. The older text-books on photography describe a method of redevelopment or intensification of collodion wet plates before fixing, by the addition of silver nitrate to the acetic acid and pyro developer.

the development, negatives that almost equal time exposures in detail and definition.

The opaque developer protects the plate from all action by light in the dark room. Precaution should be taken that the plates are not in the least light fogged while in the plate holders, as on development the fog is intensified. Further, by its use, development is reduced to a mechanical process, requiring little attention and easily carried out by any one.

The employment of argentic salts in photographic developers is as yet in the experimental stage; its possible future evolution cannot be predicted. From want of time, the experiments were confined to the development of dry plates; the action of argentic emulsions upon bromide paper is unknown.

Most of the experiments have been made with strongly alkaline eikonogen and hydroquinone developers, a few tests only with pyro, and none with ferrous oxalate or other ferrous developers.

The new developing agents requiring but little alkali, such as amidol and metol, offer the greatest encouragement for investigation. Further, this use of silver salts suggests the possible employment of other metallic salts, such as platinum and gold, in photographic developers.

In astronomical work argentic developers will probably prove of value, and in certain photographic processes requiring negatives of extreme density, they may find a place.

The prevailing rule in landscape photography is to somewhat over-expose, depending upon development to correct the consequent tendency to flatness and lack of contrast in the negatives. It is even stated that there is a greater latitude on the side of over-timing. The experiments made by the writer indicate that below normal exposure the latitude is at least proportionately as great, and that superior negatives result from exposures, which while sufficient to impress upon the film the most delicate detail in the shadows, are yet far under the time thought to be requisite to obtain the best results.

The Argentic Emulsion.

The Preparation of Silver Tartrate.—As silver tartrate is rapidly darkened and decomposed by exposure to white light, this emulsion is best prepared in the dark or under a red light.

A solution of

Nitrate of silver	200 grains,
Distilled water (cold)	12 ounces,

is precipitated by the equivalent weight of tartrate of potash; the amount varies slightly with different samples, but is, approximately,

Distilled water (cold)	2 ounces,
Tartrate of potash	105 to 120 grains.

The bulky white precipitate of silver tartrate is soluble in pure water. It is not washed, but placed upon a filter and allowed to drain. The filtrate contains some silver, which can be precipitated as chloride and recovered.

The moist precipitate of silver tartrate is removed from the filter, paper and dissolved with rapid stirring in a warm solution of

Sulphite of soda crystals (pure)	800 grains.
Distilled water (hot)	4 ounces.
Glycerine (pure)	1 ounce.

If the soda sulphite solution is not distinctly alkaline, it should be made so by the addition of carbonate of potash or soda, twenty to thirty grains, before adding the silver tartrate, to prevent the formation of a precipitate of the difficultly soluble, crystalline double tartrate of silver and potash, which separates in neutral and acid solutions.

The solution of the double sulphite of soda and silver, is nearly colourless and transparent. It is filtered, to remove a slight precipitate of silver sulphide derived from the impurities of the chemicals used.

A solution is made on a water bath, with care to avoid over-heating and decomposing the gelatine, of—

Nelson's sheet gelatine No. 2	100 grains.
Distilled water (hot)	2 ounces.

Then add—

Pure glycerine	2 ounces.

It is advisable to soak the gelatine for one hour in one half of the above quantity of cold water; the swelled gelatine quickly dissolves on the addition of the moiety at the boiling temperature.

The silver solution is gradually added to the solution of gelatine, with constant stirring to avoid the precipitation of the gelatine; both solutions should be warm when incorporated (100° to 120° Fahr.). The resulting solution is made up to a volume of twelve ounces by the addition of water. At first it is clear and transparent, but soon changes to an olive-grey opaque emulsion, that on cooling sets to a thick jelly.

When required for use, the emulsion is liquefied by immersing the bottle containing it in a dish of warm water. It is best kept in the dark, or in a bottle wrapped in opaque paper. Under such conditions this emulsion does not appear to undergo decomposition, the glycerine and sulphites of silver and soda acting as preservatives. On heating to a temperature approaching the boiling point of water, decomposition ensues, with precipitation of metallic silver in the golden-yellow allotropic form described by Carey Lea.* Not infrequently the emulsion is of a beautiful purple shade when viewed by transmitted light, indicating the presence of photo-salts of silver.

This formula affords an emulsion in which the silver salt is strongly restrained; one part of gelatine is combined with two parts of silver salts and eight parts of sulphite of soda. In order to increase the sensitiveness of the silver compound and accelerate the electrolytic action in development, the proportion of the gelatine should be decreased to possibly two-thirds or even one-half of that above given. A few experiments indicate that the addition of Rochelle salt or a solution of inverted sugar makes the electrolytic action more energetic.

It is possible to make the emulsion so sensitive that it will not keep, readily decomposing, with precipitation of metallic silver, forming during development a mirror of brilliant silver over the whole surface of the negative and the bottom of the developing tray.

In place of the tartrate of silver, the metabisulphite may be employed; the solution of nitrate of silver is precipitated by the addition of a weak solution of metabisulphite of soda or potash as long as a precipitate continues to form. The white or pinkish-white, curdy precipitate of silver metabisulphite† is washed by decantation with cold water and dissolved in a neutral solution of sulphite of soda, forming the double salt, which finally is incorporated with gelatine and glycerine in the above proportions.

The grade of photographic gelatine known to the trade as No. 2 appears to be the most suitable. The harder grades of gelatine afford thick and sticky emulsions, while soft gelatines, such as No. 1, have but feeble restraining power.

Glycerine, when forming fifteen to twenty-five per cent. of the volume of the emulsion, is an efficient preservative. The addition of glycerine renders the gelatine more tractable in incorporating the concentrated solutions forming the developer. It has but little restraining action when used alone.

W. P. Jenney, Ph. D.

(*To be concluded.*)

* *American Journal of Science*, 1887-89, 3d ser., vols. xxxiii., xxxviii.

† Whether this silver salt is a true metabisulphite is somewhat uncertain. It is different in behaviour in the emulsion from the silver sulphite produced by precipitating silver nitrate by sodium sulphite.

DENSITY RATIOS AND EXPOSURE.

The question whether latitude in exposure exists in a sensitive film, and, if so, to what extent, is of such wide importance that Mr. W. K. Burton's letter to *Photographic Scraps* on this subject is sure to attract much notice. Anything that Mr. Burton writes is sure to be useful and practical, and with the information given in his article any one can repeat the experiments for himself, and compare the results.

There are one or two points, however, to which I should like to draw attention, as either simplifying the work or tending to confuse the issue. In the first place, I should recommend all experiments to be made either with a screen of some sort or by a series of exposures, as indicated in the last paragraph of Mr. Burton's communication. It is quite easy to compare results obtained in this way, *i.e.*, a series of tints increasing in depth in a fixed ratio. It is, however, practically impossible to do more than give an opinion—in which the personal equation is liable to be unduly prominent—upon the similarity of two ordinary negatives, neither of which may correctly represent the natural original, and in which there is no certain guide as to true representation; that is to say, as to how much deposit should represent a certain portion of the view.

For like reasons a series of deposits of silver caused by the unimpeded action of light is much to be preferred to the results with a coloured screen, such as Warnerke's. It is more easy to compare the tints, and, in case accurate measurement should afterwards be required, more useful. An instrument for the purpose can be made from a half-plate printing frame with the aid of some pieces of cardboard in a

few minutes, and is always handy for comparing one lot of plates with another. Further than this, in the direction of laboratory testing, I do not think it advisable or necessary for the ordinary photographer to go.

Photography has been named an art-science, but, as far as negative-making goes, the two branches are far apart. The artist cares little as a rule as to the *appearance* of his negative, or, at all events, if he does care, he is willing to sacrifice the look of the negative to the appearance of the resulting print, if to secure a good (looking) negative means any loss in the picture itself. The aim of photography, then, to ninety-nine per cent. of its votaries and admirers is pictorial, and is an appeal to the senses through the eye. Whilst, therefore, I am altogether an advocate for the laboratory exposure test as against the negative-making test for ascertaining the qualities and rapidity of an emulsion, I think that the practical photograph for final judgment of its qualities ought to be formed, not from this test negative plate but from *photographic prints* produced in exactly the usual way from those test negatives rather than by measurement of the deposit. And I think this, on the ground which I expect to have my readers' sympathy upon, that every photographer can form his opinion as to the comparative excellence of two or more prints which ostensibly represent a series of gradations from dark to light, each tint increasing in depth in a known and appreciable degree. Moreover, any limitations of the printing process are self-evident and allowed for in the result. It is a pretty generally accepted fact that no printing process can reproduce all the gradation in a fine negative. The scientific measurement is to that extent misleading, and I prefer to compare prints. Were photography purely a science, I should prefer the use of measurements for general purposes; but, as I esteem it an art, I prefer to abide by the tribunal to which it ultimately appeals, viz., the visual faculties and critical sense. Scientific measurements are of more use to manufacturers than to the picture-maker; graphic measurements, if I may so christen my method, are principally useful to the worker.

With these ideas in my mind, I have gone over the experiments on Mr. Burton's lines as indicated in his letter, and, in order to get a wider trial, I have not limited myself to one make of plate, although there is probably little reason why much difference, if any, should be expected on this ground, except it be on the score of difference in the thickness of coating. My trials amply illustrate this point, viz,, that the thicker the coating of emulsion, the more easily is over-exposure tolerated by the plate. Still, different makes of plates do stand, and even demand, very different methods of treatment.

Briefly stated, I do not find that I can, with sensitometer tests (in which one knows what relative density to expect), get negatives, to use Mr. Burton's own phrase, *giving prints that are identical.* Not only can the negatives be distinguished by the difference in colour of the image, but the prints also are marked by certain characteristic differences which, in my experience, have occurred in a consistent and regular manner. These differences mainly are that the tones of the pictures upon the long-exposed plates are less differentiated than in the normal exposures, and that the pictures seemed to be pitched in a lower key. I have always noticed that photographers who back their plates, give long exposures, and then trust to restrained development, get pictures of this character. Now, these are very pleasing of their kind, but they are quite different from, and can be easily distinguished from pictures whose original negatives have been made with what is usually called correct exposures. I mention the point, however, as it confirms me in the belief that it is going too far to say, as Mr. Burton writes, that "*an experienced photographer cannot tell which is from the negative that has had the longest exposure,* and which from the normal exposure."

A good negative can be made from the plate receiving the longer exposure, and by the method he indicates, but it is different in gradation in the middle-tones, and with a sensitometer test, such as I mentioned in the earlier part of this article, can be fairly easily recognised.

There is one point which I should like to add to these remarks as to Mr. Burton's method of development, viz., that the developer, strong in pyro and bromide, seems to have but little effect upon a plate *if tried in error.* For example, suppose one is not sure which plate is the over-exposed one. If it be tried in the strong developer and no image appears, the plate can be washed and development recommenced with a normal solution without, I think, any perceptible alteration of tone rendering.

I have not referred here to the use of the citrates for remedying the effects of over-exposure—although I am inclined to prefer them to Mr. Burton's method — nor which sort of picture, viz., that obtained with normal or prolonged exposure, will appeal most strongly to the majority of photographers, but simply to state the opinion that, as critically examined under conditions which admit of it, the gradations in the two cases under discussion are dissimilar. A thicker coating of emulsion, and effective backing, both materially assist in reducing this dissimilarity, but do not overcome it.

S. Herbert Fry.

"IN DARKEST PHOTOGRAPHY—THE WAY OUT."

In reference to the great depression now existing in the businesses of professional photographers, and how to remedy such a state of affairs, it would, perhaps, be as well to seek the causes of the disease (which are, doubtless, many) before suggesting a remedy, and which remedy should be as complete as possible, considering the gravity of the complaint.

That a large number of workers have joined the ranks of professionalism since the introduction of gelatine plates is, alas, only too true; but, are they possessed of the same amount of skill and ability as the old wet plate workers? There can be only one answer to this question, No! Unfortunately, No!

Now, there are numbers of men in most of the large provincial towns in the kingdom who trade as so-styled artists and photographers, when they are, in fact, nothing of the kind. They have no studios, are quite incompetent to take a negative, and much less finish a print. Who are these individuals? Why, simply canvassers, men who have been previously employed by some big firm as travellers for club or subscription portraits, and by some little smattering obtained in the course of their business as to certain items in the same, and by forming a tolerably good connexion, and by saving a little money, have been enabled to dissociate themselves from their employers and make a start for themselves as "full-blown" photographers. They enlist the services of some local man (who possibly might be better employed), and arrange with him "to take" for them at a certain price per negative, which is to become their sole property. Possessed of this, they send it firstly to some firm of enlargers for an enlargement to be made therefrom, and secondly send *that* elsewhere to be finished either in colours or monochrome, according to their instructions. These gentry can purchase mounts and frames as cheap and as readily as any professional, and thus they daily, weekly, and yearly compete, with no knowledge, or very, very little, of photographic details, against the man who has served a lifetime to the profession, and who, figuratively speaking, "knows more in his little finger than they do in the whole of their bodies." Are they photographers? Have they the slightest pretensions to be styled as such? Is it not a perfect anomaly? Is it not preposterous that they should be allowed to designate themselves as such? Is it not time that the closure should be adopted towards stopping such a state of affairs?

But these are not the only delinquents who cause professional bad trade. There is another and a very big one, and possibly a more difficult problem to deal with, and that is the amateur. We are continually informed that they do no harm to the professional, that the big guns of the profession suffer in no way by them. But, for all these reiterated statements, it may yet be said they do no good. Many instances might be quoted where they have supplanted the professional and the services of amateurs have been engaged as against the man whose living it is, much to his detriment and financial loss, and it is quite obvious that a man who earns his bread by the profession that he follows *should not* be ousted by one who only attempts such work as a pastime and amusement, and draws the means of his support from some other source altogether. It seems somewhat surprising (to those especially who can remember a different state of affairs to exist) that the photographic press generally should take so much cognisance, and report the proceedings of amateurs and their societies. If less prominence were given to their savings and doings, they would most probably return to that obscurity from whence they came.

And now as to the cause of the existence of so many amateurs among us at present. The profession has certain members of their own profession to thank for that. What would you think of a photographer (?) proudly boasting of the following—that he had supplied some 200 cheap camera sets, quite promiscuously to any one that chose to buy, and on the further understanding that if they also purchased their plates, chemicals, &c., from him, *he would give them free instruction,* and supposing that the locality was already overstocked with legitimate workers, here were another 200 let loose to still further undermine the interests of the profession and inevitably cause a reduction of prices of work.

There is too great a tendency at present among professional photographers, to add the sale of apparatus, chemicals, &c., to the ordinary

branches of their businesses. It is a system much to be deprecated, and tends to lower the status of the profession, causing those who follow such a practice to descend to the level of a shopkeeper, &c.

Having now touched upon some of the most likely causes of photographic depression, let us try and suggest some means whereby to avert it. Some years ago it was strongly advocated in these columns by Mr. John Traill Taylor, and also in the *Photographic News*, by the late Mr. George Wharton Simpson and others, on the desirability of founding "A National School of Photography," whereby all who carried on the business of photographers, should be subjected to an examination to qualify as members of the profession, and there is but little doubt that the present state of affairs would not be in existence if that project had been properly entertained; the apprentice system, which nearly every one decries, would have been abolished, and the amateur would also have been nowhere.

But as the establishing of a "National School of Photography" would take some little time to bring about, and as "trade depression" requires an almost immediate remedy, the quickest, easiest, and safest mode to adopt now is the systematic "registration of photographers," no one being allowed to dub himself as such unless holding an Inland Revenue licence, the fee for which can be hereafter determined, and such licence to be given to only those who can pass a certain test examination, and at the same time afford the proper authorities such information as may be required, that the applicants intended carrying on the businesses of *bonâ fide*, and duly qualified photographers.

Any one who has really the interests of the profession at heart will not object to the test proposed, as with our leading and skilled men it would only be to them a mere matter of form after their many years' experience, and the registration and licensing of photographers would probably tend to a system of trade protection and organization, the want of which at times has been sorely felt.

The "Sale of Poisons Act," as now carried out in connexion with photography, needs some better supervision, as any amateur possessed of the scantiest of photographic knowledge can obtain any chemical, however dangerous, as easily as any professional photographer. This should not be; but, under the proposed scheme before referred to, a chemist should be empowered to refuse the sale of any poison required in photography, unless the purchaser could produce a photographer's licence.

It is hoped that, at the forthcoming Convention of the profession, to be held on the 3rd proximo at Plymouth, the proposition contained in this paper will be brought forward with the endeavour that, before the end of this year, it may be fairly on its way to realisation, and that it may prove to be a satisfactory solution to the present congested state of the profession, and a sure "way out of darkest photography."

"Pioneer."

AMIDOL-HAUFF AND METOL-HAUFF.

Having had some experience with these two developers newly put on the market, I send a short account of my experiments, hoping it may be of interest to those who are beginners, and also trusting it may lead those who have tried these developers to give their experience, as I feel sure a short discussion on this matter would be of interest to the readers of the photographic papers.

I am led to believe by what I hear that it is the general opinion of the photographic public that metol-Hauff is brought out to replace amidol-Hauff. I do not think so, as both are good developers, each having its own good points, but which is best must depend on the person who uses it. Personally, I prefer amidol-Hauff for most work, but for lantern slides and time exposures I find metol-Hauff works the best. Certainly, if one requires a developer that will keep in liquid solution, metol-Hauff is far ahead, as amidol-Hauff will not keep well in this form whatever it is mixed with. When mixed with sulphite, as per formula sent out by the makers, it will not last over eight or ten days, and when mixed with metabisulphite, as per formula I gave, it will keep much longer; but it is not certain in its results if kept over two months, and therefore in this point metol-Hauff has a distinct advantage, as it will keep well; indeed, I should say for any length of time, as I have some stock solution which I mixed when it first came out, and which is as good now as on the first day it was mixed.

But I have found that both amidol-Hauff and metol-Hauff work best when kept in a dry state and mixed as required.

Which is the best developer for one to try who has not tried either is the point upon which I should like to start a discussion. As far as my opinion goes, I say amidol-Hauff for *those who are old hands* at development, and for beginners, metol-Hauff, as I have found that in cases of bad under-exposure one can, with adding potash solution, get fog with amidol-Hauff, but in no case could I get developing fog with metol-Hauff by forcing with potash. For ordinary exposures of, say, one-fiftieth second up, I think metol-Hauff is as good a developer as it is possible to have, but for very fast exposures of, say, one-three-hundredth to one-six-hundredth, I cannot get as good results with metol-Hauff as with amidol-Hauff. This may, however, be my own fault, as one of our greatest authorities (Mr. A. Pringle) says that metol-Hauff is as good a developer as any known, and he certainly knows better than I do; but I can only say as regards myself that with fair exposures I can get about equally good results using either amidol-Hauff or metol-Hauff, but for extra fast work I prefer amidol-Hauff.

Now, as to which is the best for bromide paper, I say amidol-Hauff certainly when mixed with sulphite, as if you only use enough amidol you can get a good, clear black, and use your developer for four or five prints without loss of tone; but, when using metol-Hauff, one must not use it more than two or three times, or one will get a bad colour on the bromide print: also, on no account must one dilute the metol-Hauff developer if a good black is required. Metol-Hauff has one point which amidol-Hauff has not, viz., one can develop a bromide print to a brown tone by giving a long exposure and then diluting the developer, adding a lot of bromide, and using carbonate of soda in place of carbonate of potash. Of course, it is impossible to give a fixed rule for mixing a developer for brown tones, as so much depends on the negative used and the colour you want to get; but I can say that a good brown can be got by this developer (metol-Hauff) if used as above. I only mention it for a hint to others to help me with their experiments, as I have only been trying it a few days myself.

For lantern slides, as I said before, I prefer metol-Hauff.

Another point with metol-Hauff (not that I think it an extra good one) is that it works specially well with ammonia in place of carbonate soda or carbonate potash, and one gets very fine black on bromide paper by using ammonia. The amount of ammonia to use must be found out by experiment, as one brand of paper requires more than another.

The formulæ I use are as follows:—

Amidol (stock solution).

No. 1.

Amidol-Hauff	1 ounce.
Metabisulphite	1 „
Water	10 ounces.

No. 2.

Water	10 ounces.
Carbonate potash	2 „

For use for bromide paper take—

Amidol-Hauff solution No. 1	1 drachm.
Potash solution No. 2	1 „
Water	1 ounce.

and four to five drops of a ten per cent. solution of bromide. For ordinary snap-shot work use the same without any bromide, and for time exposures dilute by adding one ounce more water and bromide as required.

But I think the best plan is to use the amidol-Hauff dry, as it will dissolve in a few minutes. The way I use it in this case is: I keep a saturated solution of sulphite of soda on hand, a good quantity —say, ninety ounces or so—as it keeps well in a stoppered bottle. For use I take, say, saturated solution of sulphite, six ounces (six grains per ounce); amidol-Hauff, thirty-six grains; and four to five drops per ounce of a ten per cent. solution of bromide for my bromide papers and ordinary snap-shot work. For time exposures one should use the sulphite solution diluted with equal part of water and more of the bromide; but, if one wants density, the amidol-Hauff should not be reduced.

For metol-Hauff I use the formula sent out by the makers for a stock solution, or else I use it dry, as follows:—

Mix thirty-six grains of metol-Hauff in three ounces of water, and, when dissolved, add three ounces of saturated solution of sulphite, six drachms of twenty per cent. carbonate of potash, and a few drops of bromide; this works well with bromide papers and for ordinary hand-camera negatives. If the negative is under-exposed, add carbonate of potash solution, thirty drops at a time, till you get all you can out of the negative. For time exposures, use more bromide, up to one drachm or one and a half drachms of a ten per cent. solution of bromide per ounce. For density I find it best to trust to my bromide instead of diluting the developer with water.

Now, I have given my experience with these two developers, and had my say, and started the ball, and I hope others will follow, for I think that, although we have often heard of our old friend, pyro,

being replaced—but did not think it would be so yet—in my opinion either of these developers (I fancy metol-Hauff) will do it, and, being so confident, I wish to hear others on the same subject, so as to see who agrees with me.

A. R. DRESSER.

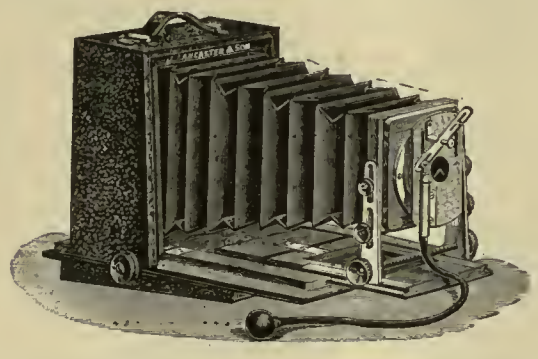
SUMMER NOVELTIES IN APPARATUS, &c.

MESSRS. J. LANCASTER & SONS, BIRMINGHAM.

In the opening pages of their Catalogue for 1893, which has just been issued, Messrs. J. Lancaster & Sons, of Colmore-row, Birmingham, point with pardonable pride to the circumstance that, up to date, they have sold 105,000 cameras and 160,000 lenses. This in itself may be accepted not only as an evidence of the prosperity of Messrs. Lancaster's business, but also as some faint indication of the extent of photography itself, which, though it may be a trite enough thing to say, is nevertheless true, that it has grasped the interest and attention of all classes of people to a degree that characterises no other pseudo-scientific recreation.

The Catalogue in question includes, in addition to illustrated particulars of the firms' many familiar specialities, several new and novel designs in photographic apparatus for the current season, many of which were shown us on the occasion of a recent visit to Messrs. Lancaster's establishment. First of these may be mentioned the aluminium-mounted Instantograph, a camera which, by reason of the substitution of aluminium mountings for brass, is ideally light.

The camera, which is made out of selected mahogany, of the smallest possible size, with a due regard to strength, has aluminium binding, aluminium front stage, plates, screws, &c., as well as double swing back, long extension, reversing back, and all recent improvements.

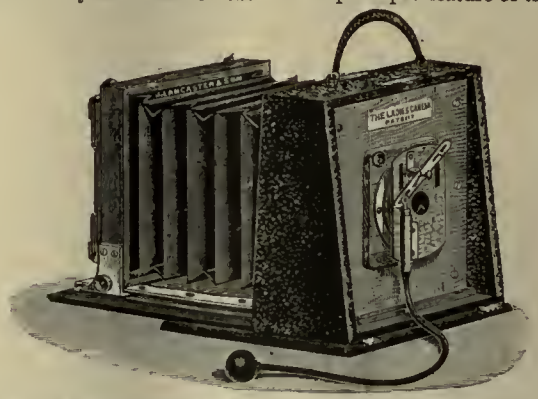


The lens is mounted in aluminium, and has the firm's patent aluminium see-saw shutter. The stand has an aluminium top.

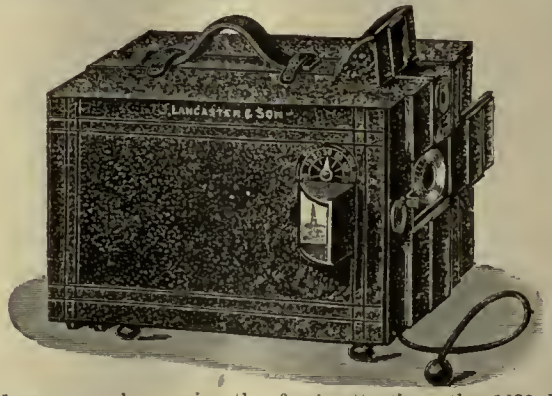
This stand top is an especially well-finished piece of work. Regarding the working of aluminium, Mr. Lancaster informs us that, in experimenting with it as a substitute for brass, considerable time and money have been expended.

The 1893 special brass-bound Instantograph is a handsome camera of the best finish, designed to meet a general wish for a high-class brass-bound camera having all necessary movements. The 1893 Portable Instantograph is a new hand and stand camera, with which a light stand is supplied for the latter purpose. It will be observed that, folded up, it presents an appearance as unlike a camera as it well could be, thus imparting to it a character which may easily elude the observation. Messrs. Lancaster are taking advantage of this happy idea to impart a "detective-camera"-like appearance to their "Ladies' Camera," a camera with but few movements, and therefore eminently suitable to the fair sex. This camera, when folded up and carried in the hand of a lady, looks not unlike a reticule or some similar receptacle which ladies are in the habit of carrying.

Among the other varieties of Messrs. Lancaster's cameras which may be mentioned are the 1893 Pocket Instantograph, which is extremely light and portable, has aluminium binding, runners, front stage, &c., and which, with the lens, shutter, and double slides, are packed and carried in a very small leather case. The principal feature of the Extra



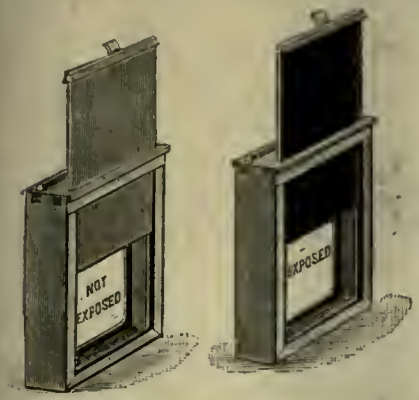
Special camera is that it has a triple extension, thus enabling one to obtain a very great length of focus. In reference to the use of aluminium, Mr. Lancaster showed us samples of the metal, which, for experimental purposes, had been gilded, to give it the appearance somewhat of brass. The Rectograph series of lenses are now aluminium-mounted if desired, and are also supplied in cases similar to those in which jewels are placed, thus giving them a highly chast and taking appearance. Among the firm's sets, that for boys at a guinea, which includes every thin necessary to enable a lad to make his first experiments in photography, is a marvel of cheapness and completeness.



Hand cameras also receive the firm's attention, the 1893 Perfect Omnigraph being their latest pattern.

Among its other features, it has horizontal and vertical finders in the same plane as the lens, registered adjustment for any focus, which is obtained

by moving the lens. It is fitted, at the pleasure of the purchaser, with either metal slides or a special changing box. The slides, which are shown in the cuts, are made of light metal, and the top of the frame is hinged, so that the plates can be removed without the least danger of scratching or rubbing. The woodcut on the left shows the slide closed, and that on the right side shows the frame open to receive plates. The plates are placed back to back in the grooves, with a sheet of opaque material between them.



The changing boxes are fitted with metal carriers, each carrier being constructed to hold two plates, with a division between them; the frame is then closed and fastened by means of a sliding pin. The three carriers are then put into the changing box.

Throughout the extensive range of the firm's specialities, a vast deal of ingenuity is involved, all classes of photographers being catered for, so that it is not surprising that Messrs. Lancaster's weekly output runs to an average of 400 cameras.

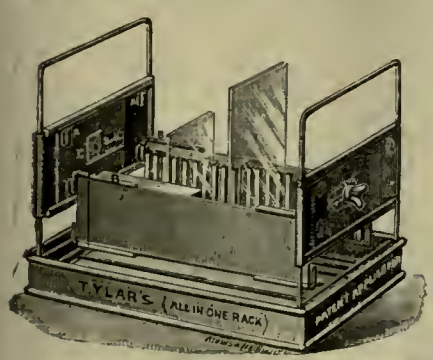
Atkinson's New Backgrounds.

Mr. J. J. Atkinson, of Manchester-street, Liverpool, showed us some new series of backgrounds which should be welcome to professional photographers on the look-out for novelty and variety in this direction. One of these, the "Children's" series, which are produced by Seavey, of New York, represents a number of artistically painted scenes, interior and exterior, which are calculated to suit youthful sitters. The backgrounds are made in the usual sizes, and the subjects are so much out of the common, both in selection and style of treatment, that they are certain to be popular with our professional friends.

Seavey's skill is also well exemplified in the Columbian series for adults, curtained windows, divans, artistic furniture, &c., being made to do duty with uniform success. A third series is that of Bryant (for whom Messrs. E. & H. T. Anthony, of New York, are the agents, but which are also in the hands of Mr. Atkinson, for this country). These represent a number of charming landscapes, unconventional and delicate in treatment. A wider adoption of natural and truthful backgrounds, such as those of Mr. Atkinson, should prove a great service to many photographers in improving the quality of their work and increasing their business.

The "All-in-One" Platewashing Racks.

Mr. W. Tylar, of High-street, Aston, Birmingham, is introducing a new form of adjustable platewasher under the above title. Its principal feature is that it takes any size up to whole-plate, either eighteen $3\frac{1}{4} \times 3\frac{1}{4}$, $4\frac{1}{4} \times 3\frac{1}{4}$, 5×4, stereoscopic, half-plate, $7\frac{1}{2} \times 5$, or nine whole-plates, being inserted at one time in the grooves, or nine whole-plates; or, for mixed sizes, nine each of either $3\frac{1}{4} \times 3\frac{1}{4}$ or quarter plate, 5×4 or $7\frac{1}{2} \times 5$, &c.



It is made of zinc, and packs up into a small compass. In use, the arms carrying the grooves are fixed at different distances on the sides of the rack, which is rendered rigid by screws at each end. The "All-in-One" should prove very convenient where a number of different plates are desired to be washed at one and the same time.

Messrs. Jas. Woolley, Sons, & Co., of Manchester, who occupy large and handsome premises in that town which are devoted to the distribution among chemists, doctors, &c., of drugs, chemical and scientific apparatus, &c., also include among their numerous departments one set aside for photography, which is filled with an extensive and assorted stock of all photographic requisites. Among the recent novelties embraced in their catalogue is the "Sandell" fixing tank, which has been introduced to meet the requirements of the Sandell plate. It has a light and dust-proof cover, and a strong rack, which can be suspended from the top. The plates are placed vertically in the tank, and for draining purposes are held in the rack at the top of it.

Calling in upon Mr. J. T. Chapman, of Albert-square, Manchester, when in that town, we were pleased to hear from him that he was extremely busy in photographic apparatus and materials, &c., a fact of which we had ocular evidence. Indeed, photography generally, or rather that branch of it which concerns itself with the supply of materials, especially to amateur workers, seems in the north of England to be in a very healthy condition—a state of things, no doubt, in some measure due to the recent fine weather.

Our Editorial Table.

Amateur Photographers' Annual for 1893.

London: Hazell, Watson, & Viney.

This Annual is illustrated by no fewer than fourteen pictures, and several articles, mainly of a practical nature. These are headed by the editor, who leads off with a good article on the carbon process, in the course of which he tells us as succinctly as possible all that is known concerning it. He is followed by Mr. A. Horsley Hinton, who treats on subjects connected with pictorial composition, and the trimming of prints. The other articles are "Practical Work," by John A. Hodges (the leading one in the volume), and "Protecting Inventions," by Naunton. Then follow, arranged in dictionary fashion, a holiday guide, in which, like the *A B C Railway Guide*, the population of numerous places, their distance from London, and other useful information are given. The Annual is well got up and will prove useful for reference.

J. Lancaster & Sons' New Catalogue.

As far as catalogues go, this one for 1893 is a work of art. It contains four pictures, taken, as may be well understood, with Messrs. Lancaster's apparatus, besides numerous cuts illustrative of cameras, lenses, stands, lamps, and every other thing required in photography. Lancaster's Catalogue, unlike others, is confined to objects of their own manufacture, and they are very numerous and varied. They fill eighty pages. The Catalogue, which sells at *4d.*, is a model of excellence.

Mills' Mountant.

Mr. G. W. Mills, Highgate, sends us a sample of a mountant he prepares for enamelled and similar prints in which the gloss is desired to be maintained. Its basis seems to be dextrine, to judge from the smell. The directions for use are to apply it to the back of the print with a stiff brush and then rub well in contact with the mount. It will answer its intended purpose well.

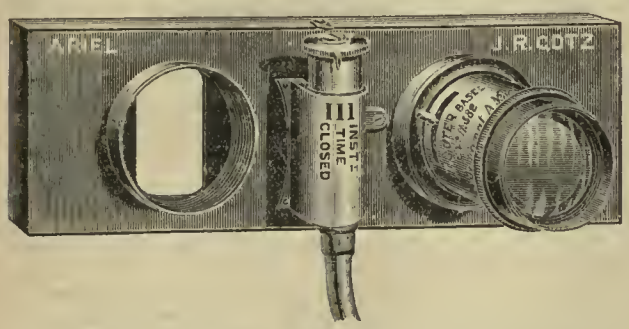
Flashlight Portraits.

By W. E. Debenham, 46, Haverstock-hill, N.W.

Mr. Debenham has submitted to us for inspection a series of portraits taken on the occasion of a fancy-dress ball by means of a flashlight. Excepting, perhaps, the presence of the cast shadows, it would be difficult to discover that these portraits were not studio work naturally lighted, the absence of harshness of lighting usually seen in such results being very noticeable. There is a roundness of feature combined with softness of texture which speak well for the management of the light and the accuracy of exposure. As examples of this kind of portraiture, Mr. Debenham's results are very successful.

New Shutter for Stereoscopic Photography.

Mr. J. R. Gotz, 19, Buckingham-street, W.C., has brought out a new form of shutter—the Ariel—which is simplicity itself, or, as Mr. Gotz expresses it, the *reductio ad absurdum* of shutter action. The



cut shows its external form. Pressure upon a pneumatic ball drives up a box piston which loosely fits the cylinder, and this, in rising, engages with a double lever by which the shutter blades are opened and closed, either instantaneously or are amenable to time exposure. The blades are cut square, so as to give a square aperture. This shutter is so convenient, and of such pocketable dimensions, as to ensure a large demand for it.

The Ilford Exposure Meter and How to Use it.

Those who possess an Almanac for the present year are doubtless familiar with Mr. John Howson's article on "The Ilford Exposure Meter," which had not at the time of issuing this Annual been quite ready. A specimen is now before us, and is illustrated by the adjoining cut. The Meter, which has been invented by Professor J. A. Scott, of Dublin, in order to furnish a convenient method for performing the various calculations necessary in estimating photographic exposures in a purely mechanical manner, consists of three movable circles or discs, which revolve freely on a central axis, to which are fixed two circular plates, one forming the centre of the front, and the other the back of the instrument. These discs respectively are: "Plate Circle," "Date Circle," "Diaphragm Circle," and "Subject Circle." On the outside is the "Exposure Circle." These are all movable, except the first and the last. The Meter is elegantly made in ebonite, and can be carried in the pocket without the slightest inconvenience, being only three inches in diameter and weighing one ounce. From the well-known reliability of everything that emanates from the Ilford Company, it is almost superfluous to say that this useful exposure meter can be quite depended upon. We endorse the statement on the front of the pamphlet of instructions, that it is a common-sense and certain means of gauging exposures.

PATENTS COMPLETED.

Improvements in Photographic Objectives.

No. 4377. Albert Barber Parvin, 3213 Powelton-avenue, Philadelphia. *May 13*, 1893.

My invention has relation to photographic objectives which are adapted to magnify the image of an object or objects at great distance, range, length, or position from the camera, and with characteristic sharpness in detail.

It is generally understood by those skilled in photography that the size of the image of an object upon the ground glass of a camera depends upon one of three conditions: first, the focal length of the objective; second, the distance of the same from the object to be photographed; and, third, upon the size of the original. Two of these conditions, under certain circumstances, are subject to variation, that is, the distance from the object and the focus of the lens. Of course, if the object to be photographed can be approached, or lenses of different focal power are at hand, then an image of the required size can be obtained, but such favonrable conditions do not exist in everyday practice of the photographer. The required approach to the desired object is often impossible or impracticable, because the required distance is too great to afford recognisable detail in the resultant negative, requiring lenses of extreme long focus, which necessarily are rather circumscribed. Suppose, for instance, a photograph is required of an inscription upon a rock about 300 feet high, to obtain a fair view without distortion the operative would have to locate about 700 feet from the rock, and this would bring the inscription about 800 feet in a direct line from the lens. To secure distinctness or sharpness as to detail, the letters of the inscription would have to appear at least four inches high on the object in the resultant picture. To attain such a result, say, with a lens of 5×6 meters focus, would require a camera with about an eighteen feet extension. Then, again, small images with subsequent enlargement suffer from the disadvantage of the grain of the plate, for even by slight enlargement such is apt to become so objectionably prominent as to destroy all detail. The efforts to overcome such difficulty in exposure has suggested the use of a telescope as a substitute for a photographic objective; but such in practice was found to be awkward and unstable, and, moreover, with the use of the firmest tripod, the slightest breath of air or the least tremor was calculated to spoil the image of the object.

The principal objects of my invention are, first, to overcome the above-mentioned disadvantages and objectionable features, and to provide a photographic objective of comparatively simple construction and effective action for enlarging the image of an object or objects at equal or unequal distances from each other with respect to the position of the camera; second, to provide a photographic objective having a non-extensible tube provided with a single negative lens ground according to a mathematical formula to certain radii, to a compound positive lens ground according to a mathematical formula to different radii, and the construction and arrangement being such that the image of an object or objects at distant points or positions from each other are appreciably enlarged or magnified with marked sharpness of detail in the resultant negative or sensitive film or plate; third, to provide a photographic objective with a non-extensible lens tube, having a slit formed in the wall thereof for the reception of a perforated slide or diaphragm for correcting marginal rays and with compound convergent positive lens and a divergent negative lens; fourth, to provide a photographic objective with a non-extensible tube, having a convergent compound lens and a divergent single lens, respectively ground to different radii, and the length of the lens tube being proportioned to the diameters of the lenses, whereby increased magnification and sharpness of detail of the image of the distant object with respect to its real location and position are obtained; fifth, to provide a photographic objective with a tube having a double front lens of certain radii, and a single back lens of different radii; sixth, to provide a photographic objective with a single divergent lens having each face or surface thereof of different radii; seventh, to provide a photographic objective with a convergent positive lens, and with a negative divergent lens having different radii in respect to the sides or surfaces thereof; eighth, to provide a lens tube having two lenses, the radii of each of which have a fixed relation with respect to the length of the tube; ninth, to provide a photographic objective having a non-extensible tube, with a concavo-convex lens of certain radii of inside curves, and of certain radii of outside curves, to afford certain focal length, and a convexo-concave lens of certain radii adapted to enlarge and to define with decided sharpness of detail the image of a distant object transferred to a film or plate; and, tenth, to provide a photographic objective adapted to an ordinary camera, and comprising a non-extensible tube, provided with a convergent compound or double lens and a divergent single lens, and the radii of said lenses with respect to each other being different on the respective faces or surfaces thereof, in order to give, by the combination, greatly increased magnification or enlargement and great depth of focus.

My invention consists of a photographic objective comprising a tube having a compound convergent lens and a single divergent lens suitably mounted therein.

My invention further consists of a photographic objective comprising a non-extensible tube, with convergent and divergent different radii lenses mounted therein.

My invention further consists of a photographic objective comprising a non-extensible tube provided with a double or compound convergent lens, and with a single divergent lens, and respectively of different radii.

My invention further consists of a photographic objective having convergent and divergent lenses of respectively different radii as to inside and outside curves, faces, or surfaces thereof, and adapted to greatly magnify or enlarge the image of distant objects with sharpness of detail.

My invention further consists of a photographic objective comprising a non-extensible tube having a fixed relation to a compound lens of certain radii, and to a single lens of two different radii, the construction and arrangement thereof being such that the image of a distant object is greatly magnified and sharply defined, so that the different positions of the objects are brought on to a film or plate with characteristic sharpness and clearness of detail.

My invention further consists of a photographic objective comprising a smal tube provided with a compound lens of certain or fixed radii of inside and out-

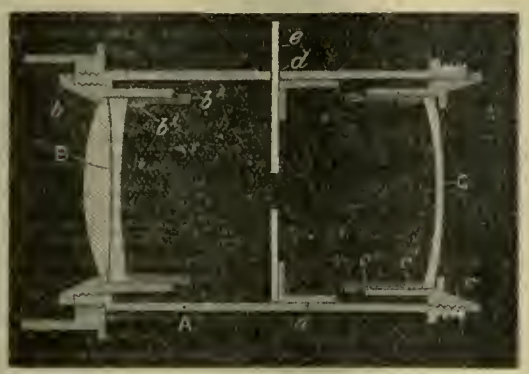
side faces, curves, or surfaces, and with a single lens of different radii of inside and outside faces, curves, or surfaces, and the lenses respectively having convergent and divergent properties, in order to give great depth of focus and permit the image of distant objects to be transferred in magnified form to a photographic film or plate, with characteristic sharpness as to detail, and with remarkable clearness or distinctiveness of field.

My invention further consists of a photographic objective provided with a non-extensible tube having convergent and divergent lenses of certain or defined radii with respect to each other and the length of the tube, and susceptible of being increased or decreased in length proportionately as the diameters of the respective lenses are increased or diminished; and

My invention further consists of the improvements in photographic objectives hereinafter described and claimed.

The nature and general characteristic features of my invention will be more fully understood from the following description taken in connexion with the accompanying drawings forming part thereof, and in which

The figure is a longitudinal central section through the photographic objective, showing a non-extensible tube provided with a detachable perforated diaphragm or slide adapted to correct marginal rays, and with a concavo-convex positive lens, and with a convexo-concave negative lens, the latter embodying features of my invention.



Referring to the drawings, A is a brass or other tube provided with a barrel, *a*, and with detachable threaded coupling rings and sleeves, *b*, b^1, b^2, *c*, c^1, and c^2, for supporting in proper position in the barrel, *a*, the respective lenses, B and C. About midway of the barrel of the tube A, and between the lenses B and C, is provided a slit, *d*, adapted for the insertion of a detachable perforated diaphragm or slide, *e*, for correcting marginal rays. The tube A is provided in the front extremity thereof with a compound lens, B, ground according to a mathematical formula with respect to the inside and outside curves, faces, or surfaces therof, to certain radii, and at the rear extremity of the barrel of the tube A is mounted a single lens, C, ground according to a mathematical formula as to inside and outside curves, surfaces, or faces, to different radii. The tube A, with the lenses B and C, constitutes what is generally known as a "photographic objective." The tube A, for a 5×7 or 5×8 plate or sensitised film may be about two and one-quarter inches in length to lenses each about one and one-quarter inches diameter. It should be borne in mind, however, that as the tube is increased or diminished in length, so proportionately the diameters of the lenses will be increased or diminished. With respect to the lenses, it may be remarked that the main feature of this invention is to provide a single lens, ground according to a mathematical formula on the inside and outside curves, faces, or surfaces to certain radii, and of a compound lens of certain other radii as to the inside and outside curves, faces, or surfaces thereof. Moreover, these lenses, mounted in the tube A, have respectively convergent and divergent proclivities, and are adapted to give greatly enlarged image of the distant object, that is to say, to the extent of ten, twenty, and even a hundred-fold without impairing in the least any of the characteristic sharpness of detail embraced within the field of the objective. Moreover, the image of the distant objects transferred to the sensitised film or plate, and in the resultant picture, according to my invention, is much more pronounced than heretofore was possible by the use of any of the commercial camera objectives. The negative single lens C, mounted in the tube A, is ground on the faces or surfaces thereof to different radii, and is used in connexion with the compound or double positive lens, ground to different radii, in lieu of the generally employed compound lenses for such purposes. Furthermore, the positive lens is a convergent one, while the negative is a divergent lens. By providing the non-extensible tube A with respectively convergent and divergent lenses, it has been found that great depth of focus is obtained, as well as magnification or enlargement of the image of distant objects, without in the least losing any of the characteristic detail required.

In order that my invention may be fully understood by those skilled in optics and in the art of photography, the relation which the back lens, C, bears to the front lens, B, will now be given.

The front compound lens comprises preferably a double convex lens, ground respectively to the radii of 2½ and 1⅞ inches, more or less, to outside curve, face, or surface thereof, and with a double concave lens, ground respectively to the radii of 1⅞ and 31 inches, more or less, to inside curve, face, or surface, and as so combined such compound lens has a focal length of 6¼ inches, more or less.

The back or single lens may be a convexo-concave or periscopic lens, ground to the radii of 25½ inches, more or less, to the outside face or surface thereof and ground to the radii of 4¾ inches, more or less, to the inside face or surface, and this lens has a focal length of 5¼ inches, more or less.

The above combination of lenses, mounted in the tube having a length of about 2¼ inches, may be applied to any ordinary commercial camera, and will give a depth of focus of about 20 inches, more or less.

In the practice of my invention with a photographic objective constructed as described, images of objects have been taken at 6600 feet to two miles distant from the camera with greater sharpness of detail in the prints than ordinarily can be obtained in prints taken at 100 feet distant from the camera. The foregoing advantageous features of my invention are due to the character of lenses employed in the non-extensible tube, and to the depth of focus obtained from the use thereof.

In the practice of my invention, neither spherical aberration nor astigmatism is present, so that the objective is achromatic.

Having now particularly described and ascertained the nature and objects of my invention, and in what manner the same is to be performed, I declare that what I claim is:—1. A photographic objective comprising a tube provided with a convergent front lens and a divergent rear lens, the construction being such that great depth of focus is obtained, and enlargement of the image of a distant object ensured in its transfer on to a sensitised film or plate, substantially as described. 2. A photographic objective comprising a non-extensible tube provided with a compound front lens and a single rear lens, of different radii with respect to each other, substantially as and for the purposes described. 3. A photographic objective comprising a non-extensible tube provided with a detachable diaphragm or slide, a compound front lens of certain radii, and a single rear lens of different radii, substantially as and for the purposes described. 4. A photographic objective, comprising a non-extensible tube, provided with a detachable perforated slide or diaphragm, a compound convergent front lens, and a single divergent rear lens, of different radii in respect to the faces or surfaces, and of different focal length, whereby great magnification or enlargement of the image of a distant object is ensured with characteristic sharpness of detail, substantially as described. 5. A photographic objective provided with a divergent rear lens having faces or surfaces of different radii, substantially as and for the purposes described. 6. A photographic objective, comprising a non-extensible tube, provided with a detachable perforated slide or diaphragm, a single convexo-concave rear lens of certain radii as to inside and outside faces or surfaces, and a compound front lens of certain radii as to inside and outside faces or surfaces, substantially as and for the purposes described. 7. A photographic objective, comprising a non-extensible tube, provided with a compound front convergent lens and a single divergent lens respectively, of different focal length, substantially as and for the purposes described. 8. A photographic objective, comprising a non-extensible tube, with a detachable perforated diaphragm, a compound front lens, and a periscopic rear lens, substantially as and for the purposes described. 9. A photographic objective, comprising a non-extensible tube, provided with a compound front lens of certain radii, and a single rear lens of certain radii, substantially as and for the purposes described. 10. A photographic objective, comprising a non-extensible tube, provided with a compound concavo-convex convergent front lens and a single convexo-concave divergent rear lens, substantially as and for the purposes described. 11. A photographic objective, comprising a non-extensible tube, having a compound front convexo-concave lens and a single periscopic rear lens, the arrangement being such that great depth of focus is obtained, and the transfer of the image of distant objects embraced within the field to a sensitised film or plate is ensured with great magnification and with characteristic sharpness of detail, substantially as described.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

JUNE 13,—Ordinary Meeting,—the President (Captain W. de W. Abney, C.B., F.R.S.) in the chair.

It was announced that the Sheffield Photographic Society had been admitted to affiliation.

THE CONSTRUCTION OF INTERCHANGEABLE LENS SCREW FITTINGS.

Mr. WILLIAM TAYLOR read a paper on this subject, prefacing it by pointing out the disadvantages of the present system, and saying that by the use of

interchangeable screws the lens would always arrive home in one place, and that there would be no trouble about the engagement of the screw, inasmuch as it would be known that three turns would complete. Lens makers were at last realising the importance of adopting standards, and it was to the credit of Messrs. Ross & Co. that they had adopted the Photographic Society's standards. He proposed to speak on the technical methods of making and measuring, and in that connexion was of opinion that the mechanical practice of opticians must reach a higher level than at present. He complained that accuracy in screw making was neglected by opticians who paid every attention to the glass work. There was an important difference between interchangeability for lenses and that for bolts, gas fittings, nuts, &c., which might be forced together, whereas lenses must fit the flanges freely. That was a condition of "free interchangeability." Before him were five lenses and five flanges, the lenses having the Society's two-inch male screw, which, if it were one-one-thousandth of an inch larger than the normal would prevent it entering the flanges. Therefore every male screw must be at least as small as the normal, and every female screw must be at least as large as the normal. These were conditions of free interchangeability. A screw had three principal elements—diameter, pitch, and the form of its threads. The distance between the two threads was the pitch. The outer diameter of the male screw was usually taken by means of the plain measuring faces of a micrometer gauge or measuring machine. The Whitworth form of thread which had been chosen by the Society was beautifully adapted to the purpose. Having described it, he said the depth of the screw was measured by a small triangular test piece of hardened steel, nicely ground, so that it touched only at the root of the thread. It might be right within one-five-thousandth of an inch would be sufficiently accurate for practical purposes. A cylindrical gauge was used for the sides of the threads. Knowing the diameter of the gauge and the angle of the threads, its proper relation to the crest and root of the thread could be calculated. He (Mr. Taylor) constructed a small gauge for each pitch, and used a series of gauges to measure the angle between the sloping sides. In the common methods of making screws he said there were certain defects. Opticians generally employed a ring gauge and a plug gauge. These must be made of steel left soft, and they were especially liable to become worn. If the ring gauge fitted easily it had to be eased, and if they were only one one-thousandth of an inch wrong, they did not fulfil the conditions of free interchangeability in keeping and assuring such accuracy as were wanted. The workmen said they were all right when they fitted loosely. How loosely? Even if the gauges were correct, any method which depended on the workmen could not be considered satisfactory. Having described the ordinary plan of cutting screws, and pointed out that it admitted of variations and errors, he said he designed a chaser several years ago which was itself a portion of a screw. It had little screws, with only two threads, and was produced in a screw-cutting lathe. The form of thread was easily measured by test pieces. The tool retained its original cutting angle and it was impossible to set it wrongly. There was no temptation for the workman to neglect the sharpening of the tool. Having described the chaser in action, Mr. Taylor said it had been used at Leicester for some time with a remarkable degree of accuracy. A hardened steel gauge was applied as a caliper to gauge the full outer diameter of male screws, one side of the gauge being one-one-thousandth of an inch less than the other. Disc gauges were used for female screws, one gauge being of the correct diameter, the other one-one-thousandth of an inch larger. Having noticed the American screw and pointed out that its flat crest allowed of the sides being easily pressed out of shape, he said the Whitworth screw was better adapted for English lenses. In conclusion, he referred to the plan he had devised of making the lenses arrive home in one position by making the threads of every male screw arrive at the thread of the female screw in one uniform position in relation to the diaphragm indicators, and compared it with the ordinary method of screwing home lenses, which he pointed out was uncertain.

Mr. Leon Warnerke congratulated Mr. Taylor on his championship of the standard-screw system.

In reply to Mr. Bolas, Mr. Taylor said the chaser he had devised was not adapted for hand work.

Mr. T. R. Dallmeyer pointed out that in manufacturing screws, opticians had for years worked with two gauges; the master gauge and the gauge for the workman. If the gauges were too large or too small the master gauge would correct them. He thought Mr. Taylor in his modesty had made too little of his work in making all lenses arrive at one point. In his experience people did not want the Society's standards, although if he (Mr Dallmeyer) were starting to morrow he would make his screws to those standards.

After other discussion, a vote of thanks was passed to Mr. Taylor.

A New Lens: "The Double Anastigmat."

Dr. C. P. Goerz, of Berlin, read a paper on this subject, in which, having briefly traced the efforts of opticians to produce lenses free from astigmatism, he alluded to the efforts of Mr. Emil Von Hoegh, his scientific adviser, to produce a symmetrical anastigmat perfectly corrected for spherical aberration and astigmatism. The lens is called the Double Anastigmat, both combinations being anastigmatic, and is composed of two compound lenses, each of which is a cemented triple. In both combinations a flint is enclosed between two crowns. One of the crowns has a higher refractive index than the middle flint (a necessary condition for anastigmatism and the other a lower index of refraction (a condition for freedom from spherical aberration). The astigmatism is corrected over the whole field up to the angle of 72°, and the image is perfectly flat. The two optical systems are placed very near each other, ensuring uniform illumination. The lens is made in two series—III., with largest stop *f*·7·7; and IV., with *f*·11. Series III. takes an angle of 70° with full aperture, and with a smaller stop 90°. Series IV. is intended for reproduction work. The paper concluded with a reference to some comparative trials of the lens against other lenses. A large number of prints in illustration of its capabilities were passed round.

Mr. W. E. Debenham complimented Dr. Goerz on the fairness of his reference to the work of other opticians, and said that, by the specimens shown, the lens appeared to him to be a great additional power in the hands of photographers, especially as it enabled them to work over a flat field without introducing small apertures.

Mr. Dallmeyer said that, by following up what had already been done in the double form of producing a system free from astigmatism, and by using triple combinations, Dr. Goerz had arrived at a larger aperture with flatness of field and greater rapidity than hitherto. He (Mr. Dallmeyer) had not been able to obtain an intensity ratio of more than 1 : 10 with three samples of Chance's glass, similar to that employed by Dr. Goerz.

Mr. Warnerke saw Dr. Goerz's lens last February, and then suggested to him to bring it before the Society. The anastigmatic properties of the lens seemed to him better evidenced in the diagrams shown than on the ground glass, and he therefore suggested that the Kew, or optical, method of testing lenses required supplementing by the camera test.

Mr. Goerz expressed his willingness to allow the lens to be tested against English lenses. The English makers' lenses would not be too much behind, but they would be a little.

The President, in proposing a vote of thanks to Dr. Goerz, which was cordially given, spoke of the excellent nature of the pictures given by the lens. He combated the remark of Mr. Warnerke that the Kew method of testing lenses should be supplemented with photographic tests, saying that just as good results could be obtained by optical means.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

June 8,—Mr. Alexander Mackie in the chair.

Mr. S. H. Fry called attention to a letter in a photographic journal referring to some remarks of Mr. Everitt at a previous meeting on the Sandell plates as to range of gradation.

Mr. P. Everitt said the complete rendering of such gradation was not possible. The scale on a plate, say, one to fifty, would be one to twenty on paper; therefore the paper renders the range imperfectly.

Mr. Debenham thought the terms gradation and density were not clearly expressed. Ordinary and Sandell plates differed in respect of density.

Mr. A. Cowan did not see why if one plate gave density another plate should not.

Mr. J. S. Teape quoted his experience as to the printability of dense parts of plates on paper, but could get a much better gradation on positive plates.

Mr. Fry, in reference to the Sandell plates, claimed that they in themselves were an advance, and that their gradation was an inducement to find a printing process better than that which now exists.

Mr. R. Child Bayley considered that, in development, it was possible to have in view the after-process of printing, but this was thought to be a reversal of the order of things.

A discussion arose on Mr. W. K. Burton's paper in *Photographic Scraps*.

Mr. Cowan promised to make some experiments with reference to what he said on the latitude of exposure, and bring results up at the next meeting.

MANCHESTER PHOTOGRAPHIC SOCIETY.

June 8,—Mr. Abel Heywood, jun. (President), in the chair.

After the election as a member of Mr. F. W. Masters,

Mr. J. Wood opened a discussion on *Development*, which, in a manner, is a subject that has been pretty well thrashed out time after time; but for all that there is always something to be learnt from the comparison of methods and results. In spite of the many new agents, ammonia and pyro, from the tone of the discussion, are not yet displaced amongst the Manchester members.

The President gave the results of some experiments in the intensification of platinum prints. He said that, seeing an article in the Journal on the subject tempted him to give the method a trial, and he considered the result he obtained on some under-developed prints showed that a flat picture could be improved to some extent. The principle was much after the manner of the silver intensification of a wet plate.

Mr. Wrigley gave a report of the first outdoor meeting at Smithell's Hall, which had been well attended and successful as regards photography. He exhibited results of his own work, which were in every way excellent. Other members also showed profitable results from the outing.

THE AFFILIATION OF PHOTOGRAPHIC SOCIETIES.

June 6,—Meeting of Delegates, at 50, Great Russell-street, Bloomsbury, Mr. Andrew Pringle (Photographic Society of Great Britain and West Kent Amateur Photographic Society), Chairman, presiding.

The minutes having been read and confirmed, a balance-sheet up to April 30, showing a balance in hand of 27*l.* 7*s.* 10*d.*, was read by the Secretary, and adopted.

It was proposed by Mr. Beckerton (Richmond Camera Club), seconded by Mr. Criswick (Greenwich Photographic Association), and carried, that a balance-sheet should be prepared by the Treasurer up to December 31 in each year, and, having been audited by two auditors appointed at the first meeting of delegates in the same year, shall be presented at the first meeting in the ensuing year.

Messrs. Hodsoll (North Kent Amateur Photographic Society) and Beckett (Hackney Photographic Association) were appointed auditors for the current year.

It was proposed by Mr. Marchant (North Middlesex Photographic Society), seconded by Mr. Bickerton, and carried, that Mr. Scamell be asked to continue to act as Treasurer.

A discussion took place upon the question of approaching the railway companies with a view to the reduction of fares to photographers. A letter from the Birmingham Photographic Society having been read upon the subject.

Mr. Horton (Birmingham Photographic Society) detailed the steps already taken by his Society in the matter.

The Secretary announced that the aggregate number of members represented by the Affiliation was, roughly, 5000.

A Committee, to consist of Messrs. Mackie (Photographic Society of Great Britain) and Oakden (South London Photographic Society), and the Secretary, was appointed to investigate the whole question of reduced railway fares to photographers, to report at the next meeting.

A letter from the Hon. Secretary of the Phototographic Society of Great Britain was read, announcing that that Society was arranging for a Congress, and asking for the consent of the Committee for the words "of Affiliated Societies" to be added to the title, "The Congress of the Photographic Society of Great Britain," which was agreed to. The letter also asked the delegates to invite suitable members of their Societies to furnish papers for the Congress.

The CHAIRMAN announced that the papers already promised were from men of the very highest standard in the photographic world. He also made some remarks as to the powers of the Committee of delegates, and, after some discussion, it was resolved that a sub-Committee be appointed to consider the question of additions or alterations to the existing rules, on the understanding that their recommendations should be on the Agenda paper of the next meeting, the sub-Committee to consist of Messrs. Mackie and Marchant.

It was agreed that the hour of meeting should be 7.30 p.m.

A discussion took place upon the subject of a uniform ticket, and it was understood that the Secretary should urge the affiliated societies to have their members' tickets stamped with the Affiliation stamp.

North London Photographic Society.—June 6, Technical Meeting. Mr. Tanner in the chair.—Mr. GROVER intimated that the Sandell plate was doubtless a good plate when you knew it, but you had got to know it first. He showed prints from a negative taken on one. Subject, the interior of a church. Exposure, one hour, in the afternoon. Development took twenty-five minutes. Around the east window there was as much halation as he knew what to do with. After taking a print, he rubbed down the density about the window, and the after-prints showed a great improvement. Mr. BISHOP had again tried the Lomberg plate, this time for portrait work, and was much pleased with the working of them. Mr. WALKER, referring to the latitude of exposure with single films, showed prints from negatives taken on Edwards's plates, backed with "anti-halation paper." No. 1 plate was exposed for twenty-three seconds (the normal exposure, according to Watkin), and, immediately after, No. 2 was exposed for two minutes fifty seconds, developed with pyro and ammonia. He could be happy with either, but perhaps preferred No. 1. There was very little difference in the prints. Mr. Bishop showed dark slides he had made of strawboard and bookbinder's cloth. A piece of the board, covered with black velvet, fitted against the back of the plate. The slides were extremely light and effective, and very ingeniously made. Mr. TANNER recommended leatherette, a material used for covering furniture instead of the bookbinders' cloth. Mr. Tanner showed a good collection of prints from negatives taken last Saturday at the Trooping of the Colours. Asked as to the necessity for obtaining permission to take photographs on the occasion, Mr. Tanner said he did not know if it was required. He used the *suaviter in modo* process, with the addition of a little free silver, and usually found that sufficient.

Hackney Photographic Society.—June 6, Mr. E. Puttock in the chair.—Mr. Magnus was elected a member. The Hon. Secretary distributed samples of the Barnet plates. Mr. A. Dean then gave in report of excursion to Loughton on Derby Day, which concluded with a social. Work was then shown by Messrs. Hensler, Dean, Richardson, and Wire. The rest of the evening was devoted to a private exchange and sale, the idea being that many members had accumulated a lot of photographic accessories which were useless to them, but would be valuable to others.

Correspondence.

☛ *Correspondents should never write on both sides of the paper. No notice is taken of communications unless the names and addresses of the writers are given.*

CENTRAL PHOTOGRAPHIC CLUB.

To the EDITOR.

SIR,—The delay in issuing the prospectus of the proposed Company has arisen owing to the time occupied in the further negotiations which have taken place between the executive and the landlords of the premises proposed to be taken, and their solicitors, with reference to the form in which the landlords are willing to lease the property.

Most of the points at issue having been now disposed of, a provisional prospectus is now being issued (a copy of which I send you). We wish to take this opportunity of apologising to the numerous applicants for copies for the apparent neglect on our part to furnish same before.—We are, yours, &c.,

W. FENTON-JONES,
CHAS. H. OAKDEN, } *Hon. Secs.*

Central Photographic Club, Fleet-lane, Ludgate-circus, E.C., June 12, 1893.

Provisional Prospectus. June 10, 1893.

THE CENTRAL PHOTOGRAPHIC CLUB COMPANY, LIMITED. FLEET-LANE, FARRINGDON-STREET, E.C.—Capital, 1000*l.*, divided into 200 shares of 5*l.* each; 2*l.* 10*s.* payable on application; 2*l.* 10*s.* payable at twenty-one days' call. *Hon. Directors:* Thomas Fall, Esq., 9 and 10, Baker-street, N.W., President of the National Association of Professional Photographers; John Howson, Esq., Brockenhurst, Ilford, E.; George Mason, Esq., 180 and 186, Sanchiehall-street, Glasgow, President of the Photographic Convention, 1893; with power to add to their number.—*Bankers:* The City Bank, Ludgate-hill, E.C.—*Auditor:* E. A. Whitby, Esq., Accountant, 26, Philpot-lane, E.C.—*Hon. Secretaries:* W. Fenton-Jones, 12, King Edward-road, Hackney, N.E.; C. H. Oakden, 51, Melbourne-grove, East Dulwich, S.E.

It is proposed to form the above Company, with such alterations in its constitution, capital, directorate, and otherwise as circumstances may render necessary, for the purpose of providing, fitting up, and furnishing a Club-house, and other accommodation and convenience for the use of the Central Photographic Club, which has recently been formed to provide a central meeting place for all gentlemen interested in photography, whether professionals, amateurs, or traders.

Negotiations have been opened with the owners of premises at the back of the Memorial Hall in Farringdon-street, which are considered most suitable for the purposes of the Club, subject to certain structural and other alterations, which, if negotiations are carried through, the owners will make.

The terms of the negotiation are, that the Company shall take a lease, subject to the usual covenants, for twenty-one years (determinable at the option of the Company at the end of seven or fourteen years), at a rental of 200*l.* per annum, in addition to the amount paid for fire insurance, and that the Company should, in some manner to be hereafter agreed upon, secure the payment of the rent, and performance, and observance of the covenants of the lease; it has been suggested that this security shall be a charge on uncalled capital of the Company to the extent of 250*l.*

The premises, if acquired by the Company, will be fitted up with dark-rooms, enlarging-room, smoking-room, and will contain a large meeting-room (capable of accommodating over 200 people), committee-room, library, and lavatories, &c. Negotiations are also in progress for suitable refreshment accommodation.

Amongst the objects aimed at in the formation of the Club are the providing of premises (1) Where photographers (amateur and professional) may develop plates, make enlargements, or leave their cameras during the day or evening. Lockers will be provided at nominal fees; (2) Where they may also have opportunities of meeting for the discussion of matters of mutual interest; (3) Where manufacturers and dealers can meet their agents, customers, and friends.

Besides these points, the usual attention will be paid to the holding of regular weekly meetings, for the discussion of photographic matters, demonstrations, lantern nights, and the exhibition of photographic novelties in apparatus and inventions.

The promises of support in the way of intending members of the Club are most satisfactory, and fully justify the promoters of the Club in saying that, if the capital necessary to suitably equip and furnish the Club premises is forthcoming, the Club will be a success, both financially and socially.

After the premises have been acquired and fitted up by the Company, they will be sub-let to the Club at a rental which, it is anticipated, will be sufficient to pay a dividend of five per cent. on the subscribed capital, and to provide a sinking fund for the sustentation of the premises, and the renewal of the furnishings, &c., and the expenses of carrying on the Company.

Before going to additional expense in the formation of the Company, and the further promotion of the Club, the promoters feel that it is necessary to ascertain how far they may hope to be supported by the photographic public in the matter of capital, and with this object you are invited to fill up and return, at the earliest possible moment, the enclosed form, specifying how many shares you will be willing to take in the proposed Company.

The liability of the shareholders will be limited to the amount of their shares, and no promotion money has been or will be paid, and, in the event of the non-formation of the Company, the provisional committee will bear all the expenses incurred.

Promises to take shares have already been received from Miss C. W. Barnes, Mrs. Welford, Messrs. Birt Acres, R. Beckett, T. Bedding, Frank Bishop, A. Cowan, Austin Edwards, B. J. Edwards, Thomas Fall, W. Fenton-Jones, J. T. French, T. E. Freshwater, J. O. Grant, John Howson, J. Martin, George Mason, T. J. Powell, John Reynolds, J. T. Sandell, Woodham Smith, J. S. Teape, E. J. Wall, H. Snowden Ward, W. D. Welford, W. Wentworth, E. A. Whitby, Britannia Works Company, and Percy Lund & Co.

Your particular attention is directed to the fact that, unless a sufficient number of shares in the Company is subscribed for and taken up by those interested in the matter, the Club, which promises to be of such great value to the photographic world, and to which so many promises of membership have been already received, will not be brought to a successful issue. You are earnestly requested, therefore, to give the matter your careful consideration, and to return the enclosed form, filled up, on or before the 24th instant.

Date.....1893.

In the event of a Limited Liability Company being formed on the lines mentioned in the Provisional Prospectus of the CENTRAL PHOTOGRAPHIC CLUB, LIMITED, *of the 10th day of June*, 1893, *with such variations as circumstances may render necessary, I will subscribe for and take up*.....*shares in such Company, to a nominal value of not exceeding* £.....*as and when I shall be required so to do.*

Name.....
Address.....

To MR. C. H. OAKDEN, 51 Melbourne-grove,
East Dulwich, S.E.

HALATION.

To the EDITOR.

SIR,—I notice a letter from Mr. Stringer in the "Correspondence" column of your last issue respecting halation, in which he disputes the tendency of very rapid plates to this fault. I spoke from my own experience as to the effect of rapid and slower plates for the difficult class of subjects alluded to, and have *invariably* found the slower plates give the best results. The reason is sufficiently simple. All emulsions, and I have made many, when examined by the transmitted light of a gas flame, are, at the outset, orange. As the emulsifying progresses, this orange colour gradually disappears, and gives place to blue or grey; at the same time the emulsion becomes more and more rapid to a certain

point, the particles of bromide having become, from a very fine closely compacted condition, in which they were when the emulsion transmitted orange light, more loosely aggregated and larger—that is, the silver salt becomes coarser when high sensitiveness is obtained, and in a much less resistent state with regard to the lateral dispersion of actinic light, than before. If we could get the orange or fine state of division, at the same time exalted sensitiveness, there is no doubt I should have reason to alter my opinion, but at present this desirable combination has not, I am aware of, been found. If iodide exists in any considerable quantity in a film, it will impart a creamy yellowness when examined by daylight, different to when it is only in minute quantities or absent, and this larger quantity of iodide I prefer for the work alluded to. Mr. Stringer may produce the best results—that is, negatives entirely free from halation—on the very rapid plates; I cannot, and I do not think myself singular in this experience.—I am, yours, &c., EDWARD DUNMORE.

THE LIGHTING OF GROUPS.

To the EDITOR.

SIR,—You would add to the interest of your "Groups" article if you would tell me how to avoid the heavy shadows and strong lights I get in outdoor work, as per the enclosed example.—Yours, &c.,

YOUNG AMATEUR.

[See Leader.—ED.]

Answers to Correspondents.

J. MILNE (Aberdeen).—Received. Thanks.

LENS.—A lens of the Euryscope type is commonly employed for studio groups.

B. MITCHELL.—The best and safest hypo eliminator from prints is water, frequently changed. Nothing is better.

W. BIRRELL.—We fear we cannot assist you in the matter. Write to the gentlemen named who may be able to advise.

N. S. BROWN.—You are wrong in your surmise as to the plates having been tampered with in the manner suggested. Some other hypothesis will have to be adopted.

F. F. W.—We cannot say the actual pressure in pounds or hundredweights that a print is subjected to in burnishing. Of course, that would all depend upon the adjustment of the regulating screw.

T. O. FOX.—In all probability the lantern you saw in the demonstrations at the Society of Arts last year was illuminated by the electric light. The arc light is, we believe, solely employed in the Society's lantern.

SINED.—We can give no definite clue to the yellow spots. They may have arisen from particles of hypo in the air that have settled on them in course of preparation, but this is merely a surmise. We do not think the mounts are in fault.

R. T. A.—Unless you have some chemical knowledge, and we gather from your letter that you have not, we fear the results arrived at will not be very conclusive. You cannot do better than get the works named: Fresenius' *Analysis: Qualitative and Quantitative*, 2 vols.

A. T.—English plates may be obtained at most of the principal towns on the Continent, but there is, of course, the possibility that they may have been a long time in stock. The only way of avoiding the chance of getting stale plates is to procure them direct from the makers and taking them with you.

COUNTRYMAN.—You will not be allowed to photograph any of the objects of the British Museum unless permission is first obtained, even with a hand camera surreptitiously, for, unless we are mistaken, parcels are not allowed to be carried about the building. There will be no difficulty in obtaining the necessary permission if you write to the Trustees stating your object.

T. W.—Although the engraving is your own property, and you have paid a high price for a proof print, it will be illegal to copy it, even as a lantern slide, without the sanction of the owners of the copyright, and that, we know, they will give. It is true the print is yours, as you have purchased it; but possessing the print does not entitle you to infringe the copyright in it.

ALF. BENYON says he recently bought a portrait lens, bearing the name of a well-known maker, through an advertisement, but cannot obtain a sharp image with it. On taking it to pieces, he finds that the back lens is a single piece of glass, a concavo-convex, and asks if the back should not be made up of two lenses?—Yes certainly. One of the glasses is missing. The front combination may, however, be used as a single lens for such purposes as it may serve; but as a portrait lens the instrument, as it is, is worthless.

MR. W. A. BEZANT writes: "Can you give me any information as to the possibilities of photography—that is to say, of obtaining pictures during a trip to Norway on one of the yachting steamers so much advertised? Of course, some work could be done on land; but what I want to know more particularly is whether much good could be done from the deck of the vessel with a stand camera, and if the light is good enough to permit of shutter exposures with, say, a Ross rapid rectilinear at *f*·16 or *f*·22, or would you recommend me to trust to a hand camera?"—Doubtless many of our friends who have photographed in Norway will be glad to give Mr. Bezant the information he requires.

S. A. H.—The studio shown in sketch No. 3 will be by far the best for general all-round work. No. 1 is very good in skilful hands, but is seldom used now. With regard to No. 2, it has only been put forth as a suggestion, and is scarcely likely to be adopted—at least by professional photographers.

T. EVANS writes: "I wanted a dead-black varnish for the inside of some lens mounts, and mixed some lamp-black with thinned white-lard varnish. The black was dead enough when dry, but the surface was quite rough and covered with small lumps. I cleaned this off and mixed some lamp-black with black varnish, and this also behaved the same. Why is this?"—The reason is that the black was not intimately incorporated with the varnish. Had it been ground up in a mortar with the varnish there would have been no unevenness.

O. Z. says: "The solar camera I am told can be used, and is used abroad, for making enlargements from small negatives direct on albumenised paper. If that is so, surely direct enlargements in carbon can also be made, as the sensitiveness is about the same, and thus avoid the trouble and cost of having to make first a transparency, then an enlarged negative to print from. Has the thing ever been tried, or is my idea original? It must certainly be practicable."—Well, the idea is not original, as enlargements are being produced daily by this means in some countries. As however the solar camera cannot be worked when the sun is not shining, the system is practically useless in this country.

RECEIVED.—H. L. Morel, John Rowden, M. H.

MR. J. BISHOP, photographer, has removed from 41, St. George's-road, N.W., to 19, Princess-road, Regent's Park-road, N.W.

LEICESTER AND LEICESTERSHIRE PHOTOGRAPHIC SOCIETY.—June 24 (half day), Barkby and district. July 13, Warwick. August 10, Chesterfield and Bolsover. September 14, Ashby and Coleorton.

NORTHERN PHOTOGRAPHIC AND SCIENTIFIC ASSOCIATION.—June 21, Lecture on *The Chemistry of the Dry Plate*, by Mr. Charles Coulter. July 1, Excursion to Natural History Department British Museum at South Kensington.

LEYTONSTONE CAMERA CLUB.—June 17, Hayes and Keston, Kent. Leader, Mr. F. Lohmeyer. The Club will proceed by the train leaving Cannon-street at quarter to three, arriving at New Beckenham at thirteen minutes past three.

THE AFFILIATION OF PHOTOGRAPHIC SOCIETIES.—The meeting of Judges of photographic Exhibitions, which has been already mentioned in our columns, will take place at 50, Great Russell-street, W.C., on Tuesday, June 20, at 7 p.m.

MANCHESTER AMATEUR PHOTOGRAPHIC SOCIETY.—June 17, Gawsworth and Marton. Leader, Mr. Fleming. Train, London-road (L. & N.W.), one o'clock p.m. for Macclesfield. Fare, 1*s.* 6*d.* By carriages, Macclesfield to Gawsworth. 21, Arley and Great Budworth. Leader, Mr. J. Davenport.

THE two following titles of papers to be read at the Convention arrived too late to be included in the list published last week:—*Our Pictorial Failures*, by the Rev. F. C. Lambert, M.A.; *Latitude in Exposure and Speed of Plates*, by Dr. F. Hurter.

WE are extremely sorry to learn that Mr. Walter Clayton, photographer, who recently disposed of his studio, Portland House, London-road, Leicester, and who has since made his home at St. Luke's-road, Bayswater, was drowned on Thursday afternoon while bathing. He was accompanied by his son, who missed his father soon after the latter had entered the water, and at once went for assistance. Three boatmen responded to his call, and succeeded in finding the body after about ten minutes' search. Efforts were made to restore animation, but without success. Mr. Clayton was staying at Torquay with his wife and family.

THE STAMPING OF WORKS OF ART.—At the inaugural dinner of the Incorporated Publishers' Association, recently held at the Hotel Victoria, considerable business was combined with the pleasure. Sir David Salomons, Mr. W. L. Wyllie, A.R.A., and Mr. Frank Walton, R.I. were elected Vice-Presidents of the Association. The rules and regulations for the stamping of literary works were adopted, and the following amendment to Clause 7 of the regulation for the stamping of works of art was carried. "That when the painter and publisher of a work of art reside in a foreign country, and the work is engraved or reproduced in another, such work may, at the option of the Council, be permitted to be stamped before the signature of the artist is affixed to the first State impressions." This amendment is introduced to meet the case of American publishers who are having native pictures reproduced in England or France, and to save them the extra outlay of time and money which a double journey across the Atlantic would entail, together with Customs and other duties.

*** *Owing to exceptional pressure on our space, several Society reports, letters, answers to correspondents, &c., have had to be held over.*

JOURNAL OF PHOTOGRAPHY.

No. 1729. Vol. XL.—JUNE 23, 1893.

JUDGING AT PHOTOGRAPHIC EXHIBITIONS.

An influential meeting of gentlemen who have been accustomed to act as Judges at Photographic Exhibitions was held in the rooms of the Photographic Society of Great Britain on Tuesday evening, under the presidency of Captain Abney, F.R.S. It was called together on the suggestion of the societies affiliated to that of Great Britain to arrive at some common basis of action relative to judging at exhibitions.

Among those who were present were Captain Abney, Valentine Blanchard, F. P. Cembrano, A. Pringle, W. England, Colonel J. Gale, L. Warnerke, Rev. F. C. Lambert, W. L. Colls, W. E. Debenham, W. D. Welford, and J. T. Taylor. Out of thirty-eight Judges, letters expressive of entire sympathy with the objects of the meeting were received from twenty-six, who, living for the most part at a distance, or owing to other engagements, could not be present. Various rules and recommendations were adopted, and those present were understood as agreeable to abide by them on all occasions on which they in future might be called upon to officiate in a judicial capacity.

In what follows, we give in condensed form the rules and recommendations adopted, it being premised that, while nothing important has been omitted, they are here given in only a somewhat crude form, for, having to go early to press, we do not wait till the Secretary has had time to draft them in regular form. When this has been accomplished, we will again reproduce them, as it is a matter of importance to all societies who purpose holding exhibitions.

In all Exhibitions the Judges' decision is to be final as regards their awards. The Judges shall have power to withhold any award. They also shall have power to give special awards when they see fit. The Judges shall have the right to exclude from the room every person while making their awards. The travelling and, where necessary, the hotel expenses of the Judges shall be paid. When the Judges have to spend a night from home, it is suggested that they should not be lodged at the house of any of the competitors. The number of awards are strongly recommended to be limited, seeing that a lavish distribution of medals tends to lower the value of such awards. No awards are to be made for pictures produced by, or sent to advertise the wares of any trading firm, and it is suggested that Committees of Exhibitions discourage any offers of assistance by special trading firms. Pictures previously medalled must be exhibited in a class by themselves. Each picture of a *set* which has received an award shall be considered as a medalled picture for competitive purposes. An award is to be made to one picture only, unless from the nature of the subject the pictures bear an obvious relationship to each other. No distinction between professionals and amateurs shall be made. No production from the same negative, whether ordinary print, enlargement, lantern slide, or otherwise, can receive more than one award. It is recommended that the number of classes in an exhibition be as few as at all possible, and it is also suggested as being very undesirable that any award take the form of a money prize. No picture shall receive more than one award at the same exhibition. With regard to lantern slides, no award shall be made for a slide without its having been projected on the screen.

For a long time past dissatisfaction, whether well or ill founded or not we shall not now stay to inquire, has been expressed with regard to the action of Judges at photographic exhibitions. Primarily, this has arisen from there not being on the one hand a set of generally recognised rules by which societies and exhibitors were to be bound, and, on the other hand, regulations to which the Judges themselves could, on occasion, refer as the source of their authority. By the heads of the agreement arrived at in the course of the meeting above referred to, these difficulties will be removed, so that in future societies, Judges and exhibitors will have the ground cleared of many obstacles to a general understanding on the subject.

As a basis for a set of working regulations, the resolutions come to at the meeting referred to strike us as difficult to improve on. In placing the powers of Judges within wide limits great wisdom is shown, especially taken in reference to the fact that the rules for exhibitors are also to be laid down with equal clearness. The movement in favour of the abolition of distinction as to classes simplifies the course to be followed by societies and individual exhibitors, and the praiseworthy determination to place under a ban those exhibitors who are fond of puffing up by their pictures individual vendors of photographic preparations will cleanse photography of an undesirable element which threatened to assume unpleasant dimensions. That there should be no distinction between amateurs and professionals for competitive purposes is also a step in the right direction; and the especial provision instituting a champion class for pictures previously distinguished by awards is also a salutary one in the interests of less successful exhibitors. On the whole, these and the various other resolutions, to which we hope to revert, are, we consider, conceived in a spirit likely to lead to the elevation of the status of Exhibition photography, and we hope that a universally acceptable set of conditions will result from them.

ANOTHER SOCIETY WANTED.

Considering that there are so many photographic societies already in existence, it may seem somewhat anomalous to suggest that even a single one more may still be desirable. There are, it is true, societies in almost every large town, yet there is not one in the whole of the United Kingdom which is confined exclusively to operative photographers. There was, and possibly is now, one in New York, and a very excellent and useful Association it was to its members. It will be remembered that an attempt was made in London a couple of years or so ago to start an Assistants' Union, but that was to have been conducted on Trade Union lines, with the object of fixing a definite rate of wages, regulating the hours of labour, and like matters. As we indicated at the time, such a combination was scarcely likely to meet with much success in a business like photography.

The society which at the present time may be desirable is one of operative photographers that would confer some kind of status upon its members. We are led to this idea by the comments made at the last meeting of the National Association of Professional Photographers with regard to the subject of *certificates*, where the President is reported to have dwelt at length on the "very unpractical character of the certificates now issued by the London Polytechnic Institution, which were merely good for a limited *chemical* knowledge." At the meeting the Council expressed a strong desire that a system should be devised to bring really capable assistants within reach of professional photographers, and it also suggested that, before the Polytechnic certificates are issued, "the students should be examined by some representative, capable, and experienced photographer." Possibly, however, this practical test might not prove altogether satisfactory to many of the students.

It may appear strange to some, now that so much of the material employed in the profession is purchased ready for use, that there should be a dearth of really capable operators; but, if one may judge from report, such seems to be the case. Some even go so far as to say that many who have gained high-class certificates in technical schools are the most incompetent in actual practice, and, what is more, they sometimes are the most difficult to teach anything beyond what they learnt in the class-room, and for which they were awarded their certificates. We have heard similar opinions expressed by Continental employers of many of the students turned out of the technical schools abroad, particularly with reference to photo-mechanical processes, a special feature in most foreign schools. One gentleman remarked to us that, in his establishment, in Germany, he preferred to take any intelligent person knowing nothing of the work, and teach him from the beginning rather than have one who had graduated in some of the technical schools. This certainly ought not to be the case either here or abroad. Still, it is a fact that many of our best and most successful workers now, and in times past, have had no theoretical or chemical knowledge whatever of the processes they employ. This was even the case with the wet-collodion process, in which a chemical knowledge was infinitely more essential than it is in modern photography.

But to go back to our subject. What professional photographers require, and what it is stated to be difficult to obtain, are assistants, not only with certificates of theoretical knowledge, but also with an assurance that they possess the practical ability to apply it in every-day practice. Seeing this, would it not be to the advantage of skilled workers in the various branches of the art to form a society or association amongst themselves for a mutual exchange of ideas, and furthering their interest generally, on a similar basis to that founded at New York? Should such a society be started, and only those of proved ability in actual practice, or of long experience in the various departments of photography, were eligible as members, its membership would carry with it credentials of a certain degree of ability, as does membership in some other crafts. The head-quarters of the society might be in London, meeting, say, monthly, with branches in most of the large towns. The meetings of these, where the members are few, might, to save expense, be held in any ordinary room. If formed, the society might be affiliated to the Photographic Society of Great Britain, which would add still further to its status. We imagine the Parent Society would gladly welcome any association established on the lines indicated, and afford it every facility. It was incidentally mentioned a little while ago, in connexion with photography as a business, that since the introduction of dry plates some people, with comparatively very little practice, and perhaps a little class instruction, feel themselves justified in styling and advertising themselves as operators. It is of this kind of thing that employers complain. Of course, this type of "operator" would not gain admission to a society such as that in question.

While writing, it occurs to us that the National Association of Professional Photographers might really take the initiative in the matter and invite operators to join their Society. Surely an operator is a professional photographer in every sense of the term, and, if he is of known ability and standing in the profession, why should he not be eligible for membership if only elected by the general body of members? The Association would then have the assurance that all those they have elected as members of their body are really capable men. It is more than possible that this idea, mentioned in the crude, if put into practice, might prove of mutual advantage to all concerned. There are plenty of societies composed professedly of amateurs, but there is not a single one consisting exclusively of professional photographers—to deal with trade subjects—which includes both employers and *employés*.

THE PERFECT FIXATION OF NEGATIVES.

Since we wrote on this subject a few weeks back, we have had a number of letters the burden of whose complaint is that there is no certain means of knowing when a plate is perfectly fixed or washed. Some of our correspondents go to the extent of averring that it is impossible to properly free some of the thickly coated plates now in use from hypo and hypo compounds so that they will go into the printing frame without danger of subsequent change.

This argument is based on the fact that after protracted immersion in the hypo solution—long after the apparent removal of the haloids—and when two, and in some cases three, successive baths have been used, followed by a washing of long duration, still signs of discolouration of the film have made their appearance in a very short time after the negative has been exposed to strong light in printing, or a worse evil has arisen when intensification has had to be resorted to. Without admitting the argument of impossibility of fixing, for we showed in our previous article the way out of that difficulty, we fully concur in the general desire expressed for a test of when a negative may be considered safe for future use in the printing frame or for further treatment with intensifiers.

It is now many years since we first decried the use of so-called "hypo-eliminators," and most of our correspondents seem to be at one with us in that matter. Although with ordinary plates—that is to say, with films of ordinary thickness, such as were the rule eight or ten years ago—and a fairly long immersion in the fixing bath, and proper washing afterwards, no harm would ensue upon the use of an eliminator even if the image had to be subsequently intensified, the case is quite different when abnormally thick films are in question. In the first instance, the fixing bath would have time to do its duty, and an hour or so's after-washing, if properly performed, would suffice to bring it into such a state that any decomposition products formed by the use of an eliminator would be present in such infinitesimally small quantity, if present at all, as to be quite harmless. Now, it is possible to put into the printing frame an apparently perfect negative which is so impregnated with silver compounds as to be itself sensitive to light, or which, if submitted to the action of any of the ordinary eliminators, or more especially to intensification, would give immediate evidence of the insufficiency of its previous treatment.

This is not a satisfactory state of affairs, and we have ourselves been latterly considerably troubled by it, but we believe we are in a position to point out a perfect safeguard against the evil of uncertainty as to the stability of the negative. The method we have to describe is neither in the form of an eliminator, nor is it a labour-saver in the matter of washing, but is a sure test of the presence of silver compounds, that may be applied without in any way injuring the negative or introducing dangerous decomposition products that may eventually lead to its destruction.

The action of the fixing bath is, we believe, pretty well understood, at least by those who take any but a mechanical interest in the production of negatives. The removal of the unaltered silver haloids is the first object aimed at, and, if this be effected in a sufficient volume of fresh solution of hypo, perhaps, under ordinary circumstances, no further difficulties would accrue. Thus, if a single negative were immersed in a considerable volume of hypo solution, until its unreduced haloids had just disappeared, it is probable that but an infinitesimally small quantity of soluble silver salts would remain in the film, the bath extracting nearly the whole, and what little remained would be easily removed by washing.

But when an unlimited number of negatives is fixed in the same bath, or when a thick film of gelatine, heavily charged with silver, is submitted to the action of even a fresh solution of hypo, the pores of the gelatine are so clogged with crystalline matter that perfect fixation becomes an impossibility, and subsequent washing, so far from helping matters, only tends to precipitate a portion of the silver as an insoluble form. Silver forms two combinations with hypo, the one soluble, the other insoluble, or nearly so; the former containing the larger proportion of hypo, and being formed only when the conditions are such as tend to perfect fixation. The latter results from the employment of a spent bath, or from insufficient action. The opalescent appearance we have spoken of as removable by washing no doubt consists of the former compound precipitated in the film, owing to its richness in silver, the comparatively small proportion of water contained in the wet gelatine being unable to hold in solution the quantity of double salt formed. Subsequent washing dissolves the bulk of it, but decomposes a portion, leaving on the film, it may be, a minute trace of the less soluble compound, which, besides being more or less sensitive to light, is also readily decomposed, leaving sulphide of silver as a brown stain.

The use of alum as an eliminator, by decomposing the sodium and silver hyposulphite, leaves the latter metal in the form partly of sulphate, partly sulphide, so that, if there be any considerable quantity present, the ultimate stain is only hastened. Peroxide of hydrogen or hydroxyl leaves the silver in the form of sulphate, a soluble salt which is removable by washing, though it leaves its influence on the gelatine, which will eventually discolour. The hypochlorites, in whatever form employed, convert the silver ultimately into chloride, besides acting upon the image itself in the same way, and without leaving any immediate signs of danger render the re-employment of the fixing bath a necessity.

It is a well-known fact that chloride, bromide, and iodide of silver dissolve in hypo in very different proportions, the first-named being very soluble, the last comparatively and slightly. If a solution of a soluble iodide be dropped into a hypo bath that has been used for fixing chloride or bromide films, even though it be far from saturated, a precipitate of iodide of silver will be formed, owing to the stronger affinity of iodide for silver in the first place, and the comparative insolubility of iodide of silver in the hypo in the second. No other decomposition occurs, and no change takes place, except between the iodine and chlorine. Here, then, is the basis of the test for perfect fixation.

If a gelatino-bromide negative be taken from the fixing bath as soon as the bromide has apparently been removed, simply rinsed in water, and immersed in a dish containing a solution of iodide of potassium, it will be found, in a very short time, to have reverted to much the same state as before it went into the hypo, in consequence of the soluble silver salts it contains having been converted into iodide. The density of the deposited iodide will, of course, depend upon a variety of conditions, but chiefly upon the thickness of the film and its original richness in silver, and upon the energy or strength of the hypo.

If the negative has been sufficiently fixed—that is to say, if the hypo has had sufficiently free access to the film to thoroughly convert the silver into the more soluble compound already alluded to—and is then submitted to a thorough washing, the iodide bath will produce no effect, and it will be known that all is right. But, if the fixing has been insufficient, and the less soluble hyposulphite of silver is present, or if the washing has not been sufficient to remove the soluble salts, then the iodide will tell its tale by converting any silver that remains into *visible* iodide, which can be removed by refixing.

The change—that is, the formation of iodide of silver—is not always rapid—does not, in fact, always make its appearance in the iodide bath itself, unless it be a case of imperfect fixation. If it is only insufficient washing, it frequently or generally occurs that the iodide is only precipitated on the film after the plate is removed into the washing water after the iodide bath, possibly on account of the solubility of iodide of silver in excess of iodide of potassium. It is desirable, therefore, always to allow the plate to rest in water for some time after treatment with iodide before finally drying.

This treatment, of course, necessitates a second fixation if silver prove to be present; but, as we have already stated, there is no danger to the negative, and the test is an infallible one. The quantity of silver remaining in the film as iodide is so comparatively small that there is little danger of a second fixing and washing leaving any at all. It should be under-

stood that the test is only to be applied after the ordinary washing is considered to have been sufficient, and preferably before the negative has seen strong daylight.

The addition of a few grains of iodine to the solution of iodide of potassium will hasten matters; but, as it may possibly lead to the formation of tetra-thionates salts, as unstable as the hyposulphites, it is better to adhere to the plain iodide.

Society of Arts Silver Medals. — The Council of the Society of Arts have awarded the Society's Silver Medal to Thomas R. Dallmeyer for his paper on *Tele-photography*, and to H. Van Der Weyde, for his paper on *The Pictorial Modification of Photographic Perspective by the use of the Photo-corrector or Visual Lenses in Portraiture and Landscape*, read during the Session 1892-93.

Technical Instruction for Beginners. — The North Middlesex Photographic Society, in their syllabus for the next few months, have arranged one or two personally conducted outings for beginners, subsequent evenings being devoted to the development of the plates then exposed. The classes are open to non-members of the Society, and should be productive of a large amount of practical good for those commencing photography. The North Middlesex Society is, so far as we are aware, the only Society that vouchsafes free instruction, and their action is deserving of every commendation.

Cheap Oxygen.—We are sure that the photographic fraternity will echo Sir H. E. Roscoe's hope—expressed in a review in *Nature*, upon the article on "Oxygen" by Dr. Thorne, in the newly completed grand *Dictionary of Applied Chemistry*—that oxygen may ere long be produced at 1*s.* per 1000 feet. According to this article, 3*s.* is the present cost, though the compressed gas necessarily costs very much more. Sir H. E. Roscoe says of the proportional cost of oxygen by the Du Motry process, improved by Fanta, given as from 3*l.* to 4*l.* per 1000, that he cannot help thinking it is incorrect. In any case, there is every chance for photography in these reduced prices. We can only hope with the reviewer that they will continue to grow—downwards.

High and Low-class Photography. — A correspondent whose business is principally with professional photographers, writing on the subject of photography as a business, remarks that in the depression of the last two or three years it is the middle-class man, who supplies a good picture at a moderate price, that has suffered most. The highest class houses, he says, have suffered less, while the lowest class with the most "cutting prices" have been least affected. If this be correct, and we have heard similar opinions expressed before, it does not look very promising for the artistic side of photographic portraiture amongst the upper middle-class public. With too many people a portrait is judged solely by the likeness, artistic quality in addition being quite ignored.

Eclipse Expedition Photographs.—Professor Therpe, the editor of the work above-named, exhibited some very interesting eclipse photographs at the recent Royal Society's *conversazione*, including autotype enlargements from photographs taken by himself, illustrative of the recent African Eclipse Expedition, the eclipse party, the observing party at Fundium Senegal, taken immediately after the eclipse, the duplex chronograph, the prismatic camera, the integrating photometer, the equatorial photometer. These were Professor Thorpe's exhibits. The Joint Eclipse Committee exhibited another class of eclipse photographs. They had photographs of the corona taken in West Africa, also of the spectra of the corona and prominences taken in West Africa, the corona taken in Brazil, photographs of the spectra of corona and prominences taken with the objective prism in Brazil; and photographs of the stations. These pictures, all taken together, greatly assisted those inspecting them in forming an idea of eclipse work, its ends, and the difficulties connected with the means.

Interference Bands.—Among the exhibits at the *conversazione* was one which possesses a special interest to photographers. Since the advent in a practical form of pinhole photography much has been said about interference bands and their effect upon the image. Indeed, the theoretical minimum diameter of a pinhole, capable of giving the best definition without interference bands destroying it, has been worked out by Lord Raleigh; but what these bands are is not very well understood. In the example we refer to light was allowed to fall on a mirror thinly silvered, so that about half of the light is reflected and half transmitted. The two rays pursue paths which are normally perpendicular, are reflected back by two ordinary mirrors, and, on meeting, interfere. The interesting part of this arrangement is that, by its means, the bands can be reflected on a screen; and this fact, together with the simplicity of the arrangements, will make the method a very useful lecture illustration.

Professor Thorpe on Past and Present Astro-Photography.—Professor Thorpe, lecturing on the Eclipse Expedition at the Royal Institution, explained how photography had altered the whole process of observing solar eclipses. Since the red-letter day, he said, in 1860, when Warren de la Rue first applied his photo-heliograph to the observation of the eclipse, the camera and its various modifications had come into use so as to practically supplant ocular observation. The camera was not troubled with nervousness, and, having no imagination, simply set down actual facts. The selection of an appropriate site for viewing the eclipse was not without difficulties. As everything depended on getting right under the moon's shadow, they had to follow that shadow about all over the earth for each new eclipse. Professor Thorpe entered into considerable detailed explanation of the arrangements, and said that the observations were very successful. The various prominences, rifts, and configurations in the great gaseous envelope of the sun were most clearly brought out, while some most important results were expected from an examination of the spectroscopic slides. One interesting question had been practically settled by these observations—namely, that the corona suffered no change of structure during short periods, for the Brazil photograph, taken one hour and a half later, was identical with the African one.

PHOTOGRAPHIC CONVENTION OF THE UNITED KINGDOM.

PLYMOUTH MEETING, JULY 3 to 8, 1893.

THE following is an official synopsis of proceedings:—

MONDAY, JULY 3.

No excursion. Opening of the Convention, and Reception by the Right Worshipful the Mayor of Plymouth (Mr. W. Law) at the Art Gallery and Lecture Hall of the Athenæum (6.30 p.m.). Presidential Address (7.30 p.m.). Optical Lantern (9 p.m.).

TUESDAY, JULY 4.

Steamer excursion to the Yealm and the River Tamar; Tavistock.

WEDNESDAY, JULY 5.

No excursion. General Meeting, 10 a.m. Meeting of General Committee, 11 a.m. Convention Group at the Guildhall-square, 12 a.m. Papers, to be read from 2 p.m. to 5.30 p.m.:—*Recent Developers*, by Mr. E. J. Wall. *Lantern-Slide Making*, by Mr. C. L. Mitchell, M.D. *Artistic Expression with the Hand Camera*, by Mr. J. Guardia. *Multiple Films*, by Mr. S. Herbert Fry. Reception at the Guildhall, Devonport, by the Worshipful the Mayor of Devenport (Mr. W. Waycott), 7 p.m. Optical Lantern, 8 p.m. Papers, to be read from 8.30 to 10.30 p.m.:—*Some Slides from the Marine Biological Laboratory*, by Mr. J. T. Cunningham, M.A. *The Special Properties of the Zeiss Anastigmatic Lenses*, by Dr. Paul Rudolph, read by Mr. J. Stuart. *Photography in Relation to Medical Record and Demonstration*, by Mr. A. Pringle. The morning and afternoon meetings will be held at the Western Law Court. The reception and papers in the evening will take place at the Guildhall, Devonport.

THURSDAY, JULY 6.

Excursion to Launceston, Totnes, and down the Dart. Leader. Mr. R. Hansford Worth (leaving Millbay at 7.55 a.m.). Excursion to Looe. Leader, Mr. G. Barnston (leaving Millbay at 9.10 a.m.). Excursion to Cheeswing. Leader, Mr. J. S. Hawker(leaving Plymouth by steamer about 8.45 a.m.). Papers to be read from 8 p.m. to 10.30 p.m.:—*Some Points in Connexion with Development*, by Mr. C. H. Bothamley. *On the Power of Compensating in Development for Variation in Exposure*, by Professor W. K. Burton. *Latitude in Exposure and Speed of Plates*, by Dr. F. Hurter and Mr. V. C. Driffield. *Our Pictorial Failures*, by the Rev. F. C. Lambert, M.A. The papers will be read the Western Law Court.

FRIDAY, JULY 7.

Excursion to Lydford. Leader, Mr. R. Burnard (leaving Millbay, North-road, or Mutley at 7.55 a.m. Excursion to Bickleigh Vale, Leader, Mr. Crook or Mr. Moore (leaving Plymouth at 8.25 or 11.20 a.m.). Excursion to Dockyard and Keyham, Cattewater. Leader, Mr. Tweedy (leaving Plymouth at 8.25 or 11.25 a.m.). Dinner and Smoking Concert at the Western Law Court at 6.30 p.m.

SATURDAY, JULY 8.

Council meeting, 9.30 a.m. Excursion to Princetown. Leader, Mr. Burnard (leaving Millbay, North-road, or Mutley at 8.45 a.m.). Excursion to Ivybridge (leaving Plymouth at 10.45 a.m.). Excursion to Virtuous Lady Mines. Leader, Mr. H. Alger (leaving Millbay at 11.20 a.m.).

All communications after June 27 should be addressed, the Hon. Secretary, Photographic Convention, Art Gallery, Athenæum-buildings, Plymouth.

A NEW STUDIO.

MESSRS. HILLS & SAUNDERS, the well-known photographers of Oxford, Eton, Harrow, &c., have recently opened a new photographic studio in London. It is situated in Sloane-street, in the very heart of the fashionable quarter of the town, among the denizens of which the quality of Messrs. Hills and Saunders' work entitles them to expect a good share of patronage.

The suits of rooms occupied by the firm is entirely on the ground floor, two tastefully furnished reception rooms, adorned with a good collection of specimens, and presenting a most agreeable *coup-d'œil* to the visitor, being immediately reached from the front entrance. To the right of the second of these is the dressing-room, an unusually attractive and spacious apartment, the appointments and decorations of which are in faultless taste. This admits a sitter to the studio.

The studio is of unexceptionable size, being seventy feet long and twenty-three feet wide, and of proportional height. It was formerly, we were told, the music room of a town mansion. Around the walls are arranged a large number of groups representing the Eton and Harrow cricket and football teams for a great many years past. The studio has evidently been arranged with an eye to handsomeness of effect, and the accessories, backgrounds, &c., are of an artistic nature. The electric light is exclusively employed, a Pilsen lamp, with a concave radiator, being swung so as to be readily adjustable. Power is derived from the Company's mains a light of eight to fifteen thousand candle power being obtained, the average exposure being from one to two seconds, which may, on occasion, be considerably reduced for children, &c.

The new studio, which we understand was arranged partly in accordance with the ideas of Mr. A. Cowan, is illuminated throughout with the electric light. It is a most elegant and luxurious addition to metropolitan studios, among which it is in several respects unique.

REVERSED NEGATIVES.

ALL who have had any experience of the different photo-mechanical processes, or of carbon or pigment printing are aware of the important part which reversed negatives play in such processes; and there is no doubt that many workers have been deterred from taking up the carbon process, in spite of its beauty and permanence, by the necessities represented by reversed negatives on one hand, and double transfer on the other. In ordinary practice, such negatives as I have referred to are prepared either by making a negative in the camera from a transparency (a carbon transparency by preference, or else by stripping the original negative film and reversing it), the process being often varied by mounting the stripped film on a collodion or gelatine skin, so that it may be conveniently handled, and, if necessary, used from either side. It has been hoped that the use of celluloid films would enable the negatives taken upon them to be used either direct or reversed; but, although this may be possible with some "rollable" films, the ordinary cut films show a marked loss of a definition if printed from the wrong side.

Having occasion to deal with some cases in which reversed negatives were needed, I have been much impressed by the advantage that would be gained could such be produced from original negatives by one process instead of by two or three, and some experiences which had occurred to me in connexion with the reversing action of light (now so fully recognised) led me to think that assistance might be found in that direction. I remembered that a good many years ago I carefully prepared a batch of emulsion for lantern plates, which was supposed to be very slow, but with which I could only print negatives. I wondered at the time what was wrong, and in my inexperience I threw the emulsion away, but since then I have learned to put the trouble down to the then practically unrecognised action of light reversal. Remembering this, and calling to mind what has been more recently written on the subject, I took up a series of experiments which have led me to a successful result.

I find that the process of making a negative from a negative by direct contact printing is as simple as printing an ordinary transparency or making a bromide print, the only difference being that the print is made on an ordinary bromide negative plate, and that the exposure is extended so as to secure the reversal of the image without over-doing the operation. Working with Ilford ordinary plates the exposure required with a good crisp negative I find to be about five seconds in strong daylight, not direct sunshine, the exposure being increased if the light be poor, even up to thirty seconds at about sunset. It is here, of course, that judgment becomes necessary, both as to the quality of the negative to be reproduced and the actinic power of the light employed, but only in the same degree as in bromide paper printing.

My earlier experiments were with the ordinary hydroquinone developer, and were successful, though development was slow. I prefer for this purpose to use pyro and ammonia, or best of all the new metol-Hauff, which, with a little bromide, works like a charm, the reversed negative coming up with all the crispness and force of an original. In the case of over-exposure, the image sometimes appears first as a ghost of a positive which sinks in and dies away as the negative comes up, but in such cases the result will not be satisfactory. If the exposure has been about correct, the negative will develop out in just the ordinary way, except that, the light having penetrated the film so deeply, care must be taken in judging density by looking through the film.

I find that I can depend definitely upon obtaining good reversed negatives every time by being careful, and I very cordially invite all who may be interested in such matters to take up the process, which theoretically should be a perfect one, and with the experience to be gained by more extended trial may, I believe, be made perfect in practice.

WM. BISHOP.

COMPENSATION IN DEVELOPMENT FOR VARIATIONS IN EXPOSURE.

[London and Provincial Photographic Association.]

ACCORDING to promise, I have brought to show you to-night the result of a few experiments on the question of "Compensation in Development for Variations in Exposure," on the lines suggested by Mr. Burton's paper. When the question was brought up at the last meeting, I ventured to say that, from my own experience, I did not think it was possible to get negatives giving identical prints, or so nearly similar, that an experienced photographer could not tell the difference between two negatives—one having the so-called correct exposure, and the other forty or eighty times more—unless the range of tones was practically limited to, say, two tones or little more. In the examples I have developed, one plate may be considered to have had a normal exposure, viz., a series of light intensities varying from half a second to thirty-two seconds, each step being double that of the previous one, and in the others an over-exposure of thirty-two times, viz., the first having sixteen seconds, and the last of the seven 1024 seconds.

I here show you the results, the negatives themselves, and also the curves of the densities as measured by the photometer, and

I scarcely think any one can imagine that the various negatives can by any possible means be considered identical. The first one (the normal exposure) was developed with—Pyro, 1 grain; anhydrous sodium carbonate, 4 grains; and potassium bromide, ½ grain; and the three over-exposed ones respectively by doubling the pyro and bromide each time, the last one having eight grains of pyro and eight grains of bromide to the ounce, the alkali in each case being kept constant. The time of development varied from six minutes in the case of the normally exposed plate to one hour and forty minutes in the case of the eight-grain pyro one.

I should explain here that what I tried to do was to make the lowest tint in the scale of each as nearly of the same density as I possibly could, leaving the higher ones to go on in their own way.

I notice that Mr. Burton in his article says his statement is not compatible at all with Messrs. Hurter & Driffield's, where they say the density ratios cannot be altered by development. Now, I think it should be clearly understood what they did say, which, if I understand them, is this: They first define what they consider to be a perfect negative, as one in which "the opacities of the gradations are proportional to the light intensities," and, after many pages of mathematical reasoning and records of many experiments, they say:—

"We have thus arrived at an answer to the question. Can negatives be produced such as we defined to be theoretically perfect? and the answer is they *can* be produced, but only by so carefully adjusting the time to the intensity of the light that the exposures may fall between the period of correct representation."

I must say, from my own trials of Mr. Burton's method, I cannot upset this contention. I may say here that I sent to four members of this Society duplicate pieces of each of the plates here shown, and I hope we may be favoured with the results of their experiments in the same direction. All I can say, in conclusion, that, at the present time, I am not able by Mr. Burton's method to upset the theory that correct exposure is the principal determinary factor in the production of correctly graduated negatives. That abnormal exposures can be made by alteration in development to give certain pictorial results, I am perfectly open to admit; but, in a subject of this kind, that is not the question. But what we are talking about is, Can forty or eighty times the correct exposure be made to give identical results by modification in development?

A. Cowan.

SUMMER NOVELTIES IN APPARATUS, ETC.

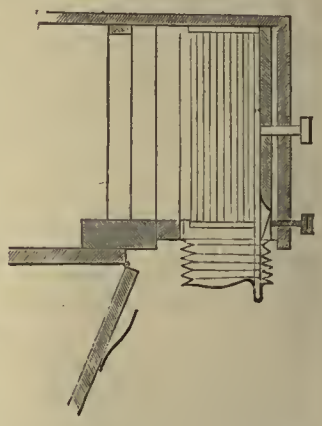
E. & T. Underwood, Granville-street, Birmingham.

When present at Messrs. Underwood's works, we were shown not merely specimens of their tourist cameras in the finished form, ready to be sent out, but the bodies and slides in various stages of completion, so that we could see the kind of work that is put in them. This we have little hesitation in saying is of a very high degree of excellence. The cameras, brass work, lens mounts, &c., are all made on the premises. Messrs. Underwood profess to keep their makes of cameras from ¼ to 15×12 in stock, but recently a difficulty has been experienced in adhering to this rule on account of the pressure of orders, which even while we were present were coming in by post. An especial favourite appears to be the "Club" camera, which, with all the requisite movements, is marked by great lightness and portability.

Among Messrs. Underwood's recent introductions are several hand cameras, which are distinguished by great simplicity of movement. "The Argosy" takes twelve plates in sheaths, the changing being effected from the outside. The sheaths being filled ready for exposure, to remove the exposed plate the camera is held with the shutter end slightly down, and the small knob at top of right side pulled out. The plate then falls forward on to the floor of the camera. The knob is pushed in again, and the second plate is in position. Every time the knob is drawn out a plate is released, and every time the knob is pushed in a plate comes forward ready for release. The sheath is held in position at each of the four corners, and, when released from the top corner, it is not allowed to go loose into the body of the instrument, as is the case in many cameras. The lower corners are provided with pivots, working in grooves, the return of the plates being prevented by suitable springs, and the plates cannot in travelling get cornerways, crossways, or in each other's way.

The "Argosy," which is fitted with finder, the ever-set shutter, and a single achromatic lens, is well made, and is exceedingly cheap.

Two other varieties of hand camera are the "City" and the "Sphynx," the latter being of a superior variety, having a rectilinear euryscope working at *f*·6·7, fitted with an iris diaphragm. The shutter is a roller blind working between the lenses. The focussing gauge outside is set instantly from five feet to forty feet, or infinity, and the camera has finders for horizontal and vertical subjects, accurately centered and deeply sunk, and measures 9½×5¼×4¼ inches. To both the "City" and the "Sphynx" cameras a bellows changing arrangement of great neatness and excellence is fitted, by which the front plate is removed to the back with ease, smoothness, and certainty in a few seconds, and without possibility of hitch, dust, or undue wear. The door at the under side of camera is unfastened and allowed to hang down, and the larger knob at the end of camera is pulled out firmly. This draws away the spring pressure, which keeps the front plate up to register, and allows it to drop into the bellows. The plate is then grasped through the flexible end of the bellows, conveyed along guides to the back, and pushed into place. The second plate of the series is then in focus and ready for exposure. The plate drops inside the bellows, clear of, and not touching, the folded sides, so that there is no wear or friction, no dust, scrapings, or loose plates. The mouth of the bellows is attached to a metal frame, fitting in a groove, and is kept in place by a small milled head outside back of case. This milled head being screwed out a short distance, the bellows are raised, the sheaths taken out, fitted with plates, replaced and screwed in.



Great simplicity is displayed in Messrs. Underwood's hand cameras, a feature which, with excellence and inexpensiveness, distinguishes all their apparatus. A handsome and serviceable 15×12 studio camera that we were shown exhibited these two latter qualities at their best.

W. I. Chadwick, St. Mary's-street, Manchester.

"What Lancashire thinks to-day England will think to-morrow," was a saying at one time frequently quoted, and that seems not unlikely to have some measure of application in the photographic world at the present time. To form an exact idea of the extent which what has been termed the stereoscopic revival has proceeded in amateur photographic circles, would be a difficult task that would, perhaps, not pay for the accompliahment; but we are probably not far wrong in the conjecture that, be that extent great or little, the immediate future will witness a still more marked popularity for stereoscopic work of possibly greater endurance than the present rage for the hand camera. If only some exalted personage would set the fashion for binocular pictures, society at large would be sure to follow, with, maybe, more æsthetic profit than is obtainable from the gentle art of pressing the button.

Photography is under a debt of gratitude to Mr. Chadwick for his efforts to revive interest in binocular photography and the stereoscope, and that considerable success has rewarded those efforts is due to the by no means common circumstance of the advocate understanding his case. For Mr. Chadwick not merely points the stereoscopic aspirant the way he should go, but lends him a helping hand. How valuable such assistance is, coming from an admittedly practical stereoscopist, everybody can appreciate who has encountered the vague apprehensions of abstruseness and difficulty which are commonly thought to be involved in stereoscopic work. To sit under Mr. Chadwick for half an hour, however, is to have stereoscopic photography presented in an aspect that looks, as the phrase runs, as easy as shelling peas.

It is not to be wondered, therefore, that Manchester, under the influence of Mr. Chadwick, has developed quite a stereoscopic colony; indeed, while in that town the other week, we were surprised at the number of amateurs who had adopted this fascinating branch of photography. That their number is so great is, of course, due to the presence in their midst of one so competent to instruct and advise as Mr. Chadwick.

The Chadwick stereoscopic camera, of which we spoke in terms of commendation two or three years ago, remains the perfection of what such an instrument should be. It takes plates of the size 6½×4¼, has two fronts, one for two lenses and one for a single lens, that are simply placed *in situ* by fitting under a brass cross piece on the front. These lens boards are reversible, so that the lenses may be packed inside the camera. The camera has a landscape-shape body; swing back, with the centre of motion in the axis of the lens, and a spring roller for the

stereoscopic division. It is made rigid by pushing the baseboard forward, and by an elongation of the slot in which the camera screw is placed it is attached to the head with a minimum of difficulty. Barnett's single dark slides are used, and altogether the camera, which has a rising and falling front, and may at will be utilised for upright single pictures, is the *beau idéal* of a well made, practicable instrument, without a single superfluous or complicated movement.

The Chadwick Improved Hand Camera.

The Chadwick Hand Camera embodies several features of a nature sufficiently distinctive to stamp it as possessing the character Mr. Chadwick claims for it, namely, practical. As we have previously pointed out, it is not a magazine camera, slides being used. It is of variable focus, from three to about six inches, focussing being effected by rack and pinion, operated by a milled head outside the camera, an aperture on the former showing a disc having an index for various distances. The lens fitted is either a single landscape at *f*-11 or a rapid rectilinear at *f*-7, the shutter being Kershaw's Instantaneous. For time exposures Mr. Chadwick recommends the use of the cap, with, of course, the camera on the stand. The view meter consists of three pin heads on the top of the camera in the form of a triangle, with its base on the extreme edge, by which the picture is sighted. The camera has a focussing screen, and may be used for both vertical and horizontal pictures. The lens front is removable and reversible, and the board having a boss when the latter operation is performed and a very short focus lens is used, the cap acts as a kind of plug. The size of the camera is $7\frac{1}{2} \times 5\frac{1}{2} \times 4\frac{1}{2}$, and the body is mahogany, polished black.

Several improvements have recently been applied to the camera. A rise and fall front, and a swing back for both upright and horizontal pictures, have been applied, and also a side swing; these adjustments do not in any way add to the size or weight, the only visible difference being two little screw heads on the side.

Scott's single dark slides for plates, or the double variety for films, are used with the camera, and as these slides are extremely light and portable, a considerable number of them may be carried about in the pocket for use as occasion demands.

Like all Mr. Chadwick's productions, the Practical hand camera is at once simple and effective, and has the advantage of having been worked out by one whom experience has given a grip of the requirements of amateur photographers.

Philip Harris & Co., Birmingham.

The Cytox Hand Camera of Messrs. Philip Harris & Co. has many points of novelty. It is of the fixed-focus type, and a small aperture in the front cuts off light from the lens, which is fitted with the usual diaphragms. A shutter of the oscillating-plate pattern, giving a minimum exposure of one-twentieth of a second, is employed. The plates are contained in

sheaths which may be bent to admit plates of any thickness. These sheaths are covered with a dead black of peculiar excellence, the preparation of which we are informed is a secret. The lens has iris diaphragms adjustable from the outside, and the camera may be used vertically or horizontally. To remove a sheath with an exposed plate a button on the top of the camera is pressed.

The camera is used as follows:—Having placed the dry plates or films in the sheaths, place the camera on the table, front downwards, then pack the sheaths one on the top of the other, inside the camera. The first one must be carefully placed, so that the front of sheath touches the wooden (c) stop in camera; when this first sheath has been put into position one hand should be placed in the camera, and the back of the fingers of this hand should slightly press the bottom of the sheath to keep it in its proper position, while the other sheaths are being put in with the other hand; the wires of sheaths must be in the grooves (B) on either side. When the twelve plates (or any less number) have been placed, insert the spring inside the camera, seeing that the wires of plate follow the grooves (B). To change the plates, press the button A on the top of camera, which presses the plunger inside and forces the front plate below the stop C. The plate then falls to the bottom of the camera, face downwards, protected from the light by the sheath and screens. The second plate is now pressed forward automatically by the spring at back, and is removed just like the first. When the camera is used in the vertical position the exposed plate must be fixed by screwing up the button D. The shutter is very simple, but very good. For instantaneous exposures pull the string as far as it will go, the shutter is then set, and may be released by a very slight pressure of the button at side. For time-exposures pull the string to the first catch, then, after exposure, press the button to close aperture.

It is the habit of Messrs. Harris before selling a Cytox to a customer to exhibit its capabilities by taking a picture with it.

Among the firm's other novelties is an electric lamp for the dark room, in which the battery consists of five cells, with an arrangement for raising or lowering the carbons and zincs of all five cells simultaneously, and fixing them, when raised, by means of side screws to allow carbons and zincs to drain, and stop action and waste of zincs. When required for use, carbons and zincs are lowered by unscrewing side screw. The lamp is five-candle power, and when ruby light is required the ruby cylinder is over it. When required for lighting, the cylinder is removed. Bichromate solution is to be used in the inner cells, and dilute sulphuric acid (1 in 35) in the outer cells. The framework is mahogany, polished, and the outer cells glass. Any number of cells may be used up to five, or any cell may be used separately.

As showing the great utility of photography to business firms, we may mention that at the time of our visit Mr. Belcher, the manager, was busily engaged in photographing chemical apparatus for a new catalogue, he explaining to us that this would obviate the engraver misdrawing the specimens, which was probable, as they were required to be arranged in a particular way. The photographic catalogue contains particulars of cheap and useful sets, &c.

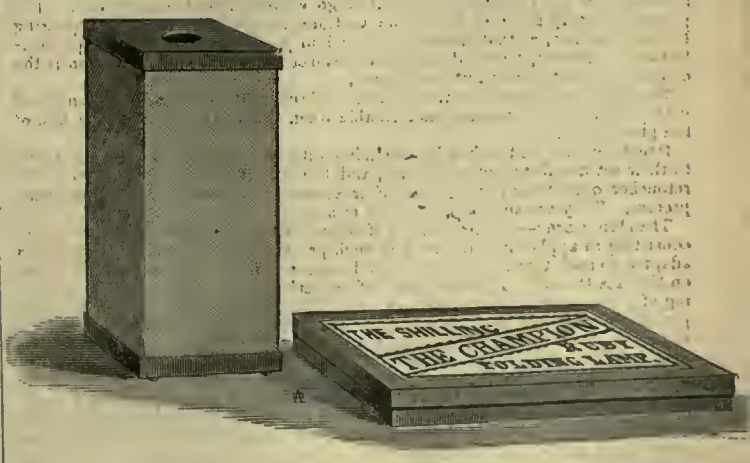
Archer & Sons, Lord-street, Liverpool.

The "Archer" combined hand or stand camera, has had several improvements applied to it since its introduction a few weeks ago, among others, the slides are held at the top and sides of the box, in which the camera proper is contained, thus economising space. For closing the back and front spring catches are applied. Messrs. Archer are also introducing an exceedingly light tripod stand, the legs of which, when opened up, are secured by a simple spring catch. The stand is made of polished walnut.

Our Editorial Table.

The Champion Folding Lamp.

In the following cut we show, both folded and erected, a lamp (procurable of all dealers, price one shilling), which occupies very little



pace when folded for travelling, while, when set up, it is roomy and well ventilated.

PATENTS COMPLETED.

Improvements in and relating to the Colouring of Photographic Prints, Transparencies, and Negatives.

No. 7343. Charles Klary, 22, Rue de Beaune, Paris, France. *May* 13, 1893.

The object of this invention is to provide a method and means for colouring photographs, which differs from other methods in the beauty of the effects which may be obtained without any previous preparation of the photograph to receive the colours.

The invention is applicable to photographic prints on paper as well as to transparencies and lantern slides on glass, and is also suitable for the retouching of negatives.

The improved method consists in colouring the photograph, if a paper print, by the application of colours, prepared as hereinafter described, to the back of the photograph, so that they penetrate the paper and appear underneath the photographic film as seen from the face of the picture.

This process, which I have termed "Chromophotophane," does not require any previous preparation of the usual paper print, either for rendering it transparent or translucid, or for removing the paper wholly or partly from the back of the film.

The colours are applicable to transparencies, lantern slides, and negatives, in fact, to any photographic film either on glass, or paper, or without, being applied to the back or front as may be most suitable. It does not interfere with the subsequent burnishing of paper prints.

The colours are prepared as follows:—Aniline colours are taken and dissolved either in water or in alcohol, such solutions being made as strong as possible whether by use of heat or in the cold. It has been found that some of the aniline colours so prepared will not soak properly into or through the paper as this process requires, and in such cases, which can be found by experiment, it is necessary and sufficient to add acetic acid to the alcohol.

The number of colours, natural or by mixture, which can thus be prepared is practically without limit, and will afford every necessary colour for this purpose.

The colours so made should be put up in bottles, which should be kept tightly corked.

The vehicle or medium for the employment of these colours is alcohol, or a mixture of alcohol and acetic acid. By use of this medium the artist may reduce any of the different colours to any state of tenuity that may be necessary to give the desired tint.

To colour a photograph, the latter is placed face downwards on a retouching desk or the like, so that it may be viewed by transmitted light, and the design on the face may be sufficiently visible from the back to guide the artist in colouring the photograph. The colours are laid on in the usual way with a brush or pencil, care being taken not to pass over the outlines. The colours immediately soak through the texture of the paper, and act more as dyes than surface colours. They quickly dry through evaporation of their solvent. The photograph may be lifted from time to time to ascertain the tint appearing beneath the film, so that the amount of colour used may be made proportionate to the tint desired, a second coating, or several if needed, being added until the desired depth of colour tint is obtained.

Photographs coloured in this manner exhibit a delicacy of tint combined with photographic clearness unattainable when colour is applied to the face of the photograph.

Negatives may be touched by colouring with the described colours according to their actinic absorbent capacities, and the use of such colours offers to the retoucher opportunity of delicacy of treatment unattainable by the ordinary process. They are applied to the face of such negative.

The claims are:—1. The method of colouring photographic prints on paper consisting in applying to the back of such prints colours dissolved in a medium adapted to soak through the paper, and appear beneath the photographic film on the face thereof. 2. The method of preparing colours for use in the colouring of photographic paper prints as described, or for the colouring of other photographic prints such as transparencies, optical slides, or for retouching negatives, consisting in dissolving aniline colours in water, or alcohol, or a a mixture of alcohol and acetic acid. 3. The method of colouring photographic prints on paper, transparencies, optical slides, or glass, or other carrying vehicle, consisting in applying to the back of paper supported films, or to the face of glass supported films, or to the back or face of unsupported films, aniline colours dissolved in water, or in alcohol, or in a mixture of alcohol and acetic acid, and diluted with a medium composed of alcohol, or of a mixture of alcohol and acetic acid. 4. The method of retouching negatives consisting in applying to their surface aniline colours in solution of suitable tenuity, and of more or less actinic absorbent nature substantially as described.

Improvements relating to Photographic Apparatus.

No. 10,796. Hermann Mackenstein, 6, Rue du Havre, Paris, France. *May* 13, 1893.

This invention relates to an improved mode of constructing photographic frames with rollers, in which the sensitive material (pellicle, paper, fabric, and the like) form a continuous strip of any length, previously wound upon a cylinder from which it is unwound to a suitable length for winding upon a second cylinder when it is necessary to bring in front of the aperture of the frame another part of the strip in order to make a new plate.

All the parts of my improved frame have been carefully thought out, and are combined in such a manner that, while reducing as much as practicable the size of the frame, I ensure the regular operation of the system, prevent the light from deteriorating in any case the roll of sensitive material, and render the use of the frame as convenient as possible.

The said frame is also provided with an automatic counter, which indicates to the operator the number of exposures he has already given, and consequently enables him to ascertain how many he can still give without having to renew the roll. It, moreover, at the same time marks this number on the plate by means of the luminous impression. A numbering device, which I will term a series-numbering device, is also arranged which provides the plate with a simple or multiple number or sign to indicate whether he has obtained the impression from the first roll put in the frame since the commencement of the operations or with the second, third, and so on; this series-numbering device is operated by hand for causing it to advance through one division each time when the roll is renewed. The details regarding the arrangement of this device as hereinafter given, will show that it enables the operator, for instance, when on an excursion to obtain a great many series numbers, which multiplied by the number of exposures in each series (that is to say for each roll employed) gives hundreds of distinctive numbers, which permits the excursionist to establish the relation between all the plates which he has been able to make and the indications in his memorandum book in which he has noted the subject of each of them. This series-numbering device can, however, be dispensed with by putting a sufficient number of discs in the device for counting the exposures for enabling it to number in succession all the plates which may be made in one excursion.

In carrying my invention into practice, the pellicle or other sensitive material, which is wound upon an upper delivery roller, passes from the latter over an upper guide roller, which also serves, as hereinafter explained, for marking the line of separation of the plates, and for actuating the device for counting the exposures; the material then passes over a lower guide roller to the receiving roller, upon which it is wound to the desired extent after each exposure, so as to replace by a fresh part of the strip or band the part which has just been used. If desired, the lower guide roller can be replaced by a fixed circular guide.

Behind the part stretched between the guide rollers is arranged a plate preferably made of aluminium and fixed upon the front of the roller-carrying frame. The said frame is situated entirely in a box or case, wherein it is held by a full sliding cover; the box is, moreover, provided with a blind, and with grooves for enabling it to be fixed to any photographic chamber.

The displacement of the sensitive strip or band after each exposure is obtained by turning the receiving rollers through the medium of a key which, as hereinafter set forth, is arranged that it can never be detached from the box or case, while it may be either attached to the axis of the cylinder for enabling it to be turned, or rendered independent of the same in order to permit the removal of the roller-carrying frame, for the purpose of again providing it with a strip or band.

The delivery roller is provided with a brake, which prevents it from turning easily, and which consists of a disc which is bent or twisted a little and pressed against the side of the frame by a disc screwed upon the axis; the action of this brake is regulated in such a manner as to give the strip or band the proper degree of tension. Besides having the effect of exposing a very plane surface to the action of the light, this tension also causes the upper guide roller to be moved by the strip or band without any sliding, so that the unwinding of a given length of the said strip necessary for a plate of a definite size always corresponds to an invariable number of revolutions of this roller, which number will, of course, be different according to larger or smaller diameter of the roller and the length of strip to be wound off.

Now, I utilise this rotary movement of the said upper guide roller firstly for causing it to mark upon the strip or band the line where it must be cut for separating the plate which has just been wound up from that which is about to be made; and, secondly, for actuating the device for counting the exposures.

For obtaining the first of these two results, I fix upon the axis of the upper guide roller a pinion which turns a toothed wheel keyed upon a transverse shaft, and I provide this shaft with two cams which, when it has made one revolution, will push back a bar arranged in this cylinder and provided with points after the manner of a comb, which then project to the outside and perforate the strid or band the extremities of the said bar pass beyond those of the cylinder for permitting this action of the cams. Spiral or other springs cause the said bar to move back with its points into the cylinder as soon as the cams escape from its extremities.

On the other hand, in order to utilise the upper guide roller for actuating the device for counting the exposures, I place at the end of the shaft outside the frame a small crank, which in every revolution turns through a distance of one tooth, a front star wheel bearing numbers corresponding to that of its teeth so that, each time when a fresh length of the strip or band is wound off, a fresh number appears at an aperture provided in the box. The star wheel engages with a similar lateral wheel which is at right angles to it, and upon the axis of which is fixed a disc bearing the same numbers as at the front star wheel; this disc is in front of the sensitive strip or band and behind the frame, which is pierced with an aperture small enough so as not to uncover more than one number at a time. It will now be understood that the numbers on the disc being cut out to form an opening upon an opaque bottom, or being opaque upon a transparent bottom, at the moment when it is exposed to the light, the latter will produce upon the sensitive strip or band the image of the number behind the aperture which is the same as that which is visible through the aperture.

As a roll of sensitive material generally provides for more exposure than the

numbers which the star wheel and the corresponding disc bears, I provide a second disc fixed upon the axis of a lateral star wheel which turns one tooth in every revolution of the lateral wheel above it, and which then also turns through a distance of one tooth, a perpendicular front wheel with which it gears; this periodical movement is obtained by placing the lateral wheels sufficiently far away from each other, so as not to touch, except at the time of the passage of one of the teeth of the latter which is longer than all the others. A second aperture is pierced in the frame for uncovering one of the numbers of the second disc, in like manner a second aperture is formed on the side of the box by the side of the first for showing a number of the lower front star wheel. With this arrangement, and by giving to each disc twelve numbers, the upper disc will print upon the first twelve plates one of the numbers from 1 to 12 respectively, while the lower disc will print upon all the number 1, the following twelve plates will be marked 1 to 12, and 2 the third dozen will be marked 1 to 12, and 3, and so on; thus all together I obtain for 144 plates (12×12) a distinctive mark consisting of a double number.

In case of necessity, it is clear that I could add one or more discs with corresponding wheels, in which case I may also add apertures in the frame and in the box.

The numbers could evidently be replaced by letters or other signs on all the discs, or on one or more of them.

In order that the operator may ascertain very easily, and with exactitude, when he has wound from the delivery roller and wound upon the receiving roller the length of sensitive material corresponding to an exposure, I have placed upon the side of the box of the frame an index, which makes one revolution while this length is developed, so that it is necessary to discontinue turning the key when this index has returned to the point whence it left. The movement of the index is obtained by means of a toothed wheel keyed upon its axis, and which is actuated by a pinion mounted upon the extremity of the axis of the upper guide roller.

It is sometimes an advantage to be able to impart to the index a rotary movement independent of the toothed wheel in order to bring this index exactly opposite the point marked upon the box, if it should not be in that position after the roller-carrying frame has been removed and put back into its place. This may be obtained by various means: the simplest, which I preferably employ, consists in mounting the toothed wheel upon a shaft in such a manner that it can slide along the latter in order to be engaged with the pinion or to be disengaged therefrom, and to subject it to the action of a spiral or other spring, taking its point of support upon the interior face of the box, and which engages it as soon as a pressure tending to draw it to the outside is released. A knob is fixed at the end of the socket, to which the toothed wheel is fixed, this knob enabling the wheel to be easily drawn to the outside for disengaging the same.

I may, if desired, dispense with the index, and also with the mechanism belonging thereto, and in lieu of this employ a ratchet device which at the proper moment will automatically prevent the continuation of the movement for winding up the sensitive material, this ratchet device being actuated by the winding-up mechanism itself. After the system has thus been fixed, it will be sufficient for releasing it to move the ratchet device by hand back to its original position.

The series or mark number which the light produces upon each plate at the same time as the number of the exposure is obtained in a similar manner to the latter by combining, every time when this may appear useful, two alphabets or two series of figures or signs, so that each letter of one of the alphabets may serve for marking a great number of plates, by employing it alone first, and then with each of the lettera of the other alphabet successively. Thus, for example, the frame may be provided at the upper or lower part with a rule bearing the letters from A to Q. all the plates of the first series—that is to say, obtained with a first roll of material—may be marked simply with A at the top. Those of the second series may be marked with A at the top, and with A below those of the third, fourth, fifth, and sixth, and further series may always bear A at the upper part; but B, C, D, E, and so on respectively, at the lower part. There are, therefore, eighteen series of plates marked with A at the top. I replace the A by B at the upper part for the following eighteen series with the different letters from A to Q successively at the lower part, then I replace the B by C, and so on, so that altogether, as there are upon each of the rules seventeen letters, I have a means of marking different signs eighteen times seventeen series—that is, 306 series—each comprising as many plates as are contained in one roll, which evidently exceeds the requirements even in the case of explorations or in any other particular cases. It is understood that I may diminish the number of the letters, figures, or signs employed, and I may also if desired augment it in like manner.

In order that the plates obtained with one frame shall not be confounded with those made in another, which would render the above-stated precautions useless, the number of the frame is likewise marked upon the plate at the moment of the impression. Thus, the plate indicates a number cut out in the lower left-hand corner of the frame. The place might manifestly vary, and also the mode of producing the number, or the letter, or other sign which is to designate the frame.

In a general manner—that is to say, in such a manner as may be conveniently used for the number of the frame as well as for the exposure numbers and the series numbers—I may mark these numbers upon the plate either in white or in black. Accordingly, they may be formed by cutting them out from an opaque piece (thin metal, natural or artificial parchment, or the like), or, without being cut out, they may be left transparent upon a piece of glass, mica, enamel or imitation enamel celluloid, or the like, the remainder of whose surface may be opaque; or, on the contrary, they may be opaque upon a transparent bottom, or cut out full with a space around.

When the letters or signs intended to indicate the series are carried by rules, each rule may be actuated by means of a rod passing out of the side of the box, and graduated so that the operator may see upon this rod what letters are exposed at the apertures in the frame.

This arrangement may be replaced by a modified arrangement, which consists in fixing upon the edge of the box a small plate, in which is arranged a disc bearing the desired letters or numbers, and which is turned through a division in each change of series so as to move to the upper part the characters which are suitable. These characters, being then exposed at an aperture pierced in the frame, projects its image upon the plate at the moment when the light acts. The disc may be pivoted to a screw, which serves as an axis for the same, or may simply be held in its place by being fitted in the plate, the said disc being milled at its circumference for enabling it to be easily turned.

In order to be able to number a greater number of series of plates, I may use several discs of this kind in the same manner as I have just indicated the employment of several numbering rules.

I may, if desired, dispense with what I have termed the series-numbering device—that is to say, rules or the discs—and retain only the exposure-numbering device by augmenting the number of the discs, the numbered wheels and the apertures, and also the actuating wheels, as much as may be necessary.

On the other hand, instead of using wheels with twelve teeth and putting twelve numbers upon the discs and upon the wheels behind the apertures in the box, I may provide these discs and wheels with the figures from 0 to 9, and employ wheels having only ten teeth, so that the first disc marks the units, the second the tens, the third the hundreds, the fourth the thousands, and so on, and in the same manner for the wheels placed behind the apertures. Each plate will then be designated only by a single number indicating its order in the plates made since the commencement of the excursion and by the invariable number of the frame.

I will now proceed to describe the special construction of the delivery and receiving cylinders, upon which is wound the pellicle or other sensitive material. Each cylinder is made of two parts, connected by a longitudinal hinge. After opening the cylinder I introduce into it the extremity of the strip, then I close it again, pinching the latter between the two parts, one of which is provided with a row of points for preventing the strip from escaping. Each cylinder has at one of its extremities a central hole, into which is inserted a journal forming the prolongation of the delivery roller axis and its nut which carries the brake disc, or a journal prolonging the receiving roller axis which receives the key. Each of these axes terminates in a small disc provided with the central journal and with two pins, and these three projections enter holes formed in a disc and in the cylinder, which is thus obliged to turn with the axis. The disc which is applied against the extremity of the cylinder prevents the light from passing through the spires of the roll of sensitive material, and from deteriorating it when it is necessary to recharge the frame outside the laboratory.

At the other extremity of each of the rollers is also a protecting jaw or disc, which is simply pierced with a hole at the centre, into which hole is inserted a journal fixed to the extremity of a spring strip, the other extremity of which is secured to the side of the frame. A similar spring-strip may, if desired, carry the above-mentioned journal. It would then be fixed upon the frame by its centre.

It will be understood that, for enabling the rollers to be removed, it is sufficient to pull the strip so as to disengage the journals from the holes of these rollers, and that, on the other hand, when the cylinders have been put back into their place, it is only necessary to let these strips pass back into their original position for holding them therein.

The axis of the receiving roller carries a ratchet, with which is engaged a spring pawl carried by one side of the frame, and which prevents the rear movement.

The frame, which composed of two cheeks of metal, connected at the front part by the plate of aluminium or other material, which serves as a support for the stretched sensitive material. This frame carries the rollers and the whole mechanism, except the parts carried by one of the sides of the box, and except the series-numbering devices, which are carried by the lateral frame fixed to the box.

It now only remains to describe the arrangement which I use for enabling the key to always remain attached to the box of the frame, while enabling it to be detached at will from the axis for permitting the removal of the roller-carrying frame, or enabling it to be fixed for permitting the turning of the receiving rollers in order to give a movement of translation to the strip or band of material.

This arrangement consists in providing the rod of the key with a shoulder where it passes through the centre of a small cylinder, against which shoulder acts a spring, which tends to push it back to the outside, but prevents its complete removal by means of a screw or other stop. On the other hand, the extremity of the rod of this key is screw-threaded, and it is sufficient to turn it by pressing above, so as to overcome the resistance of the spring for enabling it to be screwed upon the axis and unite it therewith without danger that it will turn the axis the wrong way, because, if turned to the left, it would be unscrewed.

It will be readily understood that the system herein described may be applied to frames of any dimensions and any proportions, and that the rollers and axes, which are in this case parallel with the narrow sides, might, on the contrary, be parallel with the large sides. In either case they may be mounted upon the box itself, and also the whole mechanism and the frames might be dispensed with, which would not make any material difference in the system.

On the other hand, the position of the delivery roller and of the receiving roller might be reversed; that is to say, I might place that which is below at the top, and *vice versâ*. This would simply necessitate the placing of the key and of the exposure-numbering devices on the left of the box in lieu of placing them on the right-hand side.

INSTEAD of the words attributed to him at the meeting of the London and Provincial Photographic Association, on June 8, Mr. R. Child Bayley said "that it was quite possible, by suitable development, to produce a negative which, showing the full number of gradations the plate could register, was printable throughout. A negative which possessed a scale of densities greater than could be printed was simply improperly developed."

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
June 26	Dundee Amateur	Asso. Studio, Nethergate, Dundee.
,, 26	North Middlesex	Jubilee House, Hornsey-road, N.
,, 26	Richmond	Greyhound Hotel, Richmond.
,, 27	Birmingham Photo. Society	Club Room, Colonnade Hotel.
,, 27	Great Britain (Technical)	50, Great Russell-st., Bloomsbury.
,, 27	Hackney	206, Mare-street, Hackney.
,, 27	Halifax Camera Club	
,, 27	Lancaster	Springfield Barracks, Lancaster.
,, 27	Leith	165, Constitution-street, Leith.
,, 27	Paisley	9, Gauze-street, Paisley.
,, 27	Warrington	Museum, Bold-street, Warrington.
,, 28	Bath	Roy. Lit. & Sc. Inst., Terrace-walks.

July 1	Hull	71, Prospect-street, Hull.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

JUNE 15,—Mr. A. Haddon in the chair.

Receipt of a copy of the *Amateur Photographer's Annual* for 1893 was acknowledged.

Prospectuses of the new Central Photographic Club Company were distributed.

Mr. J. Howson passed round the original prints from which the reproductions in the June number of *Photographic Scraps* illustrating Mr. W. K. Burton's remarks on density ratios were made made.

COMPENSATION IN DEVELOPMENT FOR VARIATIONS IN EXPOSURE.

Apropos of Mr. Burton's recently published experiments, Mr. Alexander Cowan read a paper on the above subject [see page 389].

Mr. W. E. DEBENHAM said that Mr. Cowan had not quoted the part of Messrs. Hurter & Driffield's theory which Mr. Burton had called in question. One might have subjects which were not within the range of correct exposure. The question was this: Seeing that we could not ensure a subject which shall only have its intensities within the limit of correct gradation, when the exposures are beyond the limit, can we by development differentiate so as to show considerable difference between the brightness of one high light and another high light? If we can differentiate those lights which are out of what is known as the limit of correct exposure, and make them show gradation something resembling the original, that is a valuable achievement. Mr. Burton showed an instance of it in direct contradiction of Messrs. Hurter & Driffield.

Mr. P. EVERITT disputed the claim that the prints shown were identical.

Mr. HOWSON said Mr. Burton's point was, Can we alter the ratios of the densities by a difference of development? He (Mr. Howson) contended that the prints shown proved that it could be done. Dr. Hurter, some time time ago, stated at the Photographic Society of Great Britain that the ratios could not be altered, but it was the general opinion of photographers that they could. The difference of opinion lay in the meaning of the terms, density and opacity.

Mr. COWAN asserted that the ratio of gradation was not altered by any known developer. Mr. Burton had said that two identical negatives could be obtained with varying exposures.

Mr. EVERITT thought that possibly the assertion of Mr. Burton had a double meaning. Did Mr. Burton mean that it was impossible to say which was the over-exposed one in the sense that both prints were identically alike, or was it that you could not distinguish between the two which was which?

Mr. T. BOLAS was of opinion that most photographers would conclude that of the prints shown the short exposure was the longer.

Mr. DEBENHAM asked Mr. Cowan if there was any reason to suppose that, carrying development a little less far, he could have got a result that appeared less exposed?

Mr. COWAN replied that in his experiments he had developed two intermediate slips, and they bore out the contention that the curve was shortened.

Mr. EVERITT challenged Mr. Debenham to take the other side and say there was *no* reason to suppose that by carrying development a little less far a less-exposed result could be obtained.

Mr. S. HERBERT FRY had made tests which bore out the contention that there was a shortening of the scale. He had made twenty-five experiments, and had matched the prints, having used Thomas's Extra Rapid and Ilford Red Label. The universal average, as judged from the prints, was, the longer the exposure the shorter the distance where the prints went black, and where there was no detail at all, thus confirming the contention that over-exposure shortened the scale and compressed it.

Mr. J. S. TEAPE showed results from the strips forwarded to him for testing by Mr. Cowan. He had erred slightly on the side of full exposure. Nos. 1 and 2 had normal exposure, one being developed for two, and the other for two and a half minutes. No. 3 had been developed by Burton's formula, substituting four grains of anhydrous sodium carbonate to the ounce, one grain pyro, four sulphite, and less than half a grain of bromide. No. 4 had been put for ten minutes in a twenty-grain solution of bromide, and then in a developer of 8 grains pyro, 20 bromide, 3 soda, and 96 sulphite. The image appeared in three minutes and was complete in twelve. It appeared to him that it was only in the densest portion there was a little difference from the normally developed strips. The normal exposures were from ½ second to 32 seconds; the abnormal 16–1024 seconds. No. 5 had to the eye very little difference. It was put for thirty minutes in a twenty-grain solution of bromide, and developed the same as No. 4; the image appeared in six minutes and was veiled; it was then put in the bromide solution for another five minutes, and then in the developer for seven minutes. He had also some negatives which he thought beat Mr. Burton's results. They had had 1 and 40 seconds' exposure on a similar subject to Mr. Burton's, and with his developer. He (Mr. Teape) would be inclined to take the one which received the longest exposure as the one which had had the shorter.

Mr. COWAN remarked that he did not see how the range of gradations in a negative could be tested without measurement. Quoting a recent article of Mr. Burton's on tentative development, in which the writer stated having given forty times the normal exposure, and the moment the image appeared he instantly put on a very powerful developer, which immediately intensified the image, Mr. Cowan said he thought this of more use than Mr. Burton's other article.

Mr. DEBENHAM said, years ago Mr. W. B. Bolton had recommended one to start with over-exposure and a normal developer, and, as soon as the image appeared, to remove the developer and apply bromide, keep that on for a short time, and then place the plate in pyro and add ammonia, when density would be obtained without proportionately bringing up the weaker parts of the negative, which should be restrained. He often used the plan with success.

Mr. Teape and Mr. Cowan had also found it practicable.

Mr. EVERITT said Mr. Cowan had sent him two normally and four over-exposed strips. Using anhydrous soda, after the lapse of a quarter of an hour no image appeared—possibly the soda was not anhydrous, or the bromide excessive. Washing off the developer, and using ordinary soda crystals as 4 : 1 of anhydrous, and reducing the bromide to Mr. Burton's proportion, the plate developed in five minutes, the image being thin throughout. No. 5 was developed in 1 grain pyro, ¼ bromide, 4 sulphite, and 4 soda to the ounce; it had more pluck throughout, taking five minutes to develop. No. 2 was developed with 8 grains pyro, 8 bromide, 32 sulphite, 16 soda carbonate; the image appeared very rapidly, and was complete in twenty minutes. No. 3 had 8 pyro, 10 bromide, 32 sulphite, 12 soda crystals; no image appeared for five minutes. Ten grains of soda were added in successive doses, and in seventeen minutes the image appeared, and was complete in twenty-two minutes. No. 6 was tried with ammonia, and was developed in about five minutes. What struck him as peculiar was that there was no marked difference between the normally and over-exposed plates.

Mr. COWAN said that Dr. Hurter had stated that a range of 3 : 60 could not be detected pictorially, but was apparent on measurement. He did not think the eye could detect these differences.

Mr. FRY said that was an argument in favour of Mr. Burton.

After other discussion the meeting closed.

Holborn Camera Club.—June 16, Mr. J. F. Stevens in the chair.—Mr. S. Herbert Fry gave a practical demonstration on the Sandell plate. Mr. FRY said he had made it a practice never to develop a plate at a club meeting, but as most of the advantages of the Sandell plate had been published, and the members of the Holborn Camera Club were nothing if not practical, he had decided to break that rule and develop a few plates. He passed round a number of prints from Sandell plates, and made a few remarks on the advantages and peculiarities of that plate. Two plates were afterwards developed, Mr. Fry demonstrating in a most practical way the method of developing these plates. On Saturday last, on the invitation of the President of the Holborn Cycling Club, the members of the Camera Club visited Mill Hill, and sat down to tea with the members of the Cycling Club.

North Middlesex Photographic Society.—June 12.—A question was asked as to the best way of copying a Daguerreotype, it being very difficult to avoid reflections. One member recommended that it should be done by artificial light by using two lamps, standing them at the sides some distance away, so that the light falls from each side of the picture. Copying could often be done this way which would be quite impossible by daylight. Mr. STEWART suggested that the method adopted in photographing silver plate might be successful, viz., to form an artificial dew on the surface, which would prevent the reflections from the bright surface of the plate. The paper of the evening was one by Mr. C. O. Gregory on *Dodges*. He covered a very wide field, giving hints on every conceivable topic, such as exposure—for which he constructed out of a small weight and piece of string a second metre—developing, dodging by means of a brush, intensification dodges by matt varnish, tissue paper, colours, pencils, &c., reduction by rubbing with spirit, printing, vignetting, printing in skies, &c. The paper was full of matter, and the simplicity of his methods caused a good deal of amusement. Six new members were nominated.

Harringay Photographic Society.—On Thursday evening last the above Society held its first half-yearly *conversazione* at the Public Hall, Finsbury Park, which was in every way a great success. It consisted of a programme of vocal and instrumental music, also an oxyhydrogen lantern entertainment. The President (Mr. Dudley Towers), in his opening remarks, said that, owing to the great increase of its members, they had moved to larger premises and a more central position at 8, Station-road, Finsbury Park, where they had much better accommodation for meetings, which in future will be on the second and fourth Thursdays in each month. The musical portion of the programme was much appreciated. During the evening a set of beautifully coloured views of London and Paris were exhibited on the screen by Mr. Towers and Mr. Ball.

Hackney Photographic Society.—June 13, the President in the chair.—Mr. Hudson showed negatives developed with his modification of pyro-soda. Mr. Beckett showed three negatives, each having had a different exposure varying from three to nine seconds, the density in each being equal. Mr. S. J. Beckett showed and explained the Ilford Exposure Meter. The HON. SECRE-

TARY said when he was away from home he had used the paper around the box of plates as a sort of store case, by cutting a lid at the end of paper, and sliding the box in and out. Mr. Barnes asked what was the best developer for Eastman's films. Mr. Sodeau preferred amidol. Mr. Salmon showed a home-made camera which could be used in the hand. The Hon. Secretary showed the "Uno" hand camera, a cheap article capable of holding twelve plates; he hoped to try the same and report on at next meeting. Mr. Houghton then read a paper on *Advice to Beginners*, and advised half-plate camera, with plenty of extension, swing back and front, with rigid tripod with large head. For lens one of eight-inch focus and wide-angle lens. He recommended that really good lenses should be bought, and advised the use of slow plates rather than films. Composition was an important matter, and should be well studied before exposing Mr. Selfe asked when a plate is fixed, and he was advised to leave it for about ten minutes after opalescence has disappeared. Mr. Green asked if frilling occurred if developer was too strong. Mr. Dean recommended the use of alum bath. Mr. Roder thought pyro-developed negatives required clearing bath. Mr. Avent thought beginners should have exposure tables simplified as much as possible. The Hon. Secretary recommended a square camera with the focussing done from the back, as otherwise, when using a short focus lens, the baseboard would cut off part of view. Mr. Gosling thought beginners should not commence with a hand camera. Mr. R. Beckett recommended trimming prints before toning. The Hon. Secretary used thin mackintosh which took up less room and was more opaque than the usual material, and could, in cases of rain, be put on the end of the tripod and used as an umbrella.

East London Photographic Society.—June 13, Mr. Pasco in the chair.—Mr. Charles Tylee gave a demonstration upon the *Carbon Process*, which appeared to be thoroughly appreciated by the members present. Mr. C. M. Minns promised to read a paper at the next meeting upon *Subjects: Where and How to find them.*

Putney Photographic Society.—June 10, an Outing to Burnham Beeches was well attended.—A meal was served on the lawn at Macro's Cottage. The omnibus from Slough stops here, and it is wise to order food before commencing the day's work. The next outing will take place on Saturday, June 24, to Leatherhead, Dorking, and Shere, returning from Guildford on Sunday evening Leader, Mr. A. E. Smith.

Brixton and Clapham Camera Club.—Ordinary meeting, held on Tuesday, June 6, Mr. W. H. Harrison in the chair.—Mr. S. H. FRY gave a demonstration on the *Sandell Plate*. In describing the properties of the plates he stated that they were made in two brands, the "General," with two films, and the "Especial," with three. Each film was of a different rapidity, and possessed different physical and chemical characteristics which were not due to the thickness of the film or the extra amount of silver. The multiple film combined the opposite characteristics of the lantern plate and the snap-shot plate, which have different qualities. There are, said Mr. Fry, two exposures for these plates; one the normal exposure, and the other the abnormal exposure. By normal exposure is meant the correct exposure for the upper or instantaneous film. Anything beyond this is an abnormal exposure. For a normal exposure the plate should be developed in the ordinary way, *i.e.*, like an ordinary single-film plate. With an abnormal exposure, development should be conducted in a tentative manner, with a weak (*i.e.*, diluted) developer, which should be well restrained. The developer should be that with which the worker is best acquainted, no special developer being necessary. Pyro and ammonia, pyro and soda, hydroquinone, eikonogen, &c., give equally good results. The image on the lower film should be first developed, and, when sufficient density has been obtained, strengthen the developer for detail in the top film.

South London Photographic Society.—June 5.—Some work from samples of Lomberg plates were shown. The negatives given by these plates are of a very soft character, and are therefore particularly well suited for portrait work. In consequence of Mr. A. R. Dresser being taken suddenly ill, his paper on *Enlarging Hand-camera Negatives* was postponed. Some information on the use of metol as a developer was given. It was found to have excellent keeping qualities. A developing solution, left in a graduate for a week, was capable of producing an image with ease. It did not stain, and would develop several plates in succession. Less exposure was required than with pyro, over-exposure was readily dealt with, density was more readily obtained with it than amidol, and it does not stain the fingers. Very fine transparencies were obtained by its use. Specimens of the "Uno" and "Queen" hand cameras were shown and placed in the hands of members by the manufacturers for trial and report to the next meeting.

Tooting Camera Club.—June 8, Mr. Dollery in the chair.—Mr. L. E. Morgan and Mr. V. Robinson were elected members. A whole-day excursion to Byfleet *viâ* Woking and Basingstoke Canal was agreed upon, but the date was left open. Mr. Dollery gave a practical demonstration of the use of cresco-fylma, a preparation for stripping and expanding the gelatine film of a negative, transparency, or lantern slide. Two quarter-plate negatives were successfully operated on. Mr. Dollery works according to the instructions given on the bottle, with the exception that he advises the use of tepid in preference to cold water in the second bath, as the film expands quicker. A transparency on an Alpha plate was then immersed in the solution, but it immediately faded away. At the desire of those present, the process was carried out to ascertain the greatest amount of enlargement that could be obtained. Mr. Child, on examining the film, which was of a dirty yellow colour, drew attention to the fact that the image was still intact and perfect, presenting an appearance similar to that obtained by the bichloride of mercury bath. He recommended that a hydroquinone developer should be tried, with a view of reducing the compound that evidently had been formed. Mr. BERGER agreed with this view, and said that no details were wanting in the picture. The suggestion was acted upon, and with complete success, the image re-developing up slowly, but yielding a vigorous picture. The only difference was that before treatment the tone was of a greenish black, but afterwards a warm sepia. This change was no doubt due to a constituent of the cresco-fylma, as the film was unwashed. A vote of thanks was given to Mr. Dollery for his lecture.

Croydon Camera Club.—A thoroughly enjoyable whole-day ramble to Weybridge, conducted by the well-known landscape artist, Mr. H. Maurice Page, was held upon Wednesday, June 14. A *genre* study representing "Faggot Binding" having been attempted, several "wood and water" compositions kept members fully occupied until two o'clock, when, upon the invitation of Mr. Page, they dined together at the "Green Dragon," Byfleet. A busy afternoon was spent on the banks of the Wey, and, tea having been enjoyed on the breezy heights of St. George's Hill, photographic operations were concluded by taking a series of views of Dead Man's Lake. Saturday, 24, Excursion to Edenbridge, conducted by the President. Train from East Croydon, three minutes past two.

Birmingham Photographic Society.—May 30, Mr. Monsley in the chair.—Mr. Hendren read a paper on *Christian Architecture in England*, which was illustrated by sketches and diagrams on the blackboard. Mr. Hendren traced the evolution of architecture from the early Grecian times, through successive stages to the Norman, where he paused, intending to resume at an early date. A number of very fine photographs by the lecturer, which were shown in illustration of his remarks, were much appreciated.

JUNE 13, Mr. W. Jones in the chair.—Mr. W. J. Belton, representing the Paget Prize Plate Company, gave a demonstration of the firm's printing-out opals and lantern plates.

Leicester and Leicestershire Photographic Society.—The first outdoor excursion of this Society took place on the 9th inst., when about a dozen members and lady friends journeyed to Dovedale, and were favoured with beautiful weather, both as regards the quantity of light and absence of wind. The party met at the Midland Station and booked for Derby, and were joined at Loughboro, by some members of that Society, where, arriving about 9.30 a.m., they were met by Mr. Thos. Scotton and Dr. Highton, who joined the party. A break had already been chartered by the kindness of Mr. Scotton, and the party drove through most charming scenery, a distance of eighteen miles, to Dovedale, where the party soon entered the glorious dale, and operations soon commenced, the President, clambering down the precipitous side of the cliff, coming in for the first "snap." The difficulty was not so much what to take as how to avoid it, so many magnificent pictures presented themselves; and, drafting off in two's and three's, the excursionists wandered about in a paradise of pictures. Leaving the Dale at 4.30, the party re-embarked and drove back to Ashbourne, where a welcome cold collation was done ample justice to, under the presidency and vice-presidency of the President (Mr. Porritt) and Dr. Highton respectively. Altogether, about seventy-two plates were exposed, and it is confidently expected that they will yield some of the outdoor prize pictures for which the President has offered silver and bronze medals.

Rotherham Photographic Society.—June 6, Dr. Baldwin (President) in the chair.—It was announced that the Rotherham Corporation had offered the use of a room in the Clifton Park Museum for a representative display of the Society's work. Mr. Jerome Harrison's Warwickshire Survey paper was discussed, and afterwards a resolution was passed recommending the committee to consider the best means of conducting a photographic survey of the Rotherham district. Negatives and prints resulting from the Ingleton excursion were exhibited and criticised. Three new members were elected.

Sheffield Photographic Society.—June 6, Mr. B. J. Taylor in the chair.—A letter from the Secretary of the Photographic Convention of the United Kingdom asked whether they intended to send delegates to Plymouth. It was decided not to do so. Mr. Sparham Camp gave a demonstration on *Printing on Rough-surface Papers*, showing the process of sizing, sensitising, and fixing ordinary drawing-paper to produce a nice soft picture.

Edinburgh Photographic Society.—June 7, the Vice-President (Mr. L. C. Oliphant) in the chair.—The Secretary, Mr. T. Barclay, submitted his report of the business and work transacted during the preceding year, which was, on the whole, a satisfactory one, showing the continuing advancement and prosperity of the Society. It emphasised the advantages of the new premises, stated the additions to the library, together with the Council's desire that the benefits of it, and of the reading room, should be more fully made use of by the members, giving the number of the latter at nearly 400. Mr. James McGlashan, Treasurer, submitted the financial report, which showed that the ordinary income for the past year had amounted to 236*l.* 1*s.* 3*d.*, and, after meeting all items of current expenditure, there remained a balance of 98*l.* 2*s.* 6*d.* to be added to the Society's credit. The Chairman congratulated the members upon their sound financial condition, and moved the adoption of both reports, which was agreed to *nem. con.* Before proceeding to the election of office-bearers, the Chairman stated that, in consequence of the state of his health, their President, Mr. John Moffat, sen., desired to thank the Society for his appointment, and asked to be allowed to dimit his office, and, in the circumstances, the appointment of his successor was delayed. The names of several gentlemen were suggested whom the Council might interview before the resumption of business next session, and this was agreed to, thus leaving the office of President meantime in abeyance. The members of Council retiring by rotation were Messrs. H. Auld, J. C. H. Balmain, A. A. Inglis, and J. R. Roddick. Mr. W. T. Bashford having been appointed Vice-President in room of Mr. Alexander Ayton, the following gentlemen were appointed office-bearers and Council. *Vice-Presidents:* Messrs. J. C. Oliphant and W. T. Bashford.—*Council:* Messrs. H. W. Bibbs, Hippolyte J. Blanc, A. R. S. A., R. W. Hawks, J. Patrick, S. Keith, A. W. McGregor, T. Wardale, Alexander Ayton, jun., J. Anderson, A. H. Baird, G. Cleveland, and R. S. Webster.—*Librarian:* Mr. Charles Fraser.—*Treasurer:* Mr. James McGlashan.—*Secretary:* Mr. Thomas Barclay, 180, Old Dalkeith-road, Edinburgh.

Cape Town Photographic Club.—The monthly meeting of the Cape Town Photographic Club was held in the dining hall of the Y.M.C.A. on April 12. The subject for the evening was *Stereoscopic Photography*, which was very ably handled by Mr. A. J. Fuller, who also had a large number of stereoscopic

slides of Cape scenery on exhibition. At the conclusion, he exhibited the various advantages of Chadwick's stereoscopic camera, which had been used in taking the views. A public limelight exhibition was announced to take the place of the usual meeting on May 10. Lantern slides by several members were exhibited on a new Aptus opaque screen, amongst them being some by Mr. Fuller on the new Pagit print-out plates, and some very fine views of Ceres and the Pearl by Mr. Steer. The South African slides, which were exhibited here some time ago, previous to their despatch for the English Societies, have commenced their home tour, and glowing notices of their reception were quoted.

FORTHCOMING EXHIBITIONS.

1893.

July 3–8 ..... Photographic Convention of the United Kingdom, Plymouth. Hon. Secretary, F. P. Cembrano, jun. 10, Cambridge-gardens, Richmond, Surrey, S.W.

August ..... Welsh National Eisteddfod. The General Secretary Pontypridd.

Sept. 25–Nov. 15 ... Photographic Society of Great Britain, 5A, Pall Mall East, S.W. Assistant Secretary, R. Child-Bayley, 50, Great Russell-street, W.C.

October 1–31 ..... Hamburg. Das Ausstellungs Committé des Amateur Photographen Verein, Schwanenwik, 33, Hamburg.

,, 9–Nov. ... Photographic Salon, Dudley Gallery, Piccadilly, W. Hon. Secretary of Organizing Committee, A. Maskell, 215, Shaftesbury-avenue, W.C.

December ..... Madras. The Hon. Secretary Amateur Photographic Society, Madras.

Correspondence.

THE DOUBLE ANASTIGMAT.

To the EDITOR.

SIR,—I notice in THE BRITISH JOURNAL OF PHOTOGRAPHY of June 16, 1893, pages 372 and 382, a report on Goerz's so-called "Double Anastigmat." Referring to those paragraphs, I hasten to state that the objective there alluded to is strictly coincident with the triple lens construction patented by Dr. P. Rudolph, of Jena (Patent No. 4692, April 22, 1893, *vide* BRITISH JOURNAL OF PHOTOGRAPHY, May 26, 1893). Mr. Goerz having communicated with several Berlin photographic societies on this subject, Messrs. Carl Zeiss, of Jena, informed the respective societies that already in March, 1892, they had made experimental lenses after the type of the double anastigmatic lens; that, however, owing to the clumsiness of the six-lens type they had preferred introducing the more important dissymmetrical types (Series I., II., and III.a). Should Messrs. Zeiss in the course of time issue this new type, they would do so for the special reason that the individual parts of their six-lens symmetrical doublet form exceedingly rapid landscape lenses.

To this general communication I appended a critique of the five photographic prints distributed by Herr Goerz which I believe to be sufficiently interesting for *verbatim* reprint.

Herr C. P. Goerz caused, on the occasion of a paper read by Herr von Hoegh on the properties of the double anastigmat *f*-7·7, comparison prints to be distributed in several Berlin photographic societies, which were intended to demonstrate the superiority of the Goerz double anastigmat and the lynkeioscope over the lenses of other makers. These prints, which have been circulated in large numbers beyond these societies, have not attached to them the name of an author who undertakes the responsibility of correctness and impartiality, and as they appear to be calculated to lead to misconceptions I believe that a few words of criticism may not be out of place.

The prints represent a test screen arranged after the manner of Zeiss's screen and serving in particular for testing the objectives with respect to astigmatism and curvature of Image.

In the article contained in the *Photographische Mittheilungen* of June, 1 1893, p. 76, a statement is made to the effect that the negative had been taken with the five best (German) objectives of the present day, and the pictures are arranged in such a manner as to produce at first sight the impression of the new double anastigmat being incomparably the most perfect objective in existence, as regards anastigmatism, and the lynkeioscope of Goerz is represented to be better than the "aplanats" of other makers, and also better that the "antiplanats." This impression will necessarily be permanent with those who have only an imperfect knowledge of the capabilities of the objectives produced by various makers, and who are satisfied with a superficial examination of the prints thus shown to them, without entering into critical examination.

I contend, in the first place, that some of the best lenses of the present time have been excluded from the comparative tests. Among these is the Zeiss anastigmat *f*-6·3 which, according to often-repeated statements contained in the publications of the Zeiss Optical Works, is emphatically the best representative of the rapid anastigmatic types as regards optical powers. The omission of this anastigmat from the tests loses nothing in its partiality by the fact that an *antiplanat* and *euryscope*, possessing similar relative aperture to that of *anastigmat* *f*-6·3 have been allowed to enter into competition. For the latter is substituted the Zeiss anastigmat *f*-7·2, the specific construction of which was governed by the postulate that lighter, cheaper, and purer glass were to be employed in its construction than is possible with the *Zeiss anastigmat* *f*-6·3, or the *Goerz double anastigmat*. Had this Zeiss anastigmat *f*-6·3 been made to form an element in the comparative tests, impartial examination would surely not have been capable of discovering marks of inferiority in this objective as compared with the double anastigmat. On the other hand, it can readily be proved that when working with wide angles the anastigmat *f*-6·3, which is half as rapid again, possesses better anastigmatism than the Goerz double anastigmat. This is, for instance, shown by negatives which were taken in the studio of the Zeiss Optical Works to obtain comparisons with a *double anastigmat* *f*-7·7 of 150 min. focus sent by Herr Goerz. When taking the negatives, the lenses were both stopped down to *f*-15, so as to obtain sufficiently uniform illumination with wide angles. The result showed that, with angles exceeding 71°, the double anastigmat rapidly diminished in definition, and exhibited considerable anastigmatic aberrations, whereas the Zeiss anastigmat within the angle of 82° employed in the experiments, exhibits a hardly perceptible amount of astigmatism, and still reproduces legibly the printing on the test screen.

Further, it is important to note that, excepting the *anastigmat* *f*-7·2, the objectives made by other firms, *i.e.*, the *antiplanat* and *euryscope* are more than half as rapid again as the Goerz objectives. Any one acquainted with the subject knows, however, that the difficulty of effecting anastigmatism increases with the rapidity of the lens.

It will thus be seen that, in the mere selection of the objectives for the purpose of making comparisons, the various types of the other firms have been placed at a disadvantage. Steinheil and Voigtlander are represented by more rapid objectives, and, in the case of Zeiss, the best of his rapid anastigmats has been ignored.

The conclusions to which a glance at these comparisons is apt to lead become under this aspect quite illusory; but, after examining the several prints more closely, the particularly surprising fact will find an explanation how it is that just the Goerz lynkeioscope compares apparently so favourably with the antiplanat, euryscope, and anastigmat *f*-7·2.

The pictures are all of the same size. Since, however, an antiplanat and euryscope of 144 and 138 mm. focus respectively are compared with a lynkeioscope and double anastigmat *f*-7·7 of a larger focal length, viz., 150 mm., the lenses of Steinheil and Voigtlaender are made to work at a considerably larger angle than the lenses of Goerz. The necessary mathematical consequence is that the antiplanat and the euryscope exhibit greater astigmatic aberrations than they would have done if employed with the smaller angle of the objectives of Goerz.

We further notice that with the antiplanat the centre is perfectly sharply defined, while at the edge the definition is normal. The euryscope shows nowhere perfect sharpness, neither in the middle nor at the edge. There is, therefore, the suspicion that the sensitive plate was placed in such a position as to cause the image to degenerate towards the edge more than would have been the case with an accurately focussed centre. The photograph taken with the lynkeioscope does not, however, show the same sharpness in the middle as in a zone, say, one and a half cm. away from the centre. This favours diminution of curvature of image and of astigmatism.

The anastigmat *f*-7·2 has, like the lenses of Steinheil and Voigtlaender, also been treated somewhat negligently. The axis of the objective was, in the experiment, not directed towards the centre of the object, but towards a point about 1·5 cm. to the left of that centre. The margin on the right corresponds, therefore, to a considerably wider angle than is the case with the lynkeioscope and the double anastigmat, with both of which the adjustments appear to have been made with due care.

Comparing these results, it must be admitted that the prints shown by Herr Goerz constitute no fair basis for comparison and for ascertaining the relative powers of the best objectives of the present day and, in particular, for determining the qualities of the antiplanats, euryscopes and Zeiss anastigmats, as compared with the double anastigmats and lynkeioscopes. I consider them, on the contrary, conducive to very one-sided and erroneous results.—I am, yours, &c., DR. PAUL RUDOLPH.

Jena, June, 1893.

TELE-PHOTO LENSES PAST AND PRESENT.

To the EDITOR.

SIR,—In your leading article of last week it would appear to ordinary readers that you yourself lay claim to the enunciation of the principle involved in the enlargement of primary images by the interposition of a negative lens.

This, of course, you must be aware, is not the case. The principle is as old as the science of optics itself. The *first application of the principle*

in a corrected and intelligent form was that of George Dollond *to the telescope* nearly sixty years ago in 1834, and described in the proceedings of the Royal Society of that year. The use of all kinds of telescopes for the production of enlarged images upon a screen, particularly of the sun, has been known and practised before and after the discovery of photography.

When lecturing at the Society of Arts this year on "Tele-photography" I took pains to be certain to whom the credit belonged for the *application* of the principle involved, to optical instruments.

Barlow's negative achromatic lens applied by Dollond in the astronomical telescope is the only record for direct enlarged primary images.

For obvious reasons telescopes, Gallilean or others, are unsuitable for photographic work, for in the latter central and excentrical pencils have to be considered.

You are good enough to mention your appreciation of the corrections of my lens before closing the leader, for which I thank you, but I write this letter as I think it is only fair that credit might be given to the *first* to turn his attention to an adequately appointed and corrected optical system for tele-photographic purposes.

Although you state that nineteen years ago "we spoke of it to one optician," it is remarkable that between a date (see former controversy) prior to your leader of October 16, 1891, and my first paper on the subject delivered before the Camera Club, in the latter part of the same year (December) you appeared to be as innocent of the suggestion as I was myself.

Advances in optical work, as in any other, are frequently brought about from suggestions as to the desirability of attaining a certain end. Photographers who would have welcomed tele-photographic lenses sooner have only to regret that your valuable and expressed "desideratum" of nineteen years ago has lain so long dormant.—I am, yours, &c.

25, *Newman-street, W., June* 19, 1893. THOMAS R. DALLMEYER.

AMATEURS *VERSUS* PROFESSIONALS.

To the EDITOR.

SIR,—Many references have been made in text-books and in our journals lately concerning amateurs, and to the professional mind it seems unfair for any one outside what is termed the profession to receive remuneration for their labour. I may at this point be allowed to remind the profession that, should the amateur be a working man whose means are very limited, but who possesses an intellectual and refined mind, and in many cases (my own included) whose every spare penny is required to obtain even a makeshift outfit, and handicapped by having to pay higher prices for most of his photographic materials than his brother of higher degree, can it be wondered at that the amateur should not be able to resist the temptation of trying to recover at least some of the wisdom-bought money that has been spent upon this expensive hobby?

It is all very well to talk about the *bonâ fide* amateurs. Who are they? I suppose, ladies and gentlemen who practise photography as a pastime. I, for one, Mr. Editor, cannot see wherein anything mean can exist in earning an honest penny.

The mysterious halo which has encircled the photographic art has, to a considerable extent, been reduced, thanks to the many manufacturers of photographic materials, who, by the way, seem to be as eager to supply the amateur with their goods as the professional, and it cannot be denied that with such advantages the intellectual and careful amateur, be he gentleman or mechanic, can make a fair show against many of the professors of the art.

If the profession perceive their craft to be in danger, let them form an Association, with power to receive such amateurs into their fold as may be deemed qualified. Then a distinction could be made between the worthless followers of photography and those who have, through careful study and dogged perseverance, attained to that perfection in the art worthy of the name of professional.

The distinguishing mark between the fit and unfit would then be the professional certificate from that body.

Of course the law of this organization would rule the profession to a certain extent, and some restraint upon its members regarding prices for work would be recognised, thereby producing less friction between local artists, whose elastic price lists and mode of securing orders in many cases are calculated to lower the dignity of the profession in the eyes of the public.—I am, yours, &c., SSENKRAK.

June 10, 1893.

TECHNICAL INSTRUCTION CLASSES.

To the EDITOR.

SIR,—The great success of the series of Instruction Evenings held by my Society which has just finished, and the keen appreciation shown by those gentlemen who attended them, has induced the Council to arrange another series for the ensuing half-year. The course is as follows:—

July 15.—Personally conducted outing.

July 19.—*Development Modified to Soften Harsh Contrasts or Brief Exposure.*

August 19.—Personally conducted outing.

August 23.—*Development Modified to Improve Flat Subjects or Over Exposure.*

September 20.—*Lantern Slides by Contact.*

October 18.—*Cold Bath Platinotype with Gelatine Development.*

December 20.—*Bromide Paper.*

There are no fees of any kind for attending these classes, and we throw our doors open to gentlemen who are not members of our Society so far as our space will permit.

If those gentlemen who are strangers to us who would like to take part in this series will kindly write me, I will send them fuller particulars than I dare trouble you with.

Trusting that you can afford me space for this announcement—I am, yours, &c., GEORGE GOSLING, *Hon. Secretary.*

North Middlesex Photographic Society, Jubilee House, Hornsey-road, N.

June 20, 1893.

LARGE CAMERAS FOR PHOTOGRAPHIC SOCIETIES.

To the EDITOR.

SIR,—Since writing my letter on the above subject, which appeared in your issue of the 9th instant, our Committee have decided to supplement the 12 × 10 outfit loaned to our members by purchasing a whole-plate camera, with rectilinear and wide-angle lenses, tripod, and shutter, for the benefit of such of our members who desire the use of a camera of that size.—I am, yours, &c., CHARLES H. OAKDEN, *Hon. Secretary.*

South London Photographic Society, 51, Melbourne-grove, East Dulwich, S.E., June 15, 1893.

DEPRESSION IN PHOTOGRAPHY.

To the EDITOR.

SIR,—I have read with much interest your leader on "The Causes of Depression in Professional Photography," also the letter signed "Hard-up Pro.," which on one hand is very amusing, but on the other a true picture of many another photographer. In my opinion, the amateurs are largely to blame for the present state of affairs, for with a few months practice they can turn out work which is not by any means first class, but it satisfies their friends because they get their pictures for nothing, or next door to it. There is a remedy, and only one, that I can see, other than was suggested in the correspondence column a few weeks ago, viz., that we have a society like the chemists, and examinations just as they have to pass before starting in business; this would clear out a vast number of pros. not worthy of the name, also a large number of amateurs who receive money for their work, because by so doing they at once become professionals. Trusting this matter will now be gone into thoroughly, and that all our professional brethren may make their opinions and suggestions known, as it is a question which needs an early settlement,—I am, yours, &c., ANOTHER PRO.

To the EDITOR.

SIR,—This is an urgent subject that the Convention might discuss one evening, or at least the professional members, and the N. A. P. P. which hardly as yet seems to have justified its existence; they might suggest some remedy although the outlook is very dark. There is, no doubt, photographers have made themselves too cheap in the past and are now reaping the fruits, also do so at present for that matter, though I cannot personally plead guilty, for I have always tried to uphold the status of my profession, to the detriment, I find, of my pocket. But it is no use bewailing the past, it is no use railing at the amateur; he is here and will stay more or less, although I could tell of some mean tricks done by so-called amateurs, but let that pass, we should get over all that sort of thing; it finds its level. Just now the two main factors in the depression are: first, the trade of the country generally is bad, very bad, so that those of us that live (or, rather try to live) in the industrial centres are the first to suffer from that cause; the other, and most serious one, is: photography seems going out of fashion, people are rather ashamed than otherwise of being photographed. That this is so, Mr. Groves's letter proves, and when the leisured classes cease to patronise any branch of the fine arts it's in a parlous case.

We have not had anything strikingly new of late years; what is wanted is a new photograph that can be produced with little expense and expeditiously, that will be likely to take the public fancy. Such a photograph I hope shortly to submit to the profession and the public; I must, however, patent it first, or it will not go, or send it to America and let it come back as a Yankee invention; then, oh, it will boom!

Another thing might rouse business a bit if we sold or exchanged studios, &c. I think three to five years is long enough for a photographer to stay in a town of 15,000 to 30,000 inhabitants, or even larger; the public like change and will often run after a new man or studio. I fear we

are something like actors, get a certain mannerism of which the public tire, which a change would do away with somewhat; but, then, what about good-wills? according to your correspondence, there is none; according to *Tit-Bits*, it is better to be a costermonger than a photographer, for costers get good-will for their pitches, so that, altogether, we seem in a bad case. "Pioneer's" suggestions are too late, we should want Acts of Parliament, and Pat's affairs stop the way and will do for many years to come; I fear there is no hope of help in that quarter. Perhaps some one else will give us some ideas or invent a new photograph; at any rate, it seems all we can do at present is to cudgel our brains for something new and wait with patience the revival of trade.—I am, yours, &c., T. S. Hicks.

373, *Glossop-road, Sheffield, June* 19, 1893.

To the Editor.

Sir,—I have read with some interest the discussion in your paper on the stagnation in the professional photographic business. It seems to me that the reason is not far to seek, and comes, firstly, from the supply exceeding the demand; or, in other words, the number of professional photographers being in excess of that required to supply the public demand; and, secondly, from the miserable work turned out by many of them. I know a country town where, with a population of 1500, there are no fewer than four photographic establishments, and I can only ask if there can be work for all of these.

Your correspondent sees fit to be down upon the amateur, and I should like to make a few remarks in reply. I know very well a very leading professional, one to whom the Judges at the chief exhibitions have awarded many gold medals. In conversation he has often told me that he considers the amateur the best friend he has, and is always pleased to have a chat with him, as he finds that there is always something interesting and instructive to be discussed and learnt about new processes, new makes of printing papers, &c. In a large town no one can help being struck with the photographs in the show-cases of all except perhaps about half-a-dozen of the best photographers. Prints from poor, under-exposed negatives, prints that a good amateur would consign to the waste-paper basket along with the negatives, are what he sees in the specimens there exhibited. People are now beginning to know good work from bad, and the end to which this tends must be that, more and more every year, the best photographers will get more and more work, while the ones that turn out bad work will get less and less, till they are driven to earn a livelihood in some other work that they are better suited for.

The paragraph in which "Pioneer" dismisses the amateurs to "the obscurity from which they came" is rather cruel, but I can tell him that no greater blow could be struck at the development and progress of photography than that his wishes should be realised. The amateur takes up photography at first, as a rule, as a pure amusement, but very soon finds so much to interest him in the chemistry, optics, and the composition and lighting of his pictures, that he reads up and studies his subject in a way that none of the legion of second-class professionals have either the time or the inclination to do. Professionals have not time to experiment with all the new things that are coming out, and it is only when the amateur has tested them, and seen that they are good, that the profession comes to adopt them. To take an example of this, how many professionals have ever tried glycerine, and different strengths of developers used with brushes, to bring out a platinotype print? The power of retarding portions of a print, or bringing on others, I think places the platinotype easily first among the printing processes, and makes the print what in etching would be called "an artist's proof."

The successful photographer will always be the one who to artistic and technical ability can add sound business capacity, power of organization, and methodical working in his establishment. In men of this stamp there is no jealousy of the amateur, but among those who do not possess these qualifications I am quite aware that the reverse is the case.

June 16, 1893. Amateur.

MR. IVES AND PHOTO-ENGRAVING.—A CORRECTION.

To the Editor.

Sir,—I notice that Mr. Ives, in his very interesting paper on "Composite Heliochromy," makes a claim which, for historical as well as personal reasons, I must traverse.

I yield to no one in admiration of the splendid work which Mr. Ives is doing in a most difficult branch of our art. I also acknowledge that in photo-engraving he has made his mark, and that it is specially to him that the net-work method has been so developed in America. Nevertheless, I must take exception to the following extract from his paper. He says: "As long ago as 1881, when I was *the only successful producer* (my italics) of half-tone process blocks for the type press, and had considerably improved upon the older methods of composite heliochromy without quite realising the true principle which I first published in 1888, *I made the first photographic reproduction of a coloured subject by three impressions from process blocks* (my italics). This three-colour print, a reproduction of a chromo-lithograph, was referred to in a leading article in the *Photographic News*, September 5, 1884, p. 561."

Now I claim, in opposition to the foregoing, that, as regards both line and half-tone photographic engraving for blocks to be printed at the type press, *Dallastype and Dallastint are the oldest processes which have been worked commercially in this or any other country.* I am quite willing to take a back seat in favour of Cousin Jonathan, John Chinaman, or even Thibetan Mahatma, if it is *proved* that any such ingenious persons have prior claims.

The first reference to Dallastype will be found in the *Photographic News* of July 27, 1866, p. 360, and the Dallastint half-tone block method in a letter of mine in the *Photographic News*, July 23, 1875. Further references to Dallastint, which I had been working commercially since July 1875, will be found in the *Photographic News* of June 15, 1877, and June 22, 1877. At the former date will be found, under the heading "Photography In and Out of the Studio," that special attention is drawn to the perfection of the gradation and detail in Dallastint blocks. Then, as to colour, I refer to a letter of mine in the *Photographic News*, June 22, 1877, p. 299, in which I mention that I had applied Dallastint to composite colour printing under the name of Chromo-Dallastint, and I drew attention to a specimen in four workings of a very difficult subject, viz., the reproduction of a sepia drawing, which I was to exhibit at the Caxton Exhibition.

I have been producing Dallastype blocks commercially since the beginning of 1869, and Dallastint blocks since 1875. During the whole period I have produced some thousands of photographically engraved blocks, not only for this country, but for America, Canada, and other places.

I claim for Dallastint blocks that they render more perfectly half-tone and detail than the net-work system. The reason why net-work is in such vogue for half-tone blocks is—egotistical as it may seem in me to say it—because Dallastint is a secret process, while the net-work method is open to all. If Dallastint were known, it would supersede net-work. The natural grain in Dallastint has a far more agreeable appearance to the eye. It can also do what is impossible to net-work, viz., render correctly the detail in photo-micrographs. Further, it is more easy to print, and requires very little "making ready." With net-work, on the contrary, it is only satisfactory when the mesh is extremely close, but then it is more easily blocked up by the ink.

A combination of Dallastint grain and net-work produces a better effect than the plain net. For best results, however, Dallastint natural grain is to be preferred.

Looking backward, it is interesting to note the evolution of the net-work system. The first use of a photographic screen or veil is in that classic patent of Mr. Fox Talbot, viz., No. 565, October 29, 1852. He employed folded gauze to obtain his grain.

Later on, viz., twenty years after the above, Walter Woodbury, that most ingenious and indefatigable worker, patented the use of "mosquito netting," and Brussels net (see Patent 3654, December 4, 1872); and again in Patent 1954, May 30, 1873, he claimed the use of "fine ruled lines." Lastly, Woodbury obtained a patent (No. 4735, October 5, 1883 for the use of "fine ruled lines, netting, gauze, dots, or a print from a grained stone." Nothing really good was done by any of these methods until Mr. Ives, in America, introduced his net-work system, which was altogether a new departure, as described in his two United States patents, viz., February 8, 1881, and August 9, 1881. The method consisted in using, not a screen, but an elastic-lined surface which was inked, and then impressed on a relief, which could be photographed. When I saw Mr. Ives some three years ago I understood that he had sold his rights to a firm which were still working his system. The next advance was made by Meisenbach, using a screen in some way of which I confess the patent did not give a clear idea. It, however, gave a great impetus to screen methods in Europe and America, and there are now several practitioners of the net-work style. I am bound to confess also that, given good printing conditions, very high-class work is produced, especially where copper is used instead of zinc for relief etching. Still, I do not hesitate to say that there will always be an artificial appearance, even with the finest net-work, and that in every respect the natural grain gives truer rendering and more agreeable effect. I can show examples of Dallastint, produced as far back as 1875 and recently, which, I think impartial critics will admit, bear out my contention. Duncan C. Dallas.

5, *Furnival-street, June* 7.

THE CONCENTRIC LENS.

To the Editor.

Sir,—A brief reply to Mr. F. H. Burton, and I will trouble you with no more words on the subject of his contentions. There seem to be too many things which have to be explained to him to make it worth while to keep up a discussion with him. Amongst these is the fact that, when one wants a negative for enlargement, he uses a stop which will bring all the planes of the subject into the sharpest definition possible, and neither the Concentric nor any other lens will bring the foreground and the distance into focus at the same time, for which reason we use, as a rule, a very small stop, that the loss by the process of enlargement may be as far as possible equalised all over the enlargement. For the same reason, when I make a negative for ordinary use in which the foreground is

important, I use the smallest, or nearly the smallest, stop, for, as a distance which does not give the most delicate definition possible is disagreeable to me, I secure that, and then do all for the foreground that is needed. If the foreground is unimportant, I work with the larger stops, only using anything smaller than *f*-16 when the light is so brilliant that over-exposure is certain, for I rarely use the mechanical shutters. *That* is what "he does stop down for."

Mr. Burton seems aggrieved that I had not paid attention to his hint to "read your very able article on the 'Focal Peculiarities of Wide-Angle Lenses,'" and had persisted in always focussing at *f*-16, as if he had not said a word! "Ye gods!" and especially Apollo! Having during the last thirty-five years used or tried all the forms of lens in the market, except the very latest Zeiss wide-angle, I think that the author of that very able article will admit that I know what a wide-angle lens is and how to use it, we having worked together not a little during that time.

Mr. Burton seems to think it discourteous to talk of "duffers" in his connexion. What does he think of his own suggestion that I do not know the difference between a negative taken through a crack in the front of my camera, pinhole fashion, and one taken through the lens?

As to sending my lens to Kew, Mr. Burton will excuse my not accepting his suggestion; but, if it would not give me what I want with *f*-16, I would send it back to Ross & Co. for correction. Its definition on the screen is so exquisite as to make it certain that when there is a falling off in the negative the fault is mine, and not that of the lens. As for others, whether duffers or experts, "they pays their money, and they has their choice."—I am, yours, &c., W. J. Stillman.

Rome, June 8.

P.S., June 11.—I have just seen the letter of Mr. Burton in The British Journal of Photography of the 9th. He is, of course, at perfect liberty to do what he thinks best to satisfy himself that he is right; it does not concern me in the least. "The proof of the pudding is in the eating," and of the lens in the photograph. But, now that the controversy is ended so far as I am concerned, I would counsel Mr. Burton, the next time he provokes a discussion, to maintain the courtesy in his letters that gentlemen are used to in personal intercourse if he expects the debate to be profitable or courteous. W. J. S.

REDUCING OVER-PRINTED GELATINE PROOFS.

To the Editor.

Sir,—I have to thank "Free Lance" for his allusion, in last week's issue, to my article on "Reducing Over-printed Gelatine Proofs," as it has called my attention to a stupid mistake in the formula given, which I wonder he did not also point out. Two ounces of alum dissolved in one ounce of water is so palpably an error that I can scarcely understand his passing it, but the formula should read as follows:—"A hot saturated solution of *alum* is made, and, when cold, to each *pint* of it two ounces of common salt and half an ounce of hydrochloric acid are added." I do not know how I managed to transpose the alum and salt, or use "ounce" instead of "pint;" but, as compositors are not, as a rule, chemists, I suppose I must he to blame for it. I learnt all about the solubility of salt in hot and cold water when I was commencing chemistry.—I am, yours, &c., W. Lindsay.

GLASS SCREENS.

To the Editor.

Sir,—In reference to patent No. 9721 (Lauder Brothers), the specification of which appears in your issue of the 12th inst., this idea has long ago been carried into practice. Apart from cases in which I have seen such screens in actual use, I may mention a large floral foreground upon glass which was some years ago in the stock rooms of Messrs. Percy Lund & Co., of Bradford.—I am, yours, &c., W. Ethelbert Henry.

Sarnia, Ontario, May 29, 1893.

Answers to Correspondents.

Photographs Registered:—

Charles Walker Clarke, Devizes.—*Photograph of Prince of Wales at Devizes.*

Herbert William Hughes, Dudley.—*Photographs of miners at work.*

William Ernest Parkin Haigh, Taunton.—*Photograph of a group of skeletons.*

Augustus Frederick Perron, Bath.—*Photograph of W. Clark Russell, Esq.*

James Thomson, Fermoy, co. Cork.—*Photograph of the Duke of Devonshire and guests at Lismore Castle.*

William Frederick Hollett, Canterbury.—*Photograph of the landing of the Huguenots, from a painting in the French Church, Canterbury.*

Tobias Kipling, Darlington.—*Photograph of "Lord" Thomas Williamson, the Darlington weather prophet, aged eighty-four; also a photograph of the "old Standards."*

Robert Millikin, Kirkcaldy.—*Two photographs of the late James Townsend Oswald, of Dunnikier, Provincial Grand Master of Fife and Kinross Lodge; two photographs of Dr. Andrew Wilson, F.R.S.E., Coombe Trust Lecturer, Edinburgh.*

Iron.—Iron phosphate is not used in photography.

J. H.—Apply to Messrs. Avery, 81, Great Portland-street, W.

T. S. H.—The address is Edward L. Wilson, 853, Broadway, New York.

C. Lesty.—Yes, as unfixed bromide enlargements contain unaltered silver salt, they are decidedly worth keeping for residue purposes.

C. Ward.—There is no Government department of photography, as such, consequently there are no competitive examinations, as in the case of Post Office and other *employés*.

Novice (Leeds) writes, asking how ammonio-nitrate of silver solution is made. Dissolve the nitrate of silver in water, then add liquor ammoniæ until the brown precipitate first thrown down is just redissolved.

P. O'Connell.—The probable cause of yellowness in the prints enclosed is that there was not sufficient gold in the toning bath. They have the appearance of having been toned by sulphur rather than by gold.

H. Glover.—If you are offered to be supplied with nitrate of silver at one shilling and eightpence per ounce, you may rely upon one of two things, namely, that it has not been come by honestly or it is not pure nitrate of silver.

W. W. G.—The examples are all fairly good as photographs, but in every case no care has been taken to have the camera level, hence most of the buildings look a long way out of the perpendicular. But for this the majority would be good pictures.

E. C.—The "sparkling, frosted" appearance of the lantern slide arises from imperfect washing, or, we might almost say, its not having been washed at all. So much hyposulphite of soda was left in the film that, with the few minutes heat of the lantern, it crystallised out.

R. Sedgwick.—Thanks for a sight of the prints. It is by no means an uncommon thing with some of the older prints that have been kept in a damp place to find that, although the mounts have become mildewed, the prints have remained intact. The pictures have been forwarded on as desired.

T. Sebbons.—The ferridcyanide and hypo reducer is a very good one, but it is obvious that, in your case, it was used much too strong. With all reducing agents it is better to use them weak and allow a longer time for their action. Particularly is this the case with any reducer with which the worker is not familiar.

T. Read.—We have had no experience with the lens in question; but, from what we know of the firm, we have no doubt it is good value for the money. You must not, however, expect to get for five pounds an instrument equal in quality to one by the best makers, whose price for the same size is about three times that amount.

T. R. J.—Although common glue is easier to mount photographs with than the best gelatine, it should never be employed on account of the acid and other impurities it usually contains. Nelson's "No. 2 Soluble," or Cox's soup gelatine, is almost as easy to use as common glue, and they, being pure articles, will have no injurious action on the pictures.

S. Cleevar.—It is quite a fallacy to imagine that good collodion for the wet process is not to be had at the present time. All the best brands are still in the market, and the consumption of them is large even now, though not, of course, for portraiture. The fact that Continental workers make their own collodion has possibly induced this idea in your mind. But foreign operators, for the most part, have always preferred to make their own collodion, more especially those making negatives for mechanical processes.

Carbonensis.—Don't be deterred from working the carbon process by the fear of the injurious action of bichromate of potash on the skin. This, so far as we know, never occurs unless by continual daily working. It is not at all likely that, working on an amateur scale, any inconvenience will be experienced. Nevertheless, it is well to be careful. Always thoroughly wash the hands to free them from the bichromate when the work is finished.

Tent.—The stuff will do very well for the operating tent, provided it is situated where it is not subjected to full sunshine when in use. If the tent is to be exposed to the rays of the sun, a more opaque material will be preferable. It will be better to purchase a waterproofed stuff in the first instance than to render it waterproof afterwards. "Willesden" canvas is very suitable. For the framework of the tent, nothing is better, or cheaper, than iron gas-pipe. It is sold under the name of "gas-barrel."

A. O. X. (Clonmel).—As the ink adheres evenly all over the paper after it has been soaked in tepid water and sponged, something is wrong. Possibly the gelatine paper, after sensitising with the bichromate of potash, was kept too long before use, or it may have been over-printed. It may be that the negative is not of the right character for photographic work. This is a very prolific failure with beginners. The negative should be very dense, while the lines are perfectly clear; indeed, as clear as the glass itself.

Young Beginner writes: "Will you kindly give me advice with regard to the following:—1. I am having a studio attached to the house; I am told it will be rateable, but how so? I am not a householder; unmarried, lodging with the tenants of the house; I am not going to have water laid on, as we have a meter. 2. The studio is being built for convenience upon wooden supports, which the landord is going to the expense of, but the studio is mine. Would the fact of the studio being on his posts give him any claim to it? and will it be necessary to have an agreement or guarantee? 3. The studio has met with the disapproval of the neighbours, inasmuch as it hinders the view, but does *not* stop the light. The house and ground are the landord's, who is quite in with it (or willing), they (the neighbours) have tried to frighten me by saying it will have to come down; have I anything to fear with respect to it?"—In reply: 1. If the value of any property is increased, as it will be by the addition of new buildings, so will the rate value be increased accordingly. 2. A definite agreement had better be made as to this point. 3. If the new building obstructs any "ancient lights," it will certainly have to come down if the neighbours object. As we do not know what bye-laws the local authorities may have, we cannot say whether the erection contravenes them. Our correspondent, to be on the safe side in the matter, had better consult a solicitor who is familiar with bye-laws of the local authorities. They vary in different towns.

H. WILKINSON.—Though the fact of your having photographed a royal prince no doubt permits you to use the words "Under Royal Patronage," the acceptance of a copy of the picture by the Queen does not entitle you to display the royal arms, by doing which you run the risk of a penalty. If you dissolve partnership, it seems to us that your partner, equally with yourself, may claim to have had royal patronage.

THORNHILL SQUARE asks: "If I send a negative to a profeasional printer to have a dozen prints made therefrom, and the negative breaks after a few prints are obtained, cannot I sue the printer for the value of the negative? In my case the negative is a valuable one, as I cannot retake it without making a journey to the West of England to do so. I have made a claim for five guineas, and this the man repudiates entirely."—The printer can be sued for the five guineas, or any other amount for that matter, but we expect that nothing will be recovered. It is a recognised custom of trade that printers and enlargers are not responsible for breakage of negatives while in use or in transit. This is usually stated on all prospectuses.

VERY PUZZLED writes: "I should feel much obliged if you will kindly explain the difficulty herein met with. The enclosed print is one of the interior of the parish church here, taken with a Ross lens, No. 3 stop, fifteen minutes exposnre. On the right-hand side of print appears an inverted image of the east window. Ilford Ordinary plate used, backed with lampblack and glycerine. The same phenomenon appears in every negative taken with this lens of the church. Camera carefully examined and covered with focussing cloth during exposure."—There is a minute hole in the camera, probably in the front, close to the lens flange, which produces another image after the manner of a "pinhole camera." This will easily be discovered by examining the interior of the camera in strong sunlight, with the head shielded with the focussing cloth.

SEVERAL correspondents in our next.

PHOTOGRAPHIC CLUB.—June 28, *Lenses up to Date.*

RECEIVED.—Glycin-Andresen, Arthur Schwarz & Co., *Photography Annual.* In our next. J. J. Moran, and others, thanks.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.—June 24, Outing to Chingford. 29, Annual Meeting. July 6, No Meeting.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—June 27, Technical Meeting. A demonstration *of Carbon Printing* by Mr. W. E. Debenham.

MANCHESTER AMATEUR PHOTOGRAPHIC SOCIETY.—June 24, Chester. Train, Exchange Station, five minutes past one. Leader, Mr. J. G. Jones.

OLDHAM PHOTOGRAPHIC SOCIETY.—June 24, Great Budworth. Depart, Central, thirty-eight minutes past twelve, for Lostock Gralam. Return fare, 3*s.* 2*d.* Leader, Mr. S. Ashton.

WE learn from Mr. Birt Acres that the firm of Messrs. Elliott & Son, Barnet, is about to manufacture plates of greater sensitiveness than they have hitherto done, the new emulsion to be prepared by Mr. J. B. B. Wellington, whose services they have secured.

MR. S. B. TURNEY, of 183, Union-street, Plymouth, writes: "I shall be glad if you will notify in your next issue that I have fitted up a convenient dark room which wil be at the *free* disposal of members of the Convention for plate-changing during the forthcoming Plymouth meeting."

CHEETHAM PHOTOGRAPHIC SOCIETY.—The studio and dark rooms of this Society are now at 4, Grosvenor-street, Cheetham Hill, Manchester. The following is a list of meetings for the immediate future:—July 4, *Bromide Printing*, by Mr. A. V. Wilkinson. 19, *Isochromatic Photography.* August 1, *Hand Cameras.* 15, *Wet Collodion Process.*

GREENWICH PHOTOGRAPHIC SOCIETY.—The first Field Day has been fixed for June 24 (Saturday), when it has been decided to visit Eynsford, Kent. Trains leave Greenwich (L. C. D. R.) at two o'clock; Nunhead, fifteen minutes past two; Brixton, fifty-four minutes past two; arrive Eynsford, twenty-seven minutes past three. Return fare, 2*s.* 10*d.* if under twenty travel; if more than twenty, fare is reduced about one-third.

LEYTONSTONE CAMERA CLUB.—June 24, Greensted Church and Ongar Leader, Mr. T. F. Sanderson. The Club will proceed by the train leaving Liverpool-street at ten minutes past two, calling at Leytonstone at thirty-nine minutes past two, arriving at Ongar at twenty-four minutes past three. 28, Second Annual General Meeting at headquarters for the purpose of receiving the balance-sheet and report, and for the election of Officers and Council for the year 1893–94. Chair taken at eight o'clock. It is hoped every member will attend.

IN reference to our paragraph of June 9, in which we expressed regret that one of our correspondents on April 29, 1892, had erroneously attributed the authorship of certain articles in a contemporary to a well-known optician, we have discovered that, by an oversight, the name of the paper was omitted, and in now giving it we accede to a request to correct our correspondent's statements implying that the *Optician* was at "the beck and call of one optician," and that "it was not the trade organ of opticians generally." These and the other statements in Cimabue Brown's letter were made, we are persuaded, under a misapprehension, and we are glad to hear that our correspondent was mistaken.

A CONGRESS of the Photographic Society of Great Britain and Affiliated Societies will be held at the time of the Exhibition of the Photographic Society. The Congress will be opened on Tuesday, October 10, with an evening meeting at the Gallery, Pall Mall, when the President will deliver his annual address and present the medals awarded in connexion with the Exhibition. On October 11, at three and eight p.m., and October 12, at three p.m., there will be a meeting at the Theatre of the Society of Arts for the reading and discussion of papers; and on October 12, at eight p.m., there will be a special lantern display in the Gallery at Pall Mall. Further particulars will be duly announced.

MANY of our wealthy readers who, in these days of bank failures, may find difficulty in investing their surplus cash, and who are tired of the uncertain and fluctuating bubble-company speculations, may be interested in knowing of an opportunity of profitably and securely investing. Freeholds of business premises in and about the city of London have surely and steadily increased in value; of late, thirty, and even thirty-three years' rental have been paid as purchase money for first-class property. This is suggested by the fact of the freehold of the premises, 99, Hatton-garden, at present occupied by Messrs. Perken, Son, & Rayment, being down in the lists of Messrs. Edwin Fox & Bousfield for sale on July 5, the estimated rental value being 500*l.* per annum.

EXPLOSION OF GUN-COTTON.—A somewhat alarming explosion occurred at the shop of Messrs. Doig & Son, chemists, High-street, Dundee, on Saturday, June 3. One of the assistants, Mr. Charles Duncan, was engaged making collodion on the shop counter, when a quantity of pyroxyline which he was handling suddenly exploded with considerable violence. He was knocked down and rendered unconscious for a short time, while he was rather severely cut about the face and hands by pieces of broken glass. Another of the assistants, Mr. Andrew Halliburton, who was standing near, also sustained some slight injuries from flying chips of glass. Medical aid was soon obtained, and the injuries were attended to. The damage done to the shop, although considered very serious at first, was found to be comparatively trifling, being confined to the breaking of two or three panels in the glass cases. It is difficult to account for such an explosion—the wax jet was not burning, and the ether bottle was not about—except that it may have been caused by some impurity—perhaps improper washing—of the gun-cotton, or that some of the more explosive trinitrocellulin may have been produced in the process of manufacture. Mr. Duncan's injuries are such that he will be confined to the house for a few days. Mr. Halliburton's are not serious.

THE CHICAGO EXHIBITION.—In reference to an article which appears in the *Chicago Tribune*, relative to the high-handed doings of the official photographer, we have received the following from a correspondent:—"Your sheet has been so outspoken in defending the rights of the public as opposed to the extortions and swindles perpetrated by the management of the Columbian Exposition, that I think you will be interested in the enclosed cutting from a Chicago paper in regard to the action of the photographic monopolists (one of whom, Mr. Higginbotham, is the son of one of the highest officials of the Exposition, as the cutting will demonstrate). The whole show is conducted on the most grasping principles—even drinking water is sold. There are huge piles of seats in an unfinished state, in which condition they have remained for weeks past, while the completion of thousands of 'chairs for hire' has been pushed to the utmost. The Fair, though it has been open for more than a month, is very incomplete still, and it probably will not be *fully* finished for a couple of months more. Many exhibits that were displayed some weeks ago are now closed up by reason of the lime and mortar dust which permeates all the cases, and injures delicate instruments. These will not be reopened until this nuisance abates. But the visitor need not fear the 'fleecing machinery' is incomplete. I cannot see how it could be carried nearer to perfection. This is the opinion of all the disinterested visitors I have talked with."

DARK ROOMS IN AUSTRIA, GERMANY, AND ITALY.—Herr E. Liesegang, Düsseldorf, has been good enough to refer us to his Almanac and Calendar for 1892, in which are given particulars of Austrian, German, and Italian dark rooms open to amateurs as asked for by a correspondent last week. This information may be of service to many of our friends who go abroad at this season of the year. *Germany and Austria:*—Baden-Baden: B. Bickel, Langestr. 20; G. Stumpf, Phot., Lichtenthalerstr. 53. Berlin: Romain Talbot, Kaiser-Wilhelmstr. 46. Dresden: C. F. Bernhardt, Palais Gutenberg; E. Kaders, Phot. Manufactur, Altst.; Otto Francke, Pragerstr. 28. THE BRITISH
JOURNAL OF PHOTOGRAPHY.

No. 1730. Vol. XL.—JUNE 30, 1893.

THE EQUIVALENT FOCUS OF A COMBINATION OF LENSES.

The letter of Mr. L. V. Drew, of Cape Colony, on another page, is only a type of similar inquiries we are receiving more or less constantly, especially from those who have taken up photography of late years. Few years only have elapsed since the catalogues of some lens-makers did not recognise the real focus of their productions, but only the "back" focus of a combination, a term which conveys no definite information. But, since the times referred to, photographers are being educated up to know something more about the tools with which they work than can be gleaned from "back focus" references, and we are glad to perceive in more recent catalogues a marked improvement in this respect. What has been said of the lack of information conveyed by the term back focus applies equally to front focus—a term, however, we hear but seldom employed.

It is the equivalent or solar focus that concerns photographers, although the back or the flange focus may prove useful to the camera-maker in affording some idea as to his measurements when making a camera. The equivalent focus may be defined as the focus measured from the optical centre of the combination when such centre has been determined for a distant object.

If there is one blunder that has more frequently been made than another in trying to determine the equivalent focus of a combination, it is the recommendation, so frequently met with, to focus upon an object situated at such a distance from the lens as to make the image upon the ground glass of the camera of precisely the same dimensions as the object, which we may assume to be an engraving or a photograph that has to be copied its own size, and then divide the distance between the object and the image by four, which, it is alleged, will give as the quotient the precise equivalent focus of the objective. But this method is incorrect for a combination of lenses separated from each other by being mounted apart in a tube, and the amount of their separation not admitted as a factor in this calculation. We mention this method first on account of the widespread belief in its accuracy, which, as we have shown, is incorrect. The method is only correct in the case of a single biconvex lens of infinite thinness, could such a lens be made, or even conceived of, in connexion with the optics of photography.

A simple method, and one which is within the powers of every one, by which to ascertain the focus of a lens, consists in directing the camera to any subject situated at a distance, and focussing it by aid of a magnifier, so as to ensure sharpness. Have the subject so arranged that a well-marked object, *e.g.*, a lamp-post, or the trunk of a tree, shall occupy positions at opposite margins of the ground glass. Now, having marked on the focussing screen the exact positions occupied by these two respective objects, unscrew the lenses from the mount and insert anywhere—by preference, and for convenience in the slit for the diaphragm—a thin piece of metal punctured with a pinhole, and, having thrown a focussing cloth over the camera, examine the image and rack the camera in or out until the pinhole image on the ground glass exactly coincides with that produced by the lens, the two marks to which we have referred aiding in this. This coincidence of images having been obtained, measure with accuracy the distance between the thin metallic plate pierced with the pinhole and the ground-glass focussing screen, and this represents the equivalent focus of the lens.

The only drawback to this method lies in the difficulty of projecting an image on the screen with such a degree of sharpness and luminosity as is necessary, for if the pinhole be too large the sharpness is defective, and if too small there may not be light enough to see the image. We have, however, by making use of lighted gas lamps as test objects, been able to employ a very small pinhole, and thus to secure a very high degree of accuracy in the measurement.

There is no method of ascertaining the true focus of a lens more beautiful and accurate than that of making the camera itself do duty as a theodolite—a method that will always be associated with the name of the late Mr. Thomas Grubb. In adopting this system, a table, on which is spread a large sheet of white paper, is brought up to a window, and the camera is placed thereon. The only preparation of the camera necessary is to draw a pencil line at each end, and from top to bottom of the ground glass, say, one inch from the edge, although any definite distance is quite immaterial so long as both sides are alike. Now, having selected any object at a distance, such as a church spire, a tree, or a chimney of a house, focus this sharply upon one of the lines drawn on the ground glass, and then with a pencil draw a straight line on the sheet of paper on the table, using the edge of the baseboard of the camera as a ruler. Without altering the focus of the lens, rotate the camera until the same selected object falls upon the second of the vertical pencilled lines, and draw another straight line on the sheet of paper, using the same side of the camera, as before, as a ruler.

The camera may now be lifted down, as the measurement is to be deduced from the paper, which contains as yet only two lines. These are to be prolonged until they meet at a point; and by a pair of compasses opened out to the distance between

the two marks on the focussing screen, these two lines are connected by a cross line like that in the letter A, that is to say, the cross line must equal the distance between these marks. The true equivalent focus of the lens by which the experiment was conducted is equal to the distance between the centre of the cross line and the junction of the two side lines.

PHOTOGRAPHY AND SCIENTIFIC RECORDING.

We are pleased to find in the Smithsonian Report for the year ending 1892 a sentence echoing a recommendation we have frequently made as to the use of photography in scientific recording, and we can only hope that it will be another strike against the neglect of photographic processes in the reduplication of phenomena or records produced by photographic means. No one more than ourselves is more willing to express estimation of the value of past illustrations of such phenomena done by the hands of skilled and careful engravers who have been able to translate through the medium of their gravers, wielded by deft fingers, the very best of sketches into valuable pictures and plans of the utmost service to scientific men. But the time is past for the bulk of that class of work, and it is but seemly that photography should repeat to any required extent by one of its many methods those results and memoranda obtained by photography. We want now not pretty, nay, beautiful engravings, but *facsimiles* of the spectral lines, the cometary pictures, the maps of stars, the hills and craters of the moon, and that multitude of results now daily obtained by the aid of lens and dry plate. Doubtless such reproductions are gradually gaining ground, but we would see all but sun-made pictures banished.

The words of the particular paragraph of the Report quoted, referring to matters of great interest, we will further allude, to are as follows: The Institution is already in communication with some of the leading observatories of the world, and they hope for "a series of photographic representations of hitherto unequalled size and definition, which shall represent the moon's surface as far as possible on a definite scale, and entirely without the intervention of the draughtsman." Of course, there are, nowadays, many draughtsmen and engravers with a knowledge of the subject they are set to work at; but they are not always available, and not always obtainable for a particular class of work. We well remember, now many years ago, the late Mr. Philip Carpenter telling us that, in getting together a set of illustrations of a particular series of shells for a conchological list he was making, he obtained the services of some skilled students from South Kensington, who, owing to their want of acquaintance with the subject, made pretty sketches, but useless science memoranda. He was forced, though little skilled in drawing, to do the work himself. What a boon photography and dry plates would have been to him!

Astronomy gives the lion's share of work at present, and its future is opening out. Take, for example, the Smithsonian Institution, the branch of astronomy to which the resources of the Observatory will be devoted will be that of exploring the great unknown region in the infra-red end of the spectrum by the method recently improved by Mr. Langley himself. We need scarcely say that this region has been investigated both by photographic and electric methods.

Every one knows what the Lick telescope has done and will do with photographic processes of recording, but a lens a yard in diameter means much more than those unfamiliar with observatory work have any conception of.

The Royal Observatory at Copenhagen follows the same course, and is to have a telescope on the lines of that of Upsala. It will be double, and the optical photographic tubes will be mounted on the same stand.

We have frequently alluded to plans and speculations about new instruments of gigantic size, their probabilities and capabilities, but at last it is possible to speak more definitely. *Astronomy and Astrophysics* for the current month is responsible for very complete details. The new instrument now to be made is the Yerkes telescope, and it will be of interest to our readers to give a brief description of the proposed monster erection.

The great tube pier is being built by the same firm who made the Lick instrument. The column will be in five sections, each weighing five and a half tons, excepting the base, which will weigh about eighteen. It rises about ten and a half yards from the base. The pier-head weighs five and a half tons, the total being thus about forty-five tons. The polar axis is steel, and fifteen inches in diameter, and thirteen feet long, the declination axis being not much smaller. The telescope tube itself is of sheet steel, and, exclusive of the arrangements at the observing end, is over sixty-two feet long, weighs six tons, and is about fifty-two inches in diameter. All the quick and slow motions and clamps can be operated from the balcony, eye-end, or floor, and either by hand or electricity, as needed.

Our readers will join us in the hope that this big camera, as long as several railway cars joined together, fixed on a camera-stand weighing as much almost as a thousand men, and as tall as a good-sized house, will do worthy photographic work, worthily recorded by photographic means alone.

TONING GELATINO-CHLORIDE PRINTS WITHOUT GOLD.

In a variety of ways the question of the possibility of toning printing-out papers without the use of gold, and the uncertainty of colour that, to some extent, attaches to that method of toning, is one that is constantly being presented to us. There is no possibility of denying the fact that the neutral black and cool grey tones obtained with developed bromide prints, so closely resembling as they do platinotypes, are growing in favour; and, though these may be imitated very closely with the ordinary printing-out papers under favourable circumstances, the result is by no means a matter of certainty. On the other hand, a good many users of those papers prefer brown tones, and meet with the same difficulty in stopping the action of the toning bath at just the right moment to secure the precise tone wanted.

In the course of last year an article appeared in these columns on the subject of the restoration of faded prints by means of a process of bleaching and subsequent redevelopment, and several correspondents have during the past few weeks suggested the possibility of systematically applying this method in preference to the ordinary gold toning bath used with printing-out papers, either gelatine or albumen. We have before us, as we write, a set of prints forwarded to us that are stated to have been made upon gelatino-chloride paper, and which yet so closely resembled platinotype that we have been induced to inquire as to the details of their production, and also to try to imitate them.

At first sight it may seem that the easiest way to obtain the tones required would be to use the bromide papers and development, but this is precisely what most of our corre-

spondents do not wish to do. It is pointed out, as the chief advantage of the printing-out papers, that the result can be watched in the printing frame, and that any subsequent change, so far as loss of strength is concerned, can be much more easily estimated and allowed for than in the case of contact printing with development papers. The development is nowadays easy enough, and, even with the suggested modified treatment of printing-out paper, has to be performed, though it is with this difference, that the formation of the image can be watched in the printing frame, and the after-treatment is little more than mechanical, the redevelopment after bleaching being only a process of reduction of the material already constituting the image, and therefore only capable of altering the colour without adding anything to it in the way of detail.

In the course of the article already referred to it was pointed out as a curious fact that, after bleaching and redeveloping an ordinary print, faded or otherwise, the original tone is in most cases reproduced with singular persistency. This observation was made in connexion with gold-toned prints, both on albumen and gelatine paper, and it applies with equal force to those that have not been previously toned. Obviously there can be nothing gained by applying the bleaching process to prints that have already been toned with gold, unless they happen to be so bad that any method of improving them is welcome, so we start with the idea of treating prints that have been passed through the hypo bath without gold toning.

Most of our readers will have met, at some time, with the so-called "magic photographs," which make their appearance upon an apparently clean piece of paper upon immersion in water in contact with another piece equally clean, or which may be developed by the smoke of a cigar or cigarette. But many are, perhaps, not aware that these are simply untoned albumen prints, bleached with bichloride of mercury, the invisible image being reproduced by the action of very weak hypo, ammonia, or any of the reagents employed under similar circumstances for the intensification of a gelatine negative.

The tones produced by weak hypo, following bleaching by mercury, are of a most pleasing sepia tint, and for albumen paper, where brown tones are desired, this treatment answers well. But for gelatine papers, in consequence of the hardening action of the bichloride and the persistency with which it clings to the gelatine, it is not to be recommended; although, given thorough washing between the different operations, it will answer as well as with albumen. Sulphite of soda, in place of hypo, is, however, better, as it gives, perhaps, a better colour, with less risk of staining.

A preferable bleaching solution is found in chloride of copper, or, better still, in bromide of copper. These salts may not be found in the ordinary photographic dark room or laboratory, but are easily extemporised out of readily obtainable materials. Sulphate of copper is obtainable at any village chemist's, and if half a drachm of that salt be dissolved in two ounces of water, and the same quantity of bromide of potassium or twenty grains of common salt be added, a solution will be formed containing bromide, or chloride of copper, as the case may be, either of which will rapidly bleach the positive image, and convert it into bromide or chloride of silver.

With either the mercury or copper salts there will, of course, be other metallic products formed in the bleaching process, though these do not appear to materially affect the final result, provided a sufficient washing be given. A better solution consists, perhaps, in a weak mixture of bichromate of potash and hydrochloric acid, ten grains of the former and twenty minims of the latter to the ounce of water. This bleaches the image with great rapidity, and, if the print be washed until the yellow tint of the bichromate is removed, it will be free from any foreign matter in the shape of metallic salts other than those of silver.

The bleaching is a merely mechanical operation, and the result does not greatly vary whatever may be the agent employed. The reduction or redevelopment is, perhaps, equally a mechanical process since the solution employed cannot possibly go beyond a certain point—that is, the complete reduction of the silver haloid present. But a great difference may be made in the colour produced. If the image is converted into chloride, it will behave much in the same way as ordinary chloride paper under development—that is to say, it will with every developer we have tried, unless very powerful, produce a yellowish-brown colour that requires toning with gold or platinum in order to make it acceptable.

If, however, a strong, fresh ferrous-oxalate developer be used, fairly good black and grey tones may be obtained if the paper be not exposed to a strong light before treatment. By exposure to light and treatment with a weak solution the result is precisely the same as with Alpha or other chloride paper.

With a bromide-bleached image, amidol or metol, if employed of the usual negative strength, will give good black tones, but if reduced in strength, as for ordinary development of bromide papers, the colour shows a strong tendency to return to the yellow-brown of the fixed untoned print. Ferrous oxalate exhibits the same tendency, though not to the full extent of the two first named; but in every case the strength of the reducing solution must be much greater than for ordinary bromide paper, more nearly that usually employed for negatives.

The fixing, bleaching, and redevelopment of prints, instead of toning with gold, may seem a round-about way of arriving at a result; but, as a matter of test, we have found it more rapid and less trouble than the ordinary process of gold-toning.

The Japan Exhibition.—The recent exhibition of photographs in Japan was chiefly composed of contributions of well-known pictures by English photographers, including a collection from the Camera Club. The credit of organizing the Exhibition belongs to Mr. W. K. Burton, who, according to opinions expressed in the native press, should be pleased at the result of his labours. About 300 pictures were hung, and the catalogue of them is a tasteful and artistic production. It was printed on tinted crape, with decorative designs on each page.

Auxiliary Lighting.—Every now and again the advantage, or otherwise, of a supplementary lighting of the plate in shortening exposures crops up. It did only last week amongst a few photographic friends, when an animated discussion was carried on for an hour or more. Now, although it was denied by some that any extra detail could be obtained by secondary lighting, the effect being to cause fogging, contrary to the opinion of others all were agreed that in the case of some under-exposed plates, such as "snapshots," a little judicious fogging of the shadows would often be an advantage, particularly when the negatives were to be used for stereoscopic transparencies or lantern slides.

The Patent Office.—The Comptroller-General of Patents has just issued a new series of abridged classes relating to agricultural and horticultural appliances. These abridgments are exceedingly useful as guides to the various specifications. They are, or rather used to be, issued on almost every subject, but unfortunately they are now in a very backward state. The latest issued relating to photography

only brings us to the end of 1883, though it bears the date of a couple of years later. The number of patents taken in connexion with photography during the past ten years is very large, and an abridgment of them would be of service to would-be patentees. Considering the profit realised by the Patent Office, it might be surmised that the compilation of the various abridgments would not have been allowed to fall so much in arrear as they are at present.

"Our Climate."—The moderated temperature of the past week or so has been a great relief to the majority of photographers, and certainly to all workers of processes dependent upon gelatine in conjunction with the alkaline bichromates. At elevated temperatures, such as have recently been experienced, some of them, such as collotype, Woodburytype, and the carbon process, are only worked with difficulty, even when the ordinary conditions of working are considerably modified. With the thermometer at 88° in the shade, Woodbury printing becomes almost, if not quite, impracticable, and collotype only workable when the plates are specially prepared to meet the exigencies of the case, which, by the way, may be changed in a few hours, and then the plates are no longer suitable. Few countries but ours can boast of a climate that can show a difference in the mid-day temperature of 27° in twenty-four hours, and, we might add, so far as gelatine photography is concerned, would desire it.

Photographing the Voice. — Professor Hermann has recently succeeded in photographing the vowel sounds. The method employed was speaking them into a phonograph that reproduced them slowly. The vibrations were recorded by a micro-telephone, in the vibrating drum of which was a smaller mirror, a ray of light from which recorded its vibrations on a travelling strip of sensitive paper. The idea of photographing sounds, however, is not new, for, when the phonograph first came out years ago, the late Professor Jenkin, of Edinburgh, together with Professor Ewin, made similar experiments to those of Professor Hermann. The phonograph, however, used by these gentlemen was the original tinfoil instrument, and the sounds reproduced were somewhat crude. Notwithstanding this, some very interesting results were arrived at, and were published at the time. What would have been thought, prior to the invention of the phonograph, of any one who might have suggested that sounds could be photographed?

Colour Blindness.—The latest suggestion as to the cause of defective colour sense is that of Messrs. Blake and Franklin, of Kansas, who have recently investigated the subject, and who attribute it to a product of civilisation, with the use of tobacco as a possible factor. It is said that colour blindness has been found to occur in about four per cent. of civilieed European and American males, and with the Finlanders and Norwegians it is said to rise to five per cent., while the Dutch go down to 1·43 per cent. According to these authorities, only seven-tenths of one per cent. of the full-blooded Indians of the Haskel Institute at Lawrence are colour-blind. It is not stated whether these Indians abstain from tobacco or not, but it is certain that the Dutch, who have a very low average assigned to them, do not. Colour blindness is suffered by many who really are not cognisant of the fact. Some photographers cannot possibly tone a batch of prints to anything like a uniform colour. One gentleman we know, who is an artist in every way, so far as photography and monochrome goes, occasionally colours a picture, and the result is little short of ridiculous. Although the execution is excellent, blues predominate to such an extent that the picture is completely spoilt.

Use of Dark Rooms.—A few days ago we received a letter from a correspondent, an amateur touring with a camera in the West of England, complaining of the churlishness of some professional photographers in refusing the use of their dark room for the changing of plates or the development of a trial plate. Curiously enough, within a few hours we had letters from two photographers in the provinces complaining, in the one case, of the "impertinence," and in the other of the "nuisance" of amateurs with regard to the use of a dark room. Both of these gentlemen say that a large proportion of amateurs seem to demand the use of a dark room as a right rather than ask it as a favour, and invariably they will not tell their business to the reception-room attendant, but insist on seeing the principal, however busy he may be, to state their requirements. One also complains of the mess made when a plate is developed, and the litter left behind when plates are simply changed, the tourist often departing without even expressing thanks. Each year we receive similar complaints to these, on both sides. Amateurs *en route* should remember, and we believe the majority do, that in asking the use of a dark room they are asking a favour, and at the same time to bear in mind that they may be causing inconvenience to one whose time during business hours is money.

A NEW DEVELOPER FOR GELATINE DRY PLATES.*

The best experimental results were obtained with the tartrate and the metabisulphite of silver. Sulphite of silver, produced by precipitating nitrate of silver by its equivalent weight of sulphite of soda, is but little soluble in water, and is easily washed. The precipitate readily dissolved in a strong solution of sulphite of soda, but when combined with gelatine is less sensitive to electrolytic action than the tartrate. An impure double sulphite of silver and soda can be readily prepared by the addition of a solution of nitrate of silver to a saturated solution of sulphite of soda, as long as the precipitate formed dissolves on stirring. The nitrate of soda produced by this reaction, if not removed, seems to have a restraining action when the developer is prepared with hydroquinone. As pyro is not as strongly influenced by the presence of nitrates, it may be found practicable to prepare the silver salt in this manner in developers in which pyrogallic acid is the reducing agent.

In like manner ammonia may be used in argentic emulsions with pyro, though the addition of ammonia to a hydroquinone developer instantly arrests all reducing action.

Developer No. 1.

Formulæ.

A.

Argentic emulsion (prepared with silver tartrate)	5 ounces.
Metabisulphite of soda	120 grains.

B.

Eikonogen	200 grains.
Hydroquinone	100 „
Metabisulphite of soda	120 „
Distilled water (hot)	4 ounces.
Pure glycerine	1 ounce.

C.

Carbonate of potash	144 grains.

D.

Caustic potash	270 to 300 grains.
Distilled water (hot)	¾ ounce.

E.

Bromide of potash	72 grains.

Solution A is prepared by warming the argentic emulsion gently on a water bath in a glass or porcelain vessel of a capacity of about sixteen ounces. The metabisulphite of soda is stirred in dry immediately before incorporation with B.

The eikonogen, hydroquinone, and metabisulphite (B) are mixed together dry, the water, heated nearly to the boiling point, is mingled with the glycerine and poured over the mass, which immediately dissolves if rapidly stirred, forming a clear golden yellow solution.

The incorporation of A and B requires careful manipulation to avoid the precipitation of the gelatine or the reduction of the silver salt. These solutions are mixed at a temperature of 110° to 140° Fahr., a few drops of B are added to A, with rapid stirring continued for several minutes, until the emulsion, which at first darkened, becomes of a lighter shade. The remainder of B is then poured gradually, a little at a time, into solution A, stirring constantly.

The emulsion should show but little change in colour; it is at once neutralised by C, mixed dry. Carbonic acid is evolved, the emulsion

* Concluded from page 375.

changes to a dark drab colour, and some gelatine separates as a dark-coloured precipitate. D is then added in successive portions, the colour of the emulsion changes to yellowish olive, and the precipitated gelatine redissolves. The amount of caustic potash required varies with the purity of the chemicals, and with any change in the formula. It is best to add to each ounce of the developer from two to four grains of caustic potash in excess of the quantity required to dissolve the precipitate.

Care should be taken to determine the least amount that will form a permanent emulsion. If the proportion of potassium hydrate is too great, the combined silver and gelatine are precipitated.

E is dissolved in the emulsion, and produces no apparent change in its appearance. Water is added sufficient to make the volume twelve ounces. The developer is bottled and cooled in a stream of water, with frequent shaking.

Thus prepared, this developer is permanent, and but little affected by a moderate exposure to daylight. It is kept in bottles of dark-coloured glass wrapped in paper.

The density and colour of the resulting negatives are much affected by the relative proportion of eikonogen and hydroquinone in the above formula. In the proportions given, of two parts eikonogen to one part hydroquinone, the negatives produced are brilliant black in the high lights and of extreme density. With 240 grains of eikonogen and 80 grains hydroquinone, a ratio of three to one, the negatives are grey black, with relatively less density, but with extreme detail.

Composition per Ounce of Developer No. 1.

Eikonogen	16·7	grains.
Hydroquinone	8·3	„
Gelatine	3·5	„
Sulphites of soda	48·	„
Carbonate of potash	12·	„
Caustic potash	25·	„
Bromide of potassium	6·	„
Tartrate of silver	4·8	„ = 1 per cent.
Glycerine	1·5	drachms=19 per cent.

It should be noted that the object of using metabisulphite of soda in the above formula is to make the solutions A and B acid when incorporated, in order to diminish the reducing action of the eikonogen and hydroquinone upon the silver salt. It is more difficult to combine these solutions when alkaline; not infrequently metallic silver is precipitated. By careful manipulation, however, an equivalent quantity of neutral sulphite of soda may be substituted for the metabisulphite.

Carbonate of potash is employed to neutralise the metabisulphite of soda; it also greatly diminishes the action of potassium hydrate upon the gelatine film, preventing, at a temperature not exceeding 60° Fahr., the frilling or cutting of the edges of the film by the caustic alkali.

Bromide of potash, in the presence of the great excess of alkaline salts in this developer, keeps the shadows clear and transparent, even with prolonged development. It has no restraining action, but, in the proportion of five to eight grains per ounce of developer, appears to act rather as an accelerator.

This developer is adjusted by a trial development upon an extreme under-timed plate. The picture should appear in twenty-five to thirty seconds; if longer, two to three grains of caustic potash and one to two grains of bromide of potassium are added to each ounce, to accelerate the action.

There are evidences that this emulsion undergoes ripening if kept in a warm place, or if heated to a temperature of 130° to 160° Fahr. for some hours; the effect of this ripening remains to be investigated; in some experiments a grey precipitate of silver bromide formed, and the electrolytic sensitiveness of the developer was increased.

The objections to the above developer are the complicated formula and the large amount of the caustic alkali used, necessitating development at a low temperature, not exceeding 60° Fahr., to avoid cutting the film. It also requires, to form a permanent emulsion, careful manipulation in compounding, and is much affected by any change in the purity of the chemicals used.

Development.

If the preparation is complicated, the development is correspondingly simple, and it is practicable, with a little experience in its use, to obtain results that are unapproachable in density, and can only be equalled in detail by skilful manipulation with pyro.

For instantaneous and under-timed exposures the developer is used without dilution; if desired, the action may be restrained by the addition of water. A somewhat larger quantity of the developer is required to properly cover the plate, owing to the viscidity of the emulsion. Two trays are used in development, the larger filled with cold water, in which the smaller tray containing the developer partly floats. The negative is placed in the developer, and disappears from view beneath the opaque emulsion; the tray is rocked until the picture comes up. It is only necessary, during the development, to occasionally rock the trays, the viscidity of the developer preventing unequal chemical action or the settling in spots upon the film of any sediment.

The progress of the development is judged by the colour and appearance of the plate when viewed by transmitted light; the low lights and shadows are indicated by white spots in the film, which become yellow-brown as the action proceeds; the development is stopped when the plate is opaque and a walnut-brown colour throughout.

The negative is thoroughly washed, and the surface of the film is rubbed with the hand under a stream of cold water to remove the adhering emulsion; it is then fixed as usual.

When working with plates that have received nearly equal exposure, the time of development furnishes the best guide in obtaining the desired detail and density. There is a wide margin in time when instantaneous views and extreme under-exposures are developed. A good negative may be obtained in six to twelve minutes; if the development be prolonged to half or three quarters of an hour, no harm is done, save that the negative, from increased density, will print very slowly. When desired, the development may be prolonged for one or two hours by changing the water in the outer tray, so that the developer is kept cool and the film uninjured.

This developer may be used repeatedly without exhausting its power or staining the film.

Intensification.

Negatives that have undergone development may be intensified before fixing. For the primary development there is probably nothing better than pyro and soda; no bromide is used, and the development is conducted so as to bring out all the detail possible, keeping back density in the high lights, in order that all parts of the image may be nearly uniformly dense. When no more detail can be obtained, the negative is thoroughly rinsed in a stream of cold water and the secondary development conducted with any of the argentic developers, preferably with No. 1. The action is quite rapid and should be carefully watched, lest the negative be over-intensified. The time required for secondary development is from three to fifteen minutes. The best guide is the appearance of the plate when viewed by transmitted light; the development is finished when the negative becomes brown and opaque, without any light spots in the film. It is then immersed in cold water, the surface of the film is gently rubbed beneath the water with the hand or with absorbent cotton, to remove any adhering emulsion, and the negative is fixed with hypo in the usual manner.

In this secondary development the action of the argentic emulsion appears to be an electrolytic building up of the image in metallic silver. This view is confirmed by the fact that a negative after fixing and washing may be slightly intensified by immersion in the argentic developer. In this case the electrolytic action is very slow, and could probably be made more energetic by increasing the sensitiveness of the emulsion, and indicates that it would be possible to make an argentic intensifier for negatives after fixing, by employing a very sensitive emulsion with ferrous sulphate as a reducing agent.

Developer No. 2.

Formula (apothecaries' weight).

A.

Argentic emulsion (prepared with silver tartrate)	6 ounces.

B.

Sulphite of soda crystals (pure and neutral)	2 ounces.
Water (hot)	8 „

C.

Amidol	120 grains.

D.

Bromide of potassium	8 grains.

The argentic emulsion is gently warmed and the sulphite of soda solution B gradually mixed with it. If a precipitate of gelatine forms from too concentrated a solution, warm the emulsion on a water bath and add gradually hot water until it dissolves. The emulsion, which is of a light olive colour, is allowed to cool; C and D

are added dry and quickly dissolve; the volume is made up to sixteen ounces by water, and the developer is immediately bottled to avoid absorption of oxygen. Tested with litmus paper, it should show a faint alkaline reaction.

Composition per Ounce of Developer No. 2.

Amidol	7·5 grains.
Gelatine	3·1 „
Sulphite soda (free)	60· „
Sulphite soda (combined with silver salt)	25· „
Bromide of potassium	0·5 „
Silver tartrate	4·4 „
Glycerine	¾ drachm = 8 °/₀

This formula is less complicated and more easily prepared than No. I. Only a minute quantity of alkali is required, the sulphite of soda acting as the accelerator, and in consequence, in prolonged development, there is little danger that the film will be attacked. It is also practicable to use a more sensitive argentic emulsion, prepared with the least proportion of gelatine that will restrain the silver tartrate, in order to increase the electrolytic action. This developer has been but little investigated; it is probable that metol, or a mixture of metol and hydroquinone can be substituted for the amidol in the above formula, and other alkalies employed, such as caustic lime, lithia, or baryta.

Development.

In hot weather, or when the development is greatly prolonged, it is advisable to keep the developer cool by an outer tray containing ice water, as heretofore described. Usually, with formula No. 2, this is not necessary, and the development is carried out much in the same manner as with pyro. The action is started with one ounce of the developer mixed with three to five ounces of water, two or three drops of a solution of

Carbonate of potash	120 grains,
Water	1 ounce,

are added to each ounce of the mixed developer to accelerate the development.

The strength is increased by the addition of fresh developer as the operation proceeds. It is only necessary to occasionally rock the tray. The action is less energetic than developer No. 1, and the negative does not so rapidly become opaque. The point at which to terminate the development is judged in the same manner as with pyro, save that, as there is no danger of fogging, it may be prolonged until the negative is dark and opaque. The plate is rinsed in water and fixed as usual. The negatives developed with amidol emulsion much resemble in appearance those produced by pyro.

With a developer of this class it would be practicable, when many negatives were developed, to employ a grooved rubber bath (such as are used for hypo) filled with the developer, and immersed in a vessel of cold water. The vertical position of the plates would prevent any sediment in the developer settling upon the films.

Conclusion.

The formulæ here given are selected from nearly fifty experimental developers, prepared with various emulsified silver salts, combined with different developing agents. They illustrate the preparation of argentic emulsions and the combination, in a chemically passive condition, of such emulsions with reducing agents, in photographic developers.

Much experimental work remains yet to be done to determine the formulæ best adapted for use. The gelatine and the silver salts have a tendency to slow the action in development. It is desirable that the time of development should be shortened, and the electrolytic action of the silver salt made more energetic. W. P. Jenney.

ON THE USE OF TIN-FOIL AS A SUPPORT FOR PHOTO-LITHOGRAPHIC TRANSFERS.

[Photographic Society of Great Britain.]

In the execution of photo-lithographic work, considerable difficulty is sometimes caused by the fact that a transfer prepared in the usual way on paper expands when damped, and also is stretched when pulled through the press in the process of transferring. The image on stone or zinc is therefore distorted, and, in cases in which it is important that the reproduction should be to scale, elaborate precautions must be taken to ensure this. This difficulty is frequently met with in the Lithographic School of the School of Military Engineering, Chatham, which is in my charge. A considerable number of plans and drawings are there reproduced, and in all cases it is desirable that distortion should be avoided. In some cases this is of special importance.

It has recently occurred to Mr. Husband, who is employed in the school as lithographic printer, that tin-foil might be used instead of paper in the preparation of transfers, so as to prevent distortion, and he, together with some of the military lithographers, have been working out the idea.

Incidentally various other advantages in the use of tin-foil (besides that of non-distortion) have come to light, as will be seen presently. Mr. Husband was for many years in charge of the Lithographic School while he was a non-commissioned officer and warrant officer in the Royal Engineers, and his name is known in connexion with his "papyrotint" process for photo-lithography in half-tone. He therefore brings a very large amount of experience to bear on the question. It should be said at once that there is no new principle involved in the process. For line work it is merely a modification of the "papyrotype" process, introduced at the School of Military Engineering by Captain Abney when he held my present appointment, while for half-tone work it is a modification of Mr. Husband's own "papyrotint" process. It is, in fact, quite possible that this identical tin-foil process is in use in other establishments, but I believe that no account of it has ever been published.

The method of procedure is as follows:—

(A) Papyrotype Transfers (for Line Subjects).

A zinc plate, such as is used for zincography, is damped with a dilute solution of gum arabic (say one part in sixty parts water). A sheet of smooth tin-foil of the size of the transfer required is laid on the zinc plate, and the two are pulled through a lithographic press together. The tin-foil adheres to the zinc plate, which thus enables it to be conveniently held during the process of coating with gelatine.

A solution of chromated gelatine is prepared as follows:—

Gelatine, common flake	1 ounce.
Glycerine	2 drachms.
Bichromate of potash	40 grains.
Water (measured independently of the other constituents)	8 ounces.

The gelatine is soaked in the water for half an hour (the water being cold); it is then dissolved by heat. When it is thoroughly dissolved, the glycerine and bichromate are added, and the whole stirred up together; in three or four minutes the bichromate is dissolved, and the mixture is ready for use.

The above quantity is sufficient to coat about eight sheets of the size of half a sheet of foolscap.

The surface of the tin-foil is then cleaned with a solution of caustic potash (strength about one part to forty parts water) to remove all grease, and the chromated gelatine solution, while still hot, is poured over it in the same way as collodion is used to coat a glass plate in wet-plate photography. The beaker containing the solution is covered with a piece of muslin, so that the liquid may be strained while it is poured out. The zinc must be slightly warmed to prevent the solution setting too quickly. The excess of solution is drained off, and as soon as the gelatine has set the plate is stood up to dry in a dark room. The process of drying takes about four hours at the ordinary temperature. If the room is warmed, it requires, of course, a much shorter time, but the results are inferior, as the transfer does not roll up so clean.

The tin-foil is then peeled off the zinc plate by lifting one corner of it with a knife. It may be kept in this condition about twelve days, or it may be used as soon as it is dry. It is placed in a photographic printing frame, and printed in the daylight behind a line negative in the ordinary way until the image is visible in all its details. After printing it is placed in water for three minutes, and then rolled in as usual with a rather soft lithographic ink of the following composition:—

White virgin wax	1 ounce.
Stearine	1 „
Common resin	1 „
Palm oil	½ „
Chalk litho printing ink	4 ounces.

The transfer is immersed for three minutes in a solution of bichromate of potash (strength five grains to one ounce of water) and dried in a dark room. It is then exposed to daylight for a period of three minutes or upwards, according to the strength of the light, so as to harden the gelatine all over. This action should not, however, be carried too far.

Before transferring, the transfer is damped for about three minutes in a "damping book" (using water only), and it is then pulled through the press on a prepared stone or zinc plate. The after-processes are the same as when a transfer on paper has been used.

With care, each sheet of tin-foil can be used a dozen or more times.

Various examples are shown of subjects which have been photo-lithographed or photo-zincographed under identical conditions, except that tin-foil has in some cases been used for the transfers, and in other cases paper. The stones or plates are quite untouched, and it will be seen that the results given by the metal transfers are sharper and cleaner than those obtained by paper. There is also decidedly less distortion in the former case.

In the case of these prints, the images on stone or zinc obtained from the foil transfers are absolutely the same size as the negatives. The images obtained from paper transfers are all stretched to the extent of $\frac{1}{20}$ to $\frac{1}{10}$ of an inch each way, *i.e.*, $\frac{1}{20}$ to $\frac{1}{10}$ of an inch in a length of four to eight inches.

The prints could, of course, be greatly improved by cleaning up and working on the stone or zinc, but it has been thought better to show the results obtained without any retouching or cleaning whatever.

The cost of the work is practically the same in both methods of transfer.

The *advantages* of the new method of preparing the transfers (as compared with paper transfers) are:—

(1) The image on stone or zinc is not distorted. The print, therefore, only has the distortion due to the stretching of the print itself in the press, and this can be eliminated by using a sufficiently stout paper and pulling the print dry.

(2) The work is finer.

(3) The work is cleaner, as specks, &c., can be more easily removed from the transfer.

(4) The transfer does not buckle in the printing frame even when it takes a long time to print and the weather is damp.

(5) Less solution is required to be made for coating a transfer of any given size.

(6) The transfer dries in about half the time.

There is the slight *disadvantage* that, in the case of zinc work, it is rather difficult to get broad lines to transfer solid; they are apt to require retouching.

It is thought that with more experience this difficulty will be overcome, especially if a softer ink is used in rolling up the transfer.

(B) Papynotint Transfers (for Half-tone Subjects).

The tin-foil is laid on a zinc plate and prepared as if for a line subject; it is coated with a solution made up of:—

Gelatine, common flake	2 ounces.
Bichromate of potash	40 grains.
Common salt	70 „
Calcium chloride	70 „
Ferricyanide of potassium	30 „
Chrome alum	8 „
Water (measured independently of other constituents)	8 ounces.

The gelatine is dissolved in the water as in the previous case, and the other ingredients are then added; the foil is dried at a temperature of 70° to 80° Fahr.

The coated tin-foil keeps in good condition for about twelve days.

The transfer is printed under a half-tone negative, rolled in as for a line subject, and then dried. It is not necessary to immerse in a second bichromate bath.

The transfer is damped in a "damping book," using dilute nitric acid (one part to sixty or eighty parts water); this tends to prevent the work becoming blurred through spreading.

The transfer is then pulled through the press on a prepared zinc plate or stone, and the after-processes are carried out as usual.

Examples are passed round showing how the tinfoil transfers compare with paper transfers.

The cost is practically the same in both cases.

The *advantages* of the use of tin-foil as compared with paper are:—

(1) The image on stone or zinc is not distorted.
(2) The transfer can be cleaned more easily.
(3) The transfer does not buckle in printing.
(4) Less gelatine solution is required.
(5) The transfer dries in about half the time.

There is one very slight *disadvantage*, viz., that, if there are any inequalities in the roller used for rolling in the transfer, the marks produced by them show up more than in the case of paper transfers.

Tin-foil transfers give more contrast in the prints, and this is an advantage as compared with the papyrotint process previously used at the School of Military Engineering, which very often produces too flat a print.

(C) Retransfers.

Tin-foil may also with advantage be used for retransfer work, by coating it with the composition ordinarily used for retransfer paper.

The distortion, which with paper is unavoidable, can in this way be prevented, and this might be a matter of considerable importance.

The results are somewhat better than those obtained with ordinary composition paper; but the foil, when coated with composition, has the disadvantage, that it is not quite so easy to store without risk of damage.

(D) Obtaining Several Retransfers of One Subject.

If a reversed negative is used, and a tin-foil transfer is prepared as described above, and, if this transfer is inked in as usual with transfer ink, a print can be taken from it on transfer paper as in the process of collotype printing. The paper print becomes, of course, a retransfer, and can be transferred to stone or zinc.

From the same original tin-foil transfer a number of paper retransfers can similarly be obtained. If these are all transferred to stone or zinc, the various stones or plates can, of course, be printed from at the same time.

For line subjects this method has no advantage as regards the final result over the ordinary method of transferring the tin-foil transfer to a stone or plate; but for half-tone subjects it seems to give much sharper and better results than the ordinary method. Also, in any case the retransfer method takes much less time, as the foil can be printed from while still wet, otherwise it has to be dried.

The experiments are not sufficiently advanced to speak positively as to the retransfer method, because up to the present time there has been a difficulty as regards getting a suitable transfer paper. It is believed, however, that this difficulty has now been surmounted.

(E) Process Work.

One other use of the tin-foil transfer suggested by Mr. Husband is, as a means of preparing a half-tone process block. If the method is a practical one, it certainly might be of very great importance. I am not able to form an opinion as to whether it could be worked, and we have no facilities at the School of Military Engineering for testing the method. In any case, as process work does not appear to be of any use from a purely military point of view, we should not be able to expend time or money on such experiments.

If a sheet of tin-foil is coated with a gelatine solution as described above for the half-tone process, a much thicker layer of solution being left on it than is required for lithographic work, the transfer obtained from such a sheet will have a much coarser grain. If such a transfer were transferred to zinc, and the metal etched with an acid, it seems possible that a half-tone process block could be obtained. Assuming that this would give satisfactory results, the method appears to be decidedly simpler than those ordinarily used.

A coarse-grained transfer when printed from zinc gives a print such as that now passed round for your inspection. Those who have a practical acquaintance with process work will be able to judge whether Mr. Husband is right in suggesting that such transfers could be utilised in this way.

Kind of Foil to be Used.

The most suitable kind of foil yet found for this work is the "4 B foil," supplied by Messrs. Betts & Co., 1, Wharf-road, City-road, N., price 10*d.* per lb. Three and one-half sheets of size 25 × 18 inches weigh 1 lb. The foil can be obtained up to 3 feet by 2 feet 6 inches in size, and no doubt still larger sheets could be got if required.

The foil contains a considerable quantity of lead. Foil made of pure tin has been tried, and has failed entirely, owing to its being too springy to be manageable. Several samples of pure lead foil have been tried, but without success. In contact with the lead, the chromated gelatine becomes of a greenish colour, and loses its sensitiveness almost entirely.

In the process above described, an immense number of variations are, of course, possible. The formulæ and method here given are those which have been found to give the best results, and they may possibly be of interest to some of our members. It is in the hope that this will be the case that I have obtained permission from the military authorities to read this short paper before the Society.

[Captain Mantell remarked that the degree of fineness of grain

might be regulated by the thickness of the gelatine solution employed, and he exhibited proofs showing the fine grain obtained by using a thin coat of chromated gelatine, and the coarser grain resulting from employment of a thicker coating. Referring to the end of paragraph D of the paper, he said it sometimes happened that the transfer paper adhered to the tin-foil, but he believed that difficulty had now been surmounted. He explained that the present communication was adapted from an official report which he recently had occasion to make to the military authorities on the subject of the experiments, which were being continued for certain military purposes.]

CAPTAIN A. M. MANTELL, R.E.

A RAPID TONING BATH FOR GELATINO-CHLORIDE PAPER.

London and Provincial Photographic Association.

LAST year I had the pleasure of bringing before your notice an exceedingly rapid and simple method of toning gelatino-chloride prints, by using a much more concentrated solution than usual. At the time I was seeking rapidity of action merely, and, as the means necessary proved to be of the utmost simplicity, that point was added also. Upon the question of the resulting tone, I also claimed an approach to platinotype, and, though my results then fully bore out the claim, I think it would be wiser now to describe the tone as of a neutral nature, neither too warm nor too cold, but ranging between the warmth of a silver print and the coldness of a platinum or bromide.

But the matter of tone altogether is so much a matter of taste, that it would be better to merely put the one obtained by my experiments as the result, without claiming anything for it. Complaints were made that the workers could not get warm, brown, and red tones with it, which caused me to wax wroth at the idiots who used a bath specially devised for cold tones, with the idea of getting warm, and then thought the bath no use in consequence. Therefore, for the present, I claim the following points as the features of my method of toning:—

1, Great speed of action; 2, absolute simplicity; 3, no trouble to work.

The idea has often occurred to me that we are sometimes too hasty in accusing a man of being old-fashioned and stick-in-the-mud, because he prefers old methods and won't change, as we, perhaps, have done, to newer ones. The point is often overlooked that the new method, however excellent in many directions, may yet lack any improvement in the particular one appreciated by the older worker.

The above bath is an illustration, and one no doubt applicable to many workers. If rapid work and simplicity be to them no attraction, then it cannot be expected that they will forsake an old friend which perchance gives them a tone they like better.

To make a personal application of this thought, I should hardly be attracted by any toning bath that was no improvement upon mine as regards speed and simplicity. Our pet ideas govern our thoughts and wishes to a greater degree than we imagine or would be willing to allow. It therefore matters but little how vast the improvement be; if it is not in our own direction, we perhaps prefer to stick in the old groove.

All my experiments have been made with the direct object of obtaining speed in toning. This I have decidedly accomplished, as I shall prove to you later on. But only those who have left the beaten track of toning baths for that of experiment know the great variety of tones obtainable—or, rather, obtained—for they are not always obtainable; at least, it is difficult to ensure the same tone again, and I have settled down into the conviction that batches of paper must vary considerably. With exactly the same bath, and under precisely similar conditions, different tones are obtained. I have practically tested this by using four pieces six months, four months, and two months old, and a piece bought the day before. These, when toned *together* in the same bath, have not resulted in the same tone. It may be that some gradual chemical action takes place in the emulsion upon the paper in the course of storage. I am convinced that it is not atmospheric influence at all, because I have carefully stored pieces nine months, and then exposed to air for a week in a dark corner pieces of absolutely new paper. The result was that the new paper did show traces of the treatment, but the old did not. It is therefore either a difference in the emulsion or a chemical action during storage.

The range of tones obtainable upon gelatino-chloride paper is simply marvellous. The fact strikes the experimenter most powerfully. Upon many occasions the results have caused me to use language which was quite warranted by the exigencies of the case, and was good English, but quite unfit for publication. The density of the negative, its colour, the length of time printing, and even the degree of washing before toning, all had a hand in the tone. However, as tone is to me at present a secondary matter, we will dip at once into actual experiment.

I fully intended last year, during the autumn, making a complete attack upon the question of rapid toning, but business did not permit, nor, for various reasons, have I been able to do much till lately. Even now, living in chambers, the opportunities and conveniences of work are most limited. Still I have convinced myself of several points. When I first introduced the bath, the extremely rapid action seemed likely to be a boon; but, when scant attention to it followed, it not being even thought worthy of insertion in the annals of progress published at the end of the year, it struck me that perhaps there wasn't very much in it, after all, and for months, though using it exclusively myself, the subject did not bother my head. Recently, however, occasion arose, after three or four months' complete absence from any printing work at all, that batches of 100 to 150 prints every night were necessary. The same bath was used, and the fact that it was a good thing came most forcibly to my mind. I determined to experiment further, and the present paper is the result.

The experiments were all made with two main objects—rapidity of toning and finality of result, leaving the resulting tone to be the unknown factor. The principles laid down were:—

1. Each print must tone completely in two minutes as a maximum.
2. There must be a definite tone (finality) which no reasonable amount of after-immersion can alter.

The reason of the first is obvious. By the second, I wanted to get the power of what may be termed "careless work," that is, that, if the print be unevenly toned, it can be put right afterwards. As a matter of fact, my first point in starting a batch is to see that they will readily tone unequally.

Two kinds of paper, "Solio" and "P. O. P.," the former in white and pink tints only, owing to inability to obtain the mauve; and the latter in all three. Prints from the same negative were toned in the four following baths:—

Bicarbonate Bath.

Gold	1 grain.
Bicarbonate of soda	25 grains.
Water	1½ ounce.

Acetate Bath.

Gold	1 grain.
Acetate soda	20 grains.
Water	1½ ounce.

Phosphate Bath.

Gold	1 grain.
Phosphate soda	25 grains.
Water	1½ ounce.

Borax Bath.

Gold chloride	1 grain.
Borax	40 grains.
Water	1½ ounce.

All these baths worked rapidly enough, but the acetate one requires mixing at least an hour before use, whereas the others can be made up immediately.

The first result arrived at is, that the tint of the paper governed the tone more than any differences in the bath. I will detail the actual results:—

Pink paper (P.O.P.)	No difference in tone at all.
White „ „	The acetate bath gave a slightly redder tone; the rest, alike.
Mauve „ „	No difference.
Pink „ (Solio)	No difference.
White „ „	Bicarbonate, grey black; phosphate, a warmer tint; borax, warmer still; and acetate, quite a purplish pink.

Upon the whole, the best results were obtained upon white Solio, mauve P.O.P., and white P.O.P. The latter, with the bicarbonate and borax baths, gives a tone very closely approaching that often obtained in platinum toning, viz., a very warm sepia. As a general rule, white paper should always be used if a grey black tone be desired.

Leaving, now, the question of tone altogether, to deal with rapidity of action, there is not much to choose between bicarbonate, phosphate, and acetate. But I certainly prefer the bicarbonate bath as the best of these four at all events. Mixtures I did not try, as I was aiming at simplicity. The less mixtures in photographic formulæ the

better is my maxim; and, certainly, in toning baths for gelatino-chloride papers we can do with a little more simplicity. Some of the concoctions put forward are a credit to the ingenuity of the chemist, viz., the number of ingredients possible to be put in without injury. They are simply preposterous.

You will see later on that my assertions as to the speed of toning will be borne out by the demonstration. I noted down the other night the time occupied by a batch. A whole-plate tray was used, and the following bath:—

Bicarbonate of soda	1½ drachms.
Chloride of gold	4 grains.
Water	6 ounces.

The prints were merely laid in the tray and kept under the solution by touching with the fingers; the tray itself was never moved. Until the last few prints it took all my time to get them in and out fast enough. Even then I lost time by having to light my pipe.

Total toned	105 quarter plates.
Full time	28 minutes.
First print	23 seconds.
Last print	70 „

One that occupied about forty seconds to tone was left for nearly an hour in the bath, and the resulting tone was no different. If we say fifty minutes, that means a period of time which may be roughly stated as twenty-five to one. The print was certainly flattened or bleached a little, but the tone was not different. This proves that my claim to a finality of tone is quite within reason.

By this means the power of what I have termed "careless" toning is acquired. A print can be half toned, the other half not touching the solution at all, laid aside for a time, and then finished. There will be no mark apparent. Or spots and streaks can be dealt with in the same way.

Of course, I in no way advocate such treatment, nor that prints should be toned for fifty minutes when forty seconds will suffice. These are merely extreme experiments, but they serve to show how easy this method of work renders the toning of gelatino-chloride paper, which it must be admitted in some toning baths is certainly not the case.

There is one point worth reference, which is that the actual amount of bicarbonate of soda in the bath is not, within limits of course, a matter of much importance. At least experiments with three-quarter drachm to two and a half drachm, the gold and water remaining the same have not produced any different results. The only thing I can fancy to have noticed is that the more bicarbonate the slower the toning and the greater tendency towards warmth of tone. But one and a half drachms is a fair workable proportion.

The mere relation of the advantages of the bath impresses no one. Every one fails to grasp its advantages to a considerable extent; but, when shown it in actual work, it is altogether different. For that reason I shall proceed to demonstrate it before you to-night, and in doing so will work completely in my usual fashion.

I claim for the bath that it is the most rapid in action and most simple in working of any one ever introduced, and the resulting tone is to me and to many others a pleasing one. W. D. Welford.

DODGES.

[North Middlesex Photographic Society.]

The subject of "Dodges" is one that should be of great interest to the amateur photographer; in fact, it goes a long way to complete his photographic education. To the profession I presume it is impossible to mention anything under this head that is not in their every-day practice; but the beginner in the art regards anything outside the elementary instructions of procedure as dodges—at least, I do. That the best workers among us indulge in dodging is admitted. One will tell you he is obliged to dodge all his negatives, another that good negatives are the exception with him rather than the rule, or another that he has no good negatives, mostly failures, and so on. Of course, a good deal of this is modesty; but it leads one to the conclusion that the production of superior work is, as of course it must be, the result of careful manipulation at every stage of the process, and knowing the means by which to avoid or overcome defects of every description as they arise, and to many of us they arise often enough. It is my intention, therefore, with your permission, to refer to a few rough-and-ready dodges that in my own limited practice of photography have been found useful, and I will also offer you a suggestion or two which I trust will be worthy of your consideration; but I would add, that my remarks (coming as they do from rather a raw recruit) are intended for the less-advanced workers chiefly.

The most interesting part of dodging refers, no doubt, to work on the negative; but before we come to that I purpose mentioning a few other items, and will commence with development, and thence of a brush. I first saw a brush used in this room for the purpose, as I understood, of preventing air-bells and keeping the developer in motion. I tried it for the latter purpose, and soon accustomed myself to use it in literally painting out under-exposed parts (after pouring off the developer), and by this method worked up detail in the weak parts without causing undue density in the high lights—to me a most important point. With usual development, when a plate was any way under-exposed, or the contrasts great, I was always liable to get the high lights developed right through to the back of the plates (when they begin to spread and cause halation) before sufficient detail was obtained in the shadows. On the other hand, with a brush, when I find the high lights progressing favourably, I pour off the developer and work out all detail, then pour on the whole of developer again, rocking the dish until sufficient density is obtained, and stopping development when the high lights are quite through the plate and before they have time to spread. The negative I pass round for your inspection was produced in this way. The white garments of the cricketers and tent came up at once, and were fully out when the lower part of the plate was bare; the black coat in central figure was also bare glass without detail; but by pouring off developer except a small quantity, and tilting the tray so that the developer only covered the bottom part, with the brush I was enabled to get out all detail of grass and black coat without losing detail in the high lights. With the ordinary mode of development I think the result would have been far different. As a curiosity, I also show you another negative of the same subject, worked up in the same way, but over-exposed, the exposure being in the proportion of three to seven; the developer was, of course, very different. You will notice there is a difference in colour of the film, but the printing quality is the same, and in this case I think the developer has modified the action of exposure, for I doubt if you can tell which is the over-exposed plate. I also pass round two other negatives, exposed and developed with the idea that development with the brush will go a long way to prevent halation. In the first the distance came up at once, but the near buildings were certainly under-exposed, being in heavy shadow. It took twenty minutes to get out detail; but the distance or central part was only a minute or so under the developer, irregularity being avoided by occasionally sweeping the wet brush over the whole of the plate. The other negative was an instantaneous exposure, treated in the same way; but you may observe that the edges of the trees are perfectly sharp, and the negative with a little other dodging gives a fair print.

Another advantage of the brush and local development is that clouds can be saved in the negative if there are any in the landscape; or, in other cases, it may be desirable to keep the sky thin, and work clouds on the back in the manner to be presently described, and I feel confident, after twelve months' trial, that the brush gives great power over the quality of the negative, and I mention it to you as a most useful dodge.

Before I leave development, I would also mention the use of the warm finger in more energetically bringing out particular parts. In lantern slides this is very useful, but it can be easily overdone. Gently move the second finger over the part you wish to bring out stronger. When the second finger gets cold, use the third finger on the place, and, by the time the third is cold, the second will be again warm enough to continue the operation, and so on until the desired effect is obtained.

Intensification is, I think, almost outside our subject, especially as the matter has been so ably dealt with on other occasions. I am tempted, however, to say my own opinion is that, if thin negatives are cases of vexation, intensification, unless performed with great judgment, is, nine times out of ten, quite as bad; but there is a dodge or two in connexion with it worth mentioning. The first is, dry your negatives quickly and in a strong light; it gives (or prevents them losing) density. You will be surprised at the difference in a negative dried in a strong light, or even in the sun, if the negative has previously passed through the alum bath, and one dried in the dark in a cold situation. The first will be of a rich brown colour, the other of a greyish tone, and of less printing density. Another dodge is slight intensification by the clearing bath, but it must be a clearing bath containing iron. The iron immediately changes the colour of the film, darkens the high lights, and at the same time clears the shadows, and so gives a crispness not possessed by the negatives before. A weak solution of plain iron, or the usual iron developer, will also intensify by changing the colour of the film.

In some instances it becomes a necessity to reduce parts of a negative. a strong light through the branches of trees, or a bright ray of light through a window, or an archway, generally causes halation, to the detriment of the negative. In most of these cases it is possible to con-

siderably modify the evil, or even entirely overcome it, by chemical or mechanical means. I recommend methylated spirit (it must be neat, not spirit and water), and must be used, after the negative is dry, by applying a little to the part to be treated until it softens (don't be in a hurry about it); then, with a piece of chamois leather, rub the part until it comes off on the leather, changing the leather when it gets black, and continue until the desired effect is obtained. I only recommend this treatment for small patches, say, not exceeding the size of a sixpence. For larger surfaces the remedy is often worse than the disease, as the result often appears unpleasantly smeary. It is effective on faces when too dense, also to bring details out in the folds of a white dress; but, like all remedies of this description, it must be used with caution and patience. Another method I have tried, rubbing down with brickdust, and find it effective on thick films. The way to use it is to rub your finger on a piece of bath brick until the ribs on the skin are worn down, and the finger quite smooth. The finger will then have adhering to it sufficient of the fine dust to reduce density on the face, &c. This will not do for thin films.

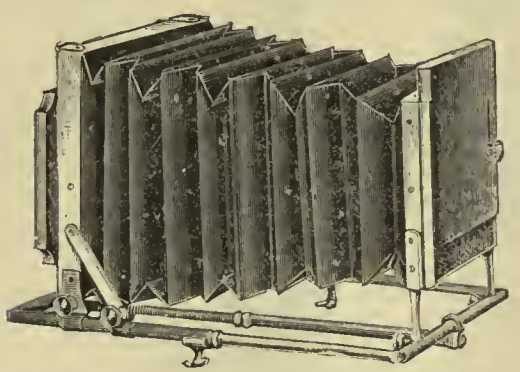
It is sometimes desirable to use quarter-plates in a half-plate dark slide, but it is a nuisance bothering with quarter-plate carriers in addition to being obliged to get a separate box of plates. Both of these troubles can be avoided by cutting a half-plate in half with one of the cheap glass cutters. Place one half in centre of dark slide, filling up the side spaces with cardboard the same thickness as plate. In this way two quarter-plates can be used back to back, or one quarter-plate and one half-plate.

(*To be continued.*) C. O. Gregory.

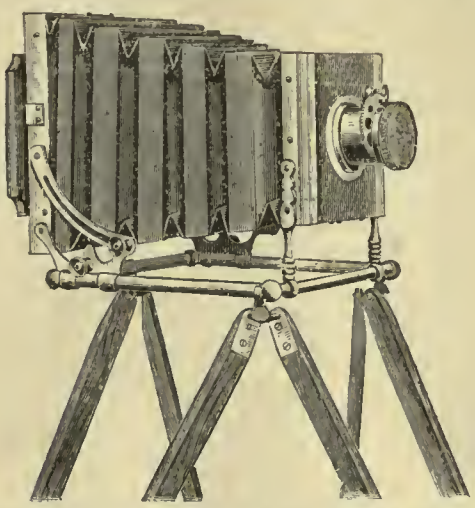
SUMMER NOVELTIES IN APPARATUS, &c.

Walter Griffiths & Co., Union-passage, Birmingham.

In the Zodiac camera of Messrs. Walter Griffiths & Co., which, they say, signalises their entry into the manufacture of general photographic apparatus, the substitution of metal, and that in a tubular form, for



several parts usually made of wood, is not only calculated to make the camera of peculiar service in trying climates, but does so without adding



to the average weight—indeed, it is claimed that it actually reduces it. The first cut shows a front view of the camera, with rising front and extending base. The camera has either a leather or a cloth bellows, and all the usual movements, long extension being obtained by means of the screw which, it will be observed, runs the whole length of the base. There is no woodwork where the joints can open, the few wooden parts that are retained being bound with brass. The double slides are entirely of metal, and, besides being only an eighth of an inch larger than the plate, are only three-eighths of an inch thick. They carry films as well as plates. Placed in the camera, they drop into the recess from the back, and are held in position by spring clips. The construction of the slide is of the simplest, it consisting, in brief, of a species of double sheath, with two shutters.

The second illustration shows the method of fixing the camera to the stand; head, screw, and loose parts thus being obviated. The camera, when folded up, is very compact. A stereo camera of the Zodiac type is also supplied by Messrs. Griffiths. Especially in such climates where wood is liable to be affected, the substitution of tubular metal will probably be found an advantage.

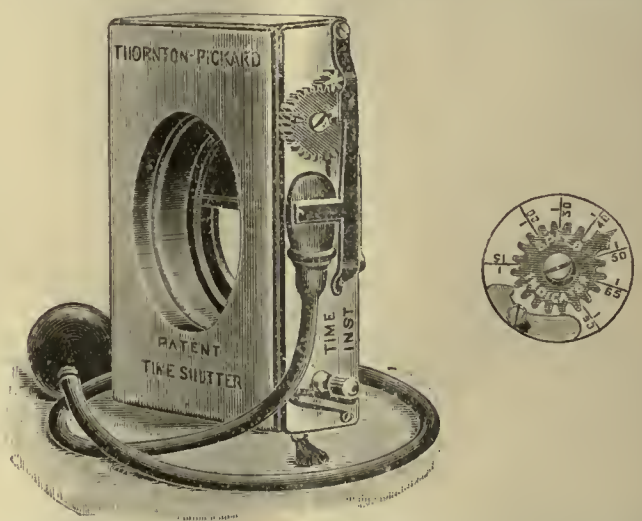
Upon their premises in Union-passage Messrs. Griffiths place a studio, dark room, and reading room at the disposal of amateurs.

Miller's new Adelphi hand camera, which was shown us by Mr. F. V. Lloyd, of South John-street, Liverpool, has now a simple but ingenious attachment in the shape of a movement which both releases the shutter and elevates the flap that intervenes between the sensitive plate and the lens. This is a very happy idea.

The Thornton-Pickard Manufacturing Company, Altrincham.

The recently erected works of the Thornton-Pickard Company at Altrincham, near Manchester, which are chiefly devoted to the manufacture of the famous shutters with which the name of the firm is identified, are in all senses interesting, not only from their extent and completeness, but as showing the great amount of ingenuity and skill which has to be specialised and concentrated upon the production of the firm's specialities. The workshops, as indeed the premises generally, are situated entirely on the ground floor, and in the first-named, which radiate, as it were, from the office as a base, it is instructive to follow the growth of a shutter in the various hands through which it has to pass. Under the guidance of Mr. Edgar Pickard, such an opportunity was recently given us.

The preparation of the mahogany boxes in which the mechanism and blind of the shutter are contained is first noticed. The parts are glued up under pressure, and the boxes as made are double, and are therefore split into two. A sand-papering machine imparts the necessary finish to them, the particles of mahogany dust created by the revolving stones being carried off by fans. For the wood in the rough a planing machine working at 5000 revolutions a minute is used. Passing by several circular saws for light and heavy work, we stop to watch a workman pressing the



little indicator wheels out of sheets of brass; an upright moulding machine for rounding off the corners of the boxes, and a cutting machine for turning out the small connexions for connecting tubing to the shutters. Other machines are devoted to polishing the pins of the shutter, turning holes in the shutter cases, &c., the machinery being driven by a seven horse-power Otto gas engine. In one corner a lad is at work at a sewing-machine preparing the blinds.

One side of the workshop is practically devoted to lacquering and blacking the various parts and the fitting together of the shutter. The spring of each shutter is tested by a weight before it leaves the shop for the testing department. A separate shop is devoted to the polishing; and in the stock-room, behind a series of carefully "blinded" divisions, stock

of the numerous parts is kept. Taking a line by the enormous numbers of each individual part—such as the indicators—which we saw in preparation, one is driven to the conclusion that the output of the Thornton-Pickard shutters is very large. This rapid and imperfect sketch of the firm's workshops does not in any way do justice to one of the completest and most interesting installations in connexion with photographic industry which we have recently inspected.

Since its first introduction, the well-known Time and Instantaneous shutter has undergone some slight modifications, although its action and principles remain the same. Among recent additions is a speed indicator, which consists of a dial, marked in fractions of a second, attached to the side of the shutter, and a pointer on the end of the spring-roller spindle. The speed is indicated on the dial in fractions of a second by the pointer, which can be set to the speed desired by means of the nob.

A similar type of shutter, the "Snap Shot," is very popular for hand cameras. The Focal Plane shutter is designed for use where the maximum degree of rapidity is required.

It is made upon the roller-blind principle. It fits into the back of the camera in the place otherwise occupied by the dark slide, the dark slide itself being placed in the back of the shutter. The shutter blind, therefore, works just in front of the plate, and has a narrow slit in it the full width of the plate, which gives the exposure as it passes rapidly across. The speed is regulated by the small knob. The shutter is set for exposure by winding the large knob at the top, and to show how far to wind there is a winding indicator at the opposite side, not shown in the engraving.

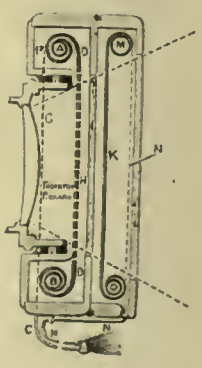
In the bottom end of the blind there is an opening the full size of the plate, by means of which the picture may be focussed on the ground glass if the blind is wound to the top.

A new patent adjustable slit is now added to the focal plane shutters in addition to the adjustable spring roller. This improvement adds greatly to the range of speed of the shutter, which now extends from one-twentieth of a second to one one-thousandth of a second. The speed is varied by means of a chain at each end of the slit, which can be lengthened and shortened at will, making the sides of the slit perfectly parallel without skill, the directions for use being as follows:—

After removing the focussing screen, take hold of the two struts which form the parallel sides of the slit in the blind, and turn them askew, at the same time drawing them forwards out of the shutter. The chains at the ends of the slit can then be manipulated. One end of the chain is fixed permanently to one strut, while the other part of the chain is linked on to the extreme end of the other strut, the end of it passing inwards along the length of the strut. This part may be pulled out and linked on to the end of the strut to make the slit wider, or allowed to spring back into the strut which makes the slit narrower. All that is necessary is to see that the same number of links are used at each end of the slit.

The speed of the shutter is found by dividing the speed given on the indicator by the number of links in use at each end. That is to say, with only one whole link the speed is that given on the indicator; with ten links (which is the extremity) it is one-tenth of the same.

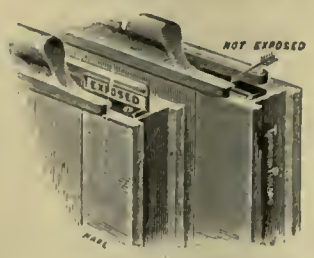
The safety blind which Messrs. Thornton-Pickard fit either to the Time and Instantaneous, or the snap-shot shutters, when fitted to the shutter, will automatically cover the opening during the act of resetting the shutter for the next exposure, so that the sensitive plate may always remain uncovered in the camera. It only adds five-eighths of an inch to the thickness of the shutter, and does not increase the dimensions otherwise.



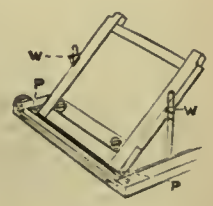
The illustration shows a section of safety blind attached to an ordinary shutter, either Time and Instantaneous or snap-shot pattern.

In action, when the tassel is pulled, the exposing blind D is wound on to the top roller A, by means of the cord C, and at the same time the safety blind K is pulled up over the top roller M by the cord N. It will be seen from the illustration that the safety blind K, and the opening H in the exposing blind, both pass across the aperture in the shutter together, so that no light can pass through. When the tassel is released, after pulling the cords as far as possible, the safety blind immediately rewinds on to the spring roller Q, leaving the exposing blind set ready for exposure.

The annexed illustration shows a small and useful device for enabling one to see at a glance which plates have been exposed, thus preventing the possibility of two pictures being taken on one plate. It consists of a small hinged plate or lid, which lies down flat before exposure, but, as soon as the shutter of the slide is withdrawn to expose the plate, the lid flies open and discloses the word "Exposed," and remains in this position until the slide is again charged with a fresh plate in the dark room. The "Recorder" may then be set ready for the next exposure by simply closing down the lid with the forefinger, at the same time closing the shutter of the dark slide. Whenever the shutter of the slide is withdrawn without exposing the plate, the "Recorder" lid may be closed again at the same time the shutter is pushed home.

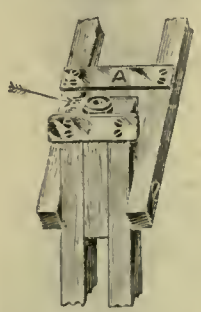


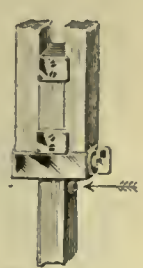
The "Ruby" camera is an exceedingly light, rigid, and portable instrument, fitted with a turntable, the centre of the latter being cut away so that the lens and shutter fold up with the camera. The front can be quickly erected, and is rigid and firm when in position. The cut shows how to fix it. After opening the camera, place the front in the position shown, leaning backwards, so that the bottom corner hooks of



the front are over the pivots marked P. Press the front down between the pivots, and then place it in the vertical position, as shown in the figure. Fasten in position by turning the winged clamping screws marked W. The camera has double pinion for focussing; it allows of the use of very wide-angle lenses, rising and sliding front, and all the other usual movements, obtainable with a minimum of trouble.

In the way of tripods the firm have very recently brought out a stand having automatically locking joints, which, while being perfectly rigid, is easily set up, and is adjustable to various heights. The lower section slides so as to be adjustable in height. On pulling out this section as far as possible the spring bolt marked by the arrow in the engraving



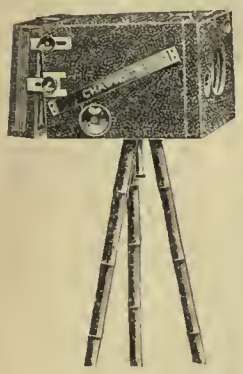


springs out and instantly locks the joint. To close again, the spring bolt is pressed with the thumb, which allows it to slide back again. A thumbscrew is provided at this joint, so that the section may be adjusted to any height, as above mentioned, and may be used in addition to the spring bolt to give extra rigidity if desired.

The upper joint is locked on exactly the same principle, but it folds instead of slides; the spring bolt is larger and stronger, and snaps into position as soon as the upper section is unfolded. The two sections are

therefore wedged together in a very practical manner, and the utmost rigidity is secured.

The rapidly increasing specialities of the firm show that a great deal of mechanical thought and application have been expended on them. All have a degree of finish and carefulness of construction which stamp them as the products of great skill, while of the practical efficiency of the series of shutters, and their adaptability to the needs of varions classes of photography and shutter-users, there can be no doubt.



THE CHADWICK IMPROVED HAND CAMERA.

The annexed cut was omitted from our notice of the Chadwick hand camera last week. It shows the camera on a stand, and the swing back in use. As may be observed, the back swings from its centre, which, in theory, it should do.

Our Editorial Table.

DR. ANDRESEN'S GLYCIN.

Arthur Schwartz & Co., Dashwood House, E.C.

THE directions for using Dr. Andresen's glycin are as follows:—

1. For soft development:

Solution A (warm slightly).

Glycin	4	parts.
Carbonate of potash	1½	„
Sulphite of soda (cryst.)	12	„
Water	100	„

Solution B.

Carbonate of potash	10	„
Water	100	„

For use, mix one part of *A* with two parts of *B*.

II. For hard development:

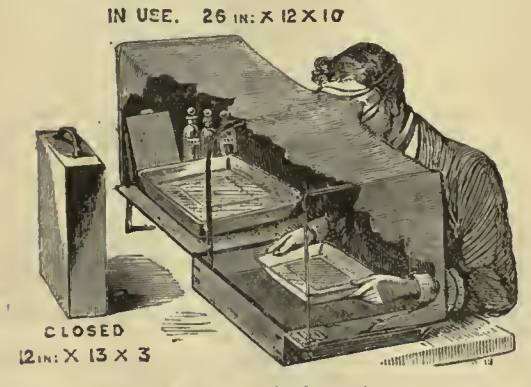
Glycin	5	parts.
Carbonate of potash	25	„
Sulphite of soda (cryst.)	25	„
Water	100	„

For use to be diluted three times its volume.

Employing the developer in accordance with the first-named formula, we find that, although it is rather slow and deliberative in action, yet it yields negatives of great harmony and softness, and of a charming colour. It is an elegant developer, likely to be of service in special cases.

BAKER'S TOURISTS' DEVELOPING TENT.

MR. C. BAKER, of Wallington, Surrey, has modified the developing tent he brought out some time since. The illustration shows its construction and general appearance. The tent when open is about



twenty-four inches long by ten inches wide and ten inches high without the sink, which is two and a half inches deep. When closed, it forms a box twelve inches square by three and a quarter inches, in which there is room for several small articles. The sides of the tent are composed of perfectly opaque material, and as the light can only enter by the red window, which is guarded by a blind, its amount can be regulated as desired. The tent is simple and efficacious in use, and should be popular.

"PHOTOGRAPHY" ANNUAL.

London: Iliffe & Son.

MR. HENRY STURMEY, the editor of this ponderous annual, may congratulate himself upon having this year issued a volume exceeding both in quantity and quality any of his two former annuals. It opens with a section devoted to reference tables, a feature that is always useful. Tips for tyros follow. Mr. C. H. Bothamley discourses on "Progress in Photographic Chemistry during 1892," and Mr. A. Taylor similarly on "Progress of Astronomical Photography." There are other articles on various phases of photographic practice, and quite a number of illustrations both of a pictorial and diagrammatic nature.

RECEIVED:—Sixtieth Annual Report of the Royal Cornwall Polytechnic Society; *The Illustrated Archæologist*, No. 1, edited by J. Romilly Allen (Chas. J. Clark, 4, Lincoln's-inn-fields, W.C.).

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
July 3	Dundee Amateur	Asso. Studio, Nethergate, Dundee.
„ 3	Peterborough	Museum, Minster Precincts.
„ 3	Putney	High-street, Putney.
„ 3	Richmond	Greyhound Hotel.
„ 3	South London	Hanover Hall, Hanover-park, S.E.
„ 3	Stereoscopic Club	Brooklands Hotel, Brooklands.
„ 4	Birmingham Photo. Society	Club Room, Colonnade Hotel.
„ 4	Brixton and Clapham	376, Coldharbour-lane, Brixton.
„ 4	Exeter	City Chambers, Gandy-st., Exeter.
„ 4	Hackney	206, Mare-street, Hackney.
„ 4	Herefordshire	Mansion House, Hereford.
„ 4	Lewes	Fitzroy Library, High-st., Lewes.
„ 4	North London	Canonbury Tower, Islington, N.
„ 4	Oxford Photo. Society	Society's Rooms, 136, High-street.
„ 4	Paisley	9, Gauze-street, Paisley.
„ 4	Rochester	Mathematical School, Rochester.
„ 4	Rotherham	5, Frederick-street, Rotherham.
„ 4	Sheffield Photo. Society	Masonic Hall, Surrey-street.
„ 4	York	Victoria Hall, Goodramgate, York.
„ 5	Leytonstone	The Assembly Rooms, High-road.
„ 5	Photographic Club	Anderton's Hotel, Fleet-street, E.C.
„ 5	Southport	The Studio, 15, Cambridge-arcade.
„ 5	Southsea	3, King's-road, Southsea.
„ 5	Wallasey	Egremont Institute, Egremont.
„ 6	Birmingham Photo. Society	Club Room, Colonnade Hotel.
„ 6	Glossop Dale	
„ 6	Hull	71, Prospect-street, Hull.
„ 6	Leeds Photo. Society	Mechanics' Institute, Leeds.
„ 6	London and Provincial	Champion Hotel, 15, Aldersgate-st.
„ 6	Oldham	The Lyceum, Union-st., Oldham.
„ 6	Tunbridge Wells	Mechanics' Inst., Tunbridge Wells.
„ 7	Cardiff	
„ 7	Croydon Microscopical	Public Hall, George-street, Croydon
„ 7	Holborn	
„ 7	Leamington	Trinity Church Room, Morton-st.
„ 7	Maidstone	"The Palace," Maidstone.
„ 8	Hull	71 Prospect-street, Hull.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

JUNE 27,—Mr. G. Scamell in the chair.

Mr. W. E. DEBENHAM gave a demonstration of *The Carbon Process*, prefacing it with a brief description of its essential principles. Speaking of the sensitising of the tissue, he said he preferred to use the bichromate in the proportion of one ounce to a quart of water. He found no advantage in the addition of ammonia, except when an excess of chromic acid is present. In drying, he recommended squeegeeing the sensitised tissue on to the glass, and leaving it thereon until it is wanted, as if dried by hanging the tendency to curl was objectionable. Having dealt with the uses of the safe edge, and demonstrated both single and double transfer, he said that for exposure he preferred the actinometer he himself devised some years ago, and which was adopted by the late Mr. Sawyer. He, however, used a portion of a portrait negative, various tints from which were made on gelatine or albumen paper, and could be matched in printing. In development, if the print was too dark, hotter water could be used.

A brief discussion followed on the continuating action of light.

Mr. H. J. BURTON remarked that, in the print developed, which was said to have been over-printed, the continuating action had taken place. There was plenty of time since the afternoon, when Mr. Debenham had made the print.

Mr. T. BOLAS agreed with Mr. Burton, and said that, if a trace of damp was present in the tissue, the effect of keeping the exposed tissue a little while in a hot place was easily recognisable.

Mr. H. CHAPMAN JONES, when exposing tissue to be kept a day, would only give it a quarter of the time as against the full time when exposing and developing the same day.

After other discussion, a vote of thanks was passed to Mr. Debenham, and the meeting closed.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

JUNE 22,—Mr. W. E. Debenham in the chair.

Mr. W. D. Welford passed round the catalogue of the exhibition of photographs recently held in Japan, also two books of pictures by Mr. W. K. Burton of snapshots and enlargements in collotype.

THE UNIVERSAL HAND CAMERA.

Mr. H. B. Sharp (Messrs. Sharp & Hitchmough, Liverpool) exhibited and explained the Universal hand camera. This is a quarter-plate camera contained in a box, the back and front of which let down, or the camera may be entirely removed from it. Focussing is effected by means of a rack and pinion attached to the body, thus rendering the camera useful for copying and lantern-slide making where it is desired not to move the lens. The camera has swing back and rising front, time and instantaneous shutter.

AN IMPROVED RETOUCHING DESK.

Mr. Sharp also showed a retouching desk having a spring, attached to which was a diaphragm, with inner diaphragms, for placing round the head or any part of a negative, and thus concentrating the light upon it. Chamois leather on the diaphragms protects the negative. At the side of the frame a small glass is let in, which is illuminated by the same light as the negative, and is used for matching tints.

"WELFORD'S TONING BATH FOR GELATINE PRINTS."

Mr. W. D. WELFORD read a paper on this subject [see p. 408], afterwards toning several prints by the bath. Toning was completed in less than a minute. Prints the halves of which were toned at intervals gave no indication of "joins." Untoned patches subsequently toned were indistinguishable from the parts first toned.

In the discussion which followed, Mr. T. BOLAS observed that he preferred a more thorough washing between the fixing and the alum solution than Mr. Welford gave.

Mr. J. S. Teape tried the bath last year, and found that, after toning a dozen prints, the others had a certain tendency to mealiness, and finally they lost quality altogether. He used the same batch of paper throughout, and noticed that many of the prints had a tendency to pinkiness.

Mr. T. E. Freshwater had succeeded well with an acetate bath for gelatine paper. The latter seemed to require much more careful washing than albumenised paper. The bath, which was supposed to be kept twenty-four hours after being made, and which he had used at once, was as follows:—

Acetate soda	1 ounce.
Gold chloride	15 grains.
Water	20 ounces.

Of this stock solution he had used two ounces in eight ounces water.

Mr. P. Everitt thought the rapidity of action of Mr. Welford's bath might be a disadvantage to many; he himself would not care to use a bath that toned so quickly. If one wanted a variety of tone, there would be a considerable difficulty in obtaining it with a very quick toning bath. He himself used one and a half grains of gold chloride in twelve ounces of water, to which a pinch of borax was added.

Mr. A. HADDON asked if Mr. Welford had noticed any difference of result between carbonate and bicarbonate of soda.

Mr. J. Weir Brown pointed out that the tones of some experimental prints shown were not the same as those of some prints which Mr. Welford had made with the bath last year.

Mr. S. Herbert Fry thought it a misfortune that Mr. Welford should advocate such a process, as the double colour in the prints was most detestable. It appeared to him that the bath had no other advantage but rapidity, and the fact that it toned so quickly proved that one had no control over it. The colours that one saw with the gelatino-chloride process were very nice, but he was inclined to think there were other processes which yielded better blacks. His (Mr. Fry's) main objection to Mr. Welford's bath was that the prints were not half so good as could be got from the negatives. The double colour was a technical defect of the worst order. This was the weakest point of gelatino-chloride printing; the sulphocyanide bath had a tendency to give it. He had found a combined bath the most convenient.

Mr. BOLAS inquired whether the tendency to pinkiness in the lights was greater when the washing had been short or imperfect?

Mr. EVERITT also asked whether the pinkiness was not more sensible when a large quantity of soda was used?

Mr. A. MACKIE suggested that the pinkiness was caused by the prints being very much over-toned. The pinkiness was more apparent at night.

After other remarks, the CHAIRMAN said Mr. Welford had claimed for the bath a power over careless toning, but it went beyond that. If we left the print in the toning bath very much longer without producing a considerable effect upon it, he thought we might take it that it had got much more gold than usual, and that might point to an advantage in the way of greater permanence, by the greater deposit of gold. It had been said that baths other than sulphocyanide were more economical of gold, a fact that had been quoted against sulphocyanide. He thought it an argument in its favour that it did put so much gold in the print. As to the tone of the prints, if we can get a tone which is consistent with a large deposit of gold and probable permanency, so much the better. In regard to prints toning differently when the paper had been kept some time, he had noticed, with some plates coated with gelatino-chloride emulsion that had been kept for some time, that they printed out a purplish colour, looking, in fact, as if they had been toned.

Mr. WELFORD, in reply, said that many of those who had spoken were answered in the paper he had just read. In reference to Mr. Teape's complaint of mealiness and pinkiness with the bath, he (Mr. Welford) found it work better with P.O.P. than with Solio. As to Mr. Fry's remarks about the double colour in gelatino-chloride, he would remind him that double colours were sometimes obtained on bromide paper. Replying to other remarks, Mr. Welford said the slight pinkiness complained of occasionally disappeared, but he was at a loss to discover the why or wherefore. In conclusion, he said he thought rapid toning tended to permanency.

A vote of thanks was passed to Mr. Welford for his paper and demonstration.

North Middlesex Photographic Society.—June 26.—Mr. Barnard showed the results of his attempt to copy a Daguerreotype, and appeared at last to be entirely successful. Mr. SMITH related a curious experience he had had, at the outing to Cassiobury Park, of two dark spots on the focussing screen, which he could not account for; he exposed, however, and, on developing, they came up black, and consequently print white, but, being in the sky space, blocking out the sky hides them. Mr. AVERY was of opinion that light must have been somehow reflected through the lens, forming the spots. Mr. MARCHANT had been troubled and puzzled by a number of flies inside the camera, and suggested this as a solution. In the end, everybody said it was curious, but no satisfactory explanation was forthcoming. A long discussion on films and their defects took place. A large number of members had found insensitive spots. One had a film strip completely from the support on taking it out of the box. Mr. MATTHEWS said that, in case of a celluloid film partly stripping, it could be made to adhere by licking with the tongue. Mr. GILL had found a great tendency of plates to frill badly lately, and inquired whether the temperature of the developer would be the cause. It was thought to be very probable. One member suggested that the fact of being coated during the hot weather might have prevented perfect adhesion to the glass. Seven new members were elected. The outings resulted as follows:—Kew: Mr. Beadle, first; Mr. Smith, second. St. Albans: Mr. Marchant, first; Mr. Smith, second. Cassiobury Park: Mr. Marchant, both first and second.

Hackney Photographic Society.—June 20. Mr. W. Fenton-Jones in the chair.—The Chairman sketched his method of taking portraits outside, which was to have a very large clothes-horse, and so make a sort of outdoor studio, placing a kind of blind over to regulate the top light. Mr. T. H. Smith showed some pictures he had taken on the Barnet plate by gaslight. One had five minutes and the other forty minutes. Both were under-exposed. Mr. AVENT had taken portraits using six Welsbach incandescent lights, and found that five or ten minutes would be about the right exposure. The CHAIRMAN then showed and explained a Wynne's exposure meter. It appeared to him to be a very good and cheap article, and he said he would try and report further on it. Mr. Penny showed two negatives. One had been enlarged by the cresco-fylma method, and the other by using hydrochloric acid two drachms to four ounces of water. The result was precisely the same. Owing to the unavoidable absence of Mr. Hensler, Mr. GOSLING started a discussion on *Toning*. He was in favour of plenty of gold, and the use of the sulphocyanide bath, for P. O. P. Mr. NUNN said he had obtained yellow tones when using borax. Mr. BARNES used a lead toning bath, but the colour was too slaty. The CHAIRMAN said he had read that chloride of aluminium was recommended in place of alum to harden the gelatine in the prints, the great recommendation being that they could be the more readily handled without injury.

Brixton and Clapham Camera Club.—June 20.—Mr. C. Goodwin Norton gave a demonstration on *Photography by Artificial Light*. He advocated the use of five or six blow-through jets arranged in a cluster, and enclosed in a box, in front of which a tissue or prepared calico screen should be stretched. The exposure averages from eight to twelve seconds, and the results are very good. The average cost per sitter is about threepence for the limes and compressed oxygen. Reflectors of some white material will be necessary in order to lighten the shadows a little. The light should be suspended from the ceiling of the room by a cord, and it should be about six feet from the ground. Better results are claimed for this light than from the magnesium flashlight. The electric light would, of course, be better, but it is beyond the reach of the majority of professional photographers at present. The whole cost of the outfit is only about 5*l.* complete. Specimen photographs taken with this light were passed round, and at the conclusion of the demonstration a discussion took place.

Croydon Camera Club.—The President (Mr. H. Maclean) conducted a party of members on Saturday, June 24, through the Edenbridge district.

The chief points of interest centered upon the banks of the Eden, which offers several attractive little bits. The neighbourhood of Lake Deadeye is both photographically and paintably good. Those present took full advantage of the somewhat trite attractiveness of this lonesome sheet of water. Rambling on towards Lingfield, several secluded scenes were come upon, and, although not in all cases taken, none the less enjoyed.

Gosport Photographic Society.—June 20.—Mr. S. HERBERT FRY, of R. W. Thomas & Co., Limited, gave a highly successful demonstration on *The Sandell Plate*. The lecturer explained the mode in which the plates were coated, and said that the great advantage of the multiple films was the extended scale of correct representation. Some specimen prints from Sandell negatives showed that a good foreground could be obtained without spoiling the background. Mr. Fry said it was best to expose for the shadows and leave the high lights to take care of themselves. He recommended development with a weak solution to commence with in cases where the exposure is known to be more than normal. Two plates of a sitting-room, with the sun shining in the window, fulfilling all the conditions of a difficult exposure, were developed. In both instances the negatives were clear and good. Another plate exposed by a member yielded good results.

Birmingham Photographic Society.—June 20, Mr. F. S. Goode in the chair.—Mr. HENDREN continued his lecture on *Christian Architecture in England*. Mr. Hendren, in the course of his very interesting remarks, showed by diagrams the various forms of arches, pointed and round, and the evolution of one from the other, also the various kinds of decorations commonly in use both on arches and pillars. Several of our well-known cathedrals and other public buildings served to illustrate this or that style of work, a large number of photographs being shown.

FORTHCOMING EXHIBITIONS.

1893.	
July 3–8	Photographic Convention of the United Kingdom, Plymouth. Hon. Secretary, F. P. Cembrano, jun., 10, Cambridge-gardens, Richmond, Surrey, S.W.
August	Welsh National Eisteddfod. The General Secretary, Pontypridd.
Sept. 25–Nov. 15 ...	Photographic Society of Great Britain, 5A, Pall Mall East, S.W. Assistant Secretary, R. Child-Bayley, 50, Great Russell-street, W.C.
October 1–31	Hamburg. Das Ausstellungs Committé des Amateur Photographen Verein, Schwanenwik, 33, Hamburg.
,, 9–Nov. ...	Photographic Salon, Dudley Gallery, Piccadilly, W. Hon. Secretary of Organizing Committee, A. Maskell, 215, Shaftesbury-avenue, W.C.
December	Madras. The Hon. Secretary Amateur Photographic Society, Madras.

Correspondence.

☛ *Correspondents should never write on both sides of the paper. No notice is taken of communications unless the names and addresses of the writers are given.*

THE FOCUS OF A COMBINATION.

To the EDITOR.

SIR,—I have a Dallmeyer 2 C Baby lens, advertised as four and a half inch focus and two and a half inch aperture. I find that, when the direct rays from the sun pass through the lens into a dark room, the dust of the room renders those rays visible, and that they converge in a cone to a point exactly five inches from the front surface of the lens and then cross and diverge; I wish to know whether this five inches may be taken as the focal length when calculating for enlargements.

The above is the question, but perhaps I may add that I have previously tried to obtain the focal length by the means suggested by Mr. Bothamley, viz., to place the lens on a rule at one end of which is a white card and to focus the image of the sun sharply upon the card, the distance from the card to the *diaphragm* will then be the focal length; by this means I made the focal length about four and three quarter inches, but in the experiment above you will notice that the distance was five inches from the nearest surface of the lens; that the rays from the sun were brought to a fine focus is, I think, proved by my having lit my pipe by this means at the point indicated.—I am, yours, &c. L. V. DREW.

Mount Ayliff, East Griqualand, Cape Colony, June 2, 1893.

[See Leader.—ED.]

DEPRESSION IN PHOTOGRAPHY.

To the EDITOR.

SIR,—I am really sorry to see you printing so many letters on depression in photographic business, such as those written by Messrs. T. S. Hicks, Another Pro., and many others, losing in so doing such valuable space in your independent BRITISH JOURNAL OF PHOTOGRAPHY, specially since "Amateur," page 398, answers so well all points. He gives the remedy in a few words, a kind of universal panacea, and without recourse to law or N.A.P.P., or any convention. All that is needed is to enlarge the amateur agglomeration, and then reduce all the professionals in larger cities to six or less first-class ones, these to be selected, of course, by a committee of amateurs. Any of these will do for that purpose, they being all superior beings, to which (as is well known now) ALL that is known in photography up to date is due.

Mr. Editor, in your modesty you have never given us a list of what we owe to the amateur. Allow me, therefore, to quote a few of the improvements they have made, or, more modestly, brought about, and to quote in rotation let me refer to page 280, over Mr. W. D. Welford's signature: 1. Increasing speed of plates (never thought of before the amateur came with his hand camera). 2. Improving apparatus generally (same remark as above). 3. Causing greater attention to small work (ditto). 4. Increasing the number of photographers (amateur wants them, singularly, reduced). 5. Naturalness of posing (ditto as above No. 1). 6. Aiding journalism and study of life (this is true). 7 Improving mental (?) and physical action (certainly around the chin, especially, to brag about all amateur achievements). Then Mr. Amateur comes in by stating that this particular class takes up chemistry, composition, and lighting, and, what is a new addition, optics, which I think was left up to date to specialists, only. What next?

Mr. Amateur must have an exceptional lot of first-class amateur acquaintances who throw away all poor negatives and prints. My experience so far has been that, if amateurs were to act in such a radical way, they are not likely to find glass too heavy and bulky to store away and want films instead. Oh dear, no!

To return to the poor professional, I would say that the amateur does him more harm by his talk than by actual work. The amateur tells how much one plate costs him and the paper to print on, and maybe the small outlay for a piece of cardboard. From this the uninitiated counts up the difference asked by the professional without adding anything for work, failures, chemicals, rent, taxes, retouching, living, help, dull times, instruments, repairs, &c., all things Mr. Amateur knows very little about, and never speaks of to others. He has one outfit and one lens, generally one that does for all work, good or bad, principally the latter. He takes views and portraits, interiors and churches, buildings, and reproductions of engravings, all with one lens, and instantaneous too. If it is bad, the plate or chemicals are at fault. If it turns out good, believe me, it is nine times out of ten a mere chance. Exceptions, Mr. Amateur, prove the rule. There are better and worse photographers the same as in any trade, whichever you take, linen, cloth, machinery, tailors, milliners, &c., photography is no exception. THE BRITISH JOURNAL OF PHOTOGRAPHY tries hard to improve the standard; but, if there are only six good ones in larger towns, the others may have some good reasons to complain, even if they are a little inferior. Remember, please, Mr. Amateur, that superiority is only possible among amateurs, and be more generous towards the poor professional that only wants to make a living.

One word more and I am through. I know of a great many amateurs whose only library consists of a sheet of paper with a formula on it and a few circulars of cheap outfits and plates, and, maybe, paper and cardboard, but no books or journals.—I am, yours, &c., A. LEVY.

Asnières, June 24, 1893.

To the EDITOR.

SIR,—There has been a good deal written lately about amateur *v.* professional photographers, but a letter in yesterday's issue of THE BRITISH JOURNAL OF PHOTOGRAPHY really requires an answer. "Ssenkrak" does not seem to understand what "an amateur" is, and writes a lot of irrelevant stuff, apparently to throw people off the line. The definition of an amateur as given by the A.A.A. is as good as it can well be, and has, I believe, been adopted by others.

"An amateur" is, as the name implies, one who does a certain thing for love of it and not for money (this is *not* the A.A.A. definition). What does it matter if he (or she) be poor? they need not make money by it.

"Ssenkrak's" second paragraph is delightful humbug. Yes, "it is all very well to talk about the *bonâ-fide* amateurs; who are they?" They are scores of people who (like myself) have practised photography from love of it, and who have never received, *either directly or indirectly*, anything beyond thanks for their gifts of pictures.

I agree with "Ssenkrak" in being unable to see wherein anything "mean can exist," &c. I don't know how any one could. It is not "mean" to be a professional pure and simple, but it *is* "mean" being a professional, earning money by the art, to pose, or try to pose, as an amateur. Be one or the other, no one can be *both*, and whichever you are don't be ashamed of it, as there is nothing in being a professional, or amateur, photographer to be ashamed of; but it is "mean" and something to be ashamed of being one thing, say a professional photographer, to try to deceive people, and make them believe that you are another, say an amateur photographer.—I am, yours, &c.,

Westward Ho! June 24. J. E. GUBBINS, *Lieut.-Col., late R.A.*

To the EDITOR.

SIR,—Your contributor, "Pioneer," under the heading of "In Darkest Photography—and the Way Out," in your issue of June 16, makes some remarks which I think are rather likely to do more harm than good.

As a shopkeeper I feel rather insulted by the manner in which he

refers to my class in the following paragraph:—"There is too great a tendency at present among professional photographers to add the sale of apparatus, chemicals, &c., to the ordinary branches of their business. It is a system to be deprecated, and tends to *lower the status of the profession, causing those who follow such a practice to descend to the level of a shopkeeper.*" The italics are mine.

Now, I would be glad if "Pioneer" would point out wherein consists the degradation of a shopkeeper as compared with any other member of society, not excepting even the aristocratic professors of photography.

I take it that, whatever occupation a man follows, if he does his duty and conducts himself in a becoming manner, he is worthy of our respect and admiration, and I fail to see what there is in the business of photography to make a photographer such a very superior person, so far above the level of a shopkeeper.

"Pioneer" should have lived in the middle ages, when wealth and power, class and lineage, were the chief factors in giving a man a status amongst his contemporaries; but in the nineteenth century people are a little more enlightened, and honour a man for what he is, and for what he makes himself by his conduct and abilities.

I would be the last to cast a slur on the business—call it profession if you like it better—of photography, and I consider I do it no dishonour if I place it on the same level as shopkeeping.

There is far too much nonsense talked of the status of the profession of photography, and it is time the "low shopkeepers" had an innings.

It is also entire nonsense to talk of Excise licenses or Acts of Parliament helping to give a status to photography, and limiting the number of photographers. An ordinary hawker has to have a license, but that does not make him a superior or inferior person more that he was before. It is character that tells.

Photography in these days is easily acquired by one year's careful study and practice, and those who are so contemptuously referred to as shopkeepers often beat, by their amateur productions, the work of a lot of professional photographers. So long as professional photographers can turn out superior work, they have no need to fear amateur competition, and "Pioneer" should remember that in this world everything is governed by natural laws, and when artificial law clashes with natural law its efforts are useless.

I have a large amount of sympathy for those professional photographers who cannot make their business pay. Here natural law comes in—the supply exceeds the demand. They must, therefore, turn their hands to some other work. And we must remember that if the amateur does injury to the professional, he does a large amount of good to photographic manufacturers and dealers; therefore, those who cannot make a living as professional photographers should take heed of the signs of the times, and make a living by catering for the increasing army of amateurs. It is merely diverting trade into another channel. No honest work or business can possibly be degrading to any man, but idleness is most reprehensible, and so is pride of class.—I am, yours, &c.,

WILLIAM JAMES FARMER.

68, *Blackburn-street, London-road, Blackburn, June* 20, 1893.

PHOTOGRAPHIC CONVENTION OF THE UNITED KINGDOM.

To the EDITOR.

SIR,—It may interest those of your readers who intend attending the Convention to know that the Great Western Railway issue third-class excursion return tickets to Plymouth for 21s. by the trains leaving Paddington on Saturday, July 1st, at 7.55 a.m. and 1.55 p.m. Passengers can return on the following Saturday, Monday week, Saturday week, or Monday fortnight. Times of return trains on Saturdays and Mondays, 8 a.m. and 12.30 p.m.—I am, yours, &c.,

10, *Cambridge-gardens, Richmond, S.W.* F. P. CEMBRANO, JUN., *Hon. Sec.*

DEVELOPMENT OF OVER-EXPOSED PLATES.

To the EDITOR.

SIR,—Many readers of THE BRITISH JOURNAL OF PHOTOGRAPHY for June 2, 1893, p. 251, and those of *Photographic Scraps* for this month, must have been greatly interested in the record there given of Prof. W. K. Burton's experiments respecting the successful development of greatly over-exposed gelatine plates, and will be looking forward to the time when full details of his system of treating such long exposures are published in the photographic journals. I understand that he will read, or send to be read, a paper on this subject to the Photographic Convention for 1893, which will give full details of his method, no doubt, which will greatly assist any one who is interested in this important matter, for the speed of the gelatine dry plates is being increased by some maker or another almost every week, which, of course, will tend to favour over-exposure greatly; therefore a reliable method of overcoming it will, or should, be welcome to all photographers.

Judging from a description I read a short time ago, the new developing agent known as "Glycin-Hauff" appears specially adapted for the successful development of greatly over-exposed gelatine plates. It may also interest many readers to know that a successful method of developing both *under-exposed and over-exposed gelatine plates* was published in THE BRITISH JOURNAL OF PHOTOGRAPHY for May 29, 1885, pp. 342 and 343, also in the ALMANAC of the same JOURNAL for 1887, pp. 197 to 199; in the latter, additional details were given. The developer used was pyro, bromide, and ammonia. I have tried the formula given there for under-exposure, and found it work well, and have no doubt but what those recommended by the writer of the article referred to, Mr. F. T. Leon, would be found equally satisfactory. He said the formulæ he gave suited all the gelatine plates then upon the market, therefore it is very probable that they would be equally successful if tried at the present day; indeed, I intend to do so at the earliest possible moment, and may send you a report of my success, or otherwise, for publication, should you be able to spare space for it.—I am, yours, &c., J. T. HACKETT.

Fleet, Hants.

Exchange Column.

*** *No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance. The full name of the advertiser must in all cases be given for publication, otherwise the Exchanges will not be inserted.*

Will exchange 12s. 6d. set of Nameit (new) for *Photography*, by A. Brothers.—Address JOHN WEIR, photographer, Moffat, N.B.

Wanted, changing bag; will give Lancaster's patent folding lamp in exchange.—Address, H. WARD, the Stratford Studio, the Delph, Brierley Hill.

Will exchange embossing press and four dies for cabinets and C.D.V.'s, by Marion, cost 5l. 5s., for other photographic apparatus.—Address, W. WALKER, 155, Noel-street, Nottingham.

Wanted, whole-plate modern camera and three double slides, in good condition, in exchange for tricycle in good condition. Can be seen any day.—Address, A. L. SMITH, 233, Uxbridge-road, W.

Will exchange quarter-plate camera (by Talbot & Farmer), three double hook slides three-fold tripod, also silver Geneva watch, for half-plate camera, three doubl slides, and tripod.—Address, J. K. SMITH, Little London, Rawdon, Leeds, Yorks.

Will exchange a Robinson's quarter-plate single landscape lens and a enrryscope, *f*-6 quarter-plate rapid rectilinear lens, and 5s., for a really decent whole-plate lens.—Address, CHARLES J. HARRIS, 3, Pentyre-terrace, Sea-view, Plymouth.

Will exchange Moss & Mitton's twelve-inch enameller, nickelled roller, perfect as new for 12×10 outdoor camera, with all movements, three double slides, tripod, &c., posing chair, or first-class backgrounds.—Address, THOMPSON, 72, Market-street, Bradford.

Will exchange a rigid brown waterproof camera case, nine and a half inches in height, eight and a half inches wide, and fourteen and a half inches long, never used, also changing bag and half-plate sliding mahogany tripod, for English and foreign stamps, envelopes, and post-cards.—Address, Dr. WATERS, 21, Westbourne-park-road, Bayswater, W.

Will exchange a Cox quarter-plate portrait lens (*f*-5) and a wide-angle quarter-plate Lancaster lens (*f*-16) for a Wray special rapid rectilinear hand-camera lens of six-inch equivalent focus, working at *f*-8; or, for a portable half-plate square-bellows camera, double extension, with rack work, double swing back, rising and cross front, and three or more double or single dark slides.—Address, J. T. HACKETT, 191, Albert-street, Fleet, near Winchfield, Hants.

Answers to Correspondents.

*** *All matters intended for the text portion of this* JOURNAL, *including queries and Exchanges, must be addressed to* "THE EDITOR, THE BRITISH JOURNAL OF PHOTOGRAPHY," 2, *York-street, Covent Garden, London. Inattention to this ensures delay.*

*** *Correspondents are informed that we cannot undertake to answer communications through the post.*

*** *Communications relating to Advertisements and general business affairs should be addressed to Messrs.* HENRY GREENWOOD & CO., 2 *York-street, Covent Garden, London.*

*** *It would be convenient if friends desiring advice respecting apparatus, failures in practice, or other information, would call at the Editorial Office either on Wednesdays from* 4 *to* 6, *or Thursdays from* 9 *to* 12 *noon, when some one of the Editorial staff will be present.*

HUGH BLACKWOOD.—In our next.

E. EDWARDS.—On such a purely legal point we cannot hazard an opinion. Better consult a soliciter.

J. T. SIMINS.—If you will refer to our rules, &c., for exchanges, you will see that we make it a condition that the name of the advertiser must be given.

READER.—We cannot trace the number of the patent. A visit to the Patent Office, where you can refer to the alphabetical list of patentees, will give you the desired information.

OTHELLO.—1. So far as we are aware, no explanation has been forthcoming as to why, upon applying a drop of water to a dried negative, a reduction of density takes place. 2. It would be better to fix out the silver salt in the usual way, and recover by means of liver of sulphur.

THROGMORTON.—Photography is largely practised in an amateur way by members of the Stock Exchange who are also members of different photographic societies, but we have no knowledge of a "Stock Exchange Photographic Society," nor do we think that any such Society exists.

F. GOLDBY.—Each formula, as given in the ALMANAC, is complete in itself, and should be adhered to. If additions of one formula to the other be made, unless the various chemical equivalents be taken into consideration and compensated, failure will probably result. Why wish to add acid to the washing water?

A. B.—If the copyright is not registered, no proceedings can be taken against pirates. It was a pity, when such an event would never occur again, and the negative was obtained under such extreme difficulties, that registration, as its cost is so little, should have been neglected. The only thing now is to "grin and bear it."

W. H. CROUCHER.—This correspondent, in the course of a letter on "Depression in Photography," dubs the amateur an "eyesore to the professional," and suggests that both professionals and amateurs should be licensed—the latter to the extent of ten or twelve guineas a year, "which would soon wipe out the amateurs" who are "a curse to the professional."

A. X. L.—If the two rival inventions have been patented abroad prior to their being patented in England, the first application here need not be the most valid patent in this country. Consult an established patent agent, giving him fuller particulars as to what has been done in foreign patent offices than is given in the communication, and get his opinion on the subject.

T. STOKES.—The two negatives received. If they are fair examples of your general work, we are by no means surprised that you fail with the platinum process. No one could obtain vigorous prints in platinotype from such thin or veiled negatives. For platinum printing, to obtain the best results, tolerably vigorous negatives are an essential. Plates returned as requested.

W. G. HONEY.—A method of printing resembling that about which you write was introduced several years ago by the late Oliver Sarony; nay, if we are not mistaken, he obtained a patent for it, but it has long since been lost sight of. However, it is a good method, and we shall be pleased to see it reintroduced with such modifications as are suggested by knowledge and experience.

CICI writes: "Will you oblige me by letting me know if there is any silver in the hypo solution after the plates have been fixed? Why I ask you is because I found that, after a week, some thick dark matter settles on the bottom of the jars. Is it worth while to keep it on? What would throw the silver down quickly?—Of course there is silver in the fixing solution, and it is certainly worth saving in a large business. Sulphide of potassium is the best precipitant.

J. SMITH.—1. The best varnish for your purpose is one that is now being extensively used as a lacquer for silver goods by jewellers and others. It emanated originally from the Frederick Crane Company of America, and is obtainable from several firms in this country, among these being J. R. Gotz, Buckingham-street, London, W.C. It is a solution of celluloid in acetate of amyl, modified by the presence of other matter. 2. The mirrors next to the eye may be 2×3 inches each.

W. H. C.—1. No such work is published. Better get a few practical hints from a professional photographer. 2. The articles that have recently appeared on studio-building give all that is necessary. Supply any builder with plans according to your requirements and the space at disposal, and he will do the rest. 3. Dark blue or light green for the roof, of such materials as is usually supplied for window blinds. Unbleached sheeting or pale blue will answer well for the side blinds. 4. See Leader on another page. 5. A reflecting screen or two is always useful in a studio. A frame covered with pale blue calico answers every purpose. Any blind-maker will supply one.

S. E. SLADE says: "I have some very old stereoscopic transparencies bearing the name of Ferrier that in the stereoscope are very different from any of the modern ones I possess, and they are infinitely superior. On looking at them in the stereoscope, the towns and villages seem like models, and not as those of the present day do—pictures with a certain degree of relief. Why is this, and why do not modern workers aim to obtain the same effects as described?"—The effect described is obtained by placing the lenses or the cameras very wide apart, sometimes many feet, and not, as at present, about the distance, or a little more, than the eyes are apart. The pictures alluded to are untrue to nature as the eyes see it.

ROBERT BRUCE asks: "What lighting would you advise me to have for a studio which is to be constructed for reproduction exclusively? I mean to reproduce all classes of work, engravings, maps, photographs, &c., for photo-mechanical processes. I simply want to know what you consider the best lighting for this class of work, as the studio can be constructed to get the light from any point."—For general work of this kind a ridge-roof studio running north and south, with light on both sides, and the north end also glass, with a complete set of blinds, will be the most useful: then light may be obtained on the subject in any direction that may be required. Sometimes the "tunnel" form of studio is adopted; but, on the whole, the form referred to is more useful.

STEREO asks: "What lenses are best for stereoscopic work and lantern-slide negatives?"—For general work lenses of from four and a half to five and a half inches focus are the most useful. As lantern pictures are required, we should recommend a pair of lenses of the rapid type of about four and a half inches focus for architectural and instantaneous work, and a pair of single lenses of something like five and a half inches focus for other purposes. As for the distance apart, from three to three and a half inches will be best for most subjects.

ANS-LONGA writes: "The light of my studio is situated on my neighbour's side. She has had some door and window cases from some old building brought to her house, and has placed them in front of my side light, which will very much affect my work. Does the law permit her to take such a course, or can I compel her to remove them?"—The neighbour has the right to place anything she likes on her own property, even to the extent of stopping out the whole of the light from the side of the overlooking studio, unless that enjoys the privilege of "ancient lights"—that is to say, it has had an unobstructed light for not less than twenty years. Unless the studio has enjoyed this, law will give no remedy. Perhaps, however, a polite request for the removal of the thing will accomplish what legal proceedings will not.

HACKNEY PHOTOGRAPHIC SOCIETY.—July 4, Open Night.

NORTHERN PHOTOGRAPHIC AND SCIENTIFIC ASSOCIATION.—July 1, South Kensington Museum.

GOSPORT PHOTOGRAPHIC SOCIETY.—July 6, Winchester. Leaves Gosport thirty-five minutes past ten a.m.

MR. WILLIAM ENGLAND has been awarded a silver medal for his Alpine studies at the Lille Photographic Exhibition, recently opened.

MANCHESTER AMATEUR PHOTOGRAPHIC SOCIETY.—July 1, Healey Dell, Leader, Mr. E. Ashman. Train leaves Victoria (No. 5) at one p.m.

ERRATUM.—In Mr. Gosling's letter published last week, the word "gelatine," as applied to the cold-bath platinotype developer, should read "glycerine."

FROM Mr. John Rowden, St. Leonards, we have received a sample of his sensitised albumenised paper of the "Incomparable" brand. It is claimed to be very rich in silver and free from blistering.

MR. WILFRED EMERY (South-street, Baker-street, W.) sends us specimens of his work as a retoucher and printer. They are in platinum and silver. The retouching is effective, and the work is good in every way.

A CORRESPONDENT writes: "*Re* the amateur difficulty, I suggest that, to end the matter satisfactorily to professionals, each professional should invite an amateur acquaintance to dinner, and then attack him with a club. *Hic jacet* amateur!"

DINNER AND TESTIMONIAL.—On the termination of the three years engagement of Mr. J. B. B. Wellington with the Eastman Company as the Manager of their factory in Wealdstone, Harrow, he was entertained at dinner by a number of the *employés*, who, upon his leaving, desired to testify their esteem for him both as a manager and as a personal friend. The chairman after dinner in the name of those present presented Mr. Wellington with a handsome marble clock.

"DRY PLATES" for June says: "In accordance with the promise made in the last number of our magazine, we have made a series of experiments to determine the alteration in speed due to using our developing formulæ instead of the standard formula for speed testing. The result is that the speed number should be multiplied by two with our developer at 65° Fahr. It may be asked why we do not give speed numbers with our own developer. This would not leave our numbers comparable with those of other makers using the Hurter & Driffield system; we therefore use the formula up to the present used by two makers for this testing purpose. Our minimum lightning speed is now fixed at 80° H. & D. = 160° if our developers are used."

METAL *VERSUS* PAPER FOR PHOTO-LITHOGRAPHIC TRANSFERS.

The paper read by Captain Mantell at a recent meeting of the Photographic Society of Great Britain, which we were enabled to give in our last issue, on a method of producing photo-lithographic and photo-zincographic transfers, as worked out by Mr. Husband at the School of Military Engineering, Chatham, is one of more than passing interest to experimentalists in photo-mechanical processes generally. From the paper it will be seen that the sensitive film is, as usual, bichromated gelatine. But the novelty is the material upon which it is formed, namely, tin-foil instead of paper, the material generally employed for the purpose.

After all, however, this system is by no means new; but that does not detract from any merits it may possess. Tin-foil, if we mistake not, was first used for photo-litho transfers by Senor Rodriguez, of Lisbon, now some dozen or more years ago, and with success too. Why the method has lain dormant so long it is a little difficult to conceive, unless it be that the foil then used *was* tin-foil, and also very thin. It was said at the time that the thinner it was the better it was for the purpose, provided it was perfectly free from holes, a condition difficult to secure in exceedingly thin foil. Now, as will be seen by reference to the paper, a thicker foil is used, and, instead of its being tin, an alloy, probably of tin and lead, is employed. It will readily be understood that the inking up, and handling generally, of even a moderate-sized sheet of extremely thin tin foil, coated with bichromated gelatine, without stretching or distorting it, was by no means an easy operation.

Let us now compare the advantages claimed for metal over those of paper for transfers. Photo-lithography, which, by the way, is perhaps worked by a larger number of persons than any other photo-mechanical process, is principally employed for line subjects; and in the majority of instances, as with maps and plans, the work has to be done strictly to scale. It is in such cases as this that the inconvenience of paper is most experienced. The image on the bichromated gelatine has to be printed from the negative while the paper is in a dry state, and it has to be transferred to the stone or zinc plate, as the case may be, when it is in a moist condition. Now, paper, it is well known to most persons, expands more or less when it is wetted; consequently the image, as printed from the negative, becomes of a different size from what it was at first by the time it is ready for transferring. But that is not all. Machine-made papers, and they are the ones used, expand more in one direction than they do in another. The expansion is greatest in the width of the paper, that is, the width of the web as it leaves the machine. This, of course, need not be represented by the width of the sheets; that will necessarily depend upon whether they are cut transversely or longitudinally from the roll. Lengthwise, the expansion with some papers is next to *nil*, while crosswise it may be considerable. Furthermore, even with the same make of paper, the degree of expansion is not always the same, for the age of the material appears to be a factor in the case. Hence it will be seen that, when extreme accuracy is a necessary condition, paper transfers may, and frequently do, give considerable trouble to photo-lithographers and photo-zincographers.

It is just the above difficulty that the process, worked by Mr. Husband to a successful issue, is intended to meet. The metal foil retains its original dimensions alike when it is wet and when it is dry. The only thing that is likely to cause any variation is temperature, and that, in the case of the metal recommended, will be under ordinary conditions so trifling that it may be quite disregarded in actual practice. Another advantage of the metal over paper is that, in contact with the negative, the print is not liable to buckle or cockle in damp weather with a long exposure to the same extent as is the latter. We also anticipate another advantage from the use of metal foil over paper. It is that the bichromated film upon it will be retained for a longer time in good working condition than would be a similar one on paper, as the latter material often contains aluminous and other matters that exert an insolubilising action on the sensitive gelatine, while the metal may be expected to be perfectly inert.

It might well be asked why this system of making photographic transfers, which was published so long ago and working details given which, by the way, do not differ materially from those published by Captain Mantell, has not been taken up by those who practise photo-lithography commercially. It may be that, as is tolerably well known, lithographic and other printers are usually very conservative, and seem to have an aversion to any innovation, or indeed anything that will necessitate any deviation from the tract with which they are already familiar. It is quite possible, however, that the system may be in actual use, for it is tolerably well known that those who work photo-mechanical processes commercially keep their methods as profound trade secrets.

Now, however, that the system has been prominently brought before the photographic world, it will probably receive more attention than it hitherto has from experimentalists in photo-mechanical work, as it is obvious that the use of metallic transfers is not confined to photo-lithography and photo-zincography alone. In the foregoing remarks no attempt has been

made to indicate the various directions in which metal transfers may prove more convenient than paper ones, or how the methods of preparing them may be modified. The object of the present article is to emphasise the advantage in some ways of metal over paper for photographic transfers in fatty ink.

TONING GELATINO-CHLORIDE PRINTS WITHOUT GOLD.

When we wrote on this subject last week, we were under the impression that the general principles of the bleaching and redevelopment method were sufficiently well known to most of our readers to warrant us in treating the subject in a general way, without going very minutely into detail. But it now appears that there is room for a few additional remarks, in order to make clear certain points on which some of our correspondents are in doubt.

We would, in the first place, protest mildly against the careless manner in which some readers follow the instructions given, and also against the way in which others modify those instructions to suit their own ideas, and then complain because they do not succeed. For instance, in spite of the warning we gave in connexion with the use of bichloride of mercury on the score of the extremely careful washing required afterwards, we find that more than one correspondent has used that salt, probably because it was ready to hand, and then, according to the descriptions of what followed, has neglected the necessary washing, and so failed to get results as satisfactory as anticipated. Another states that, having used a solution composed of bichromate of potash and chloride of sodium, "which is practically the same" as that given by us, he failed, in some cases, to get any image at all on redevelopment, while, at the best, he could only develop a mere shadow. We shall show presently that the two solutions are certainly not either practically or theoretically similar in action.

With regard to the use of bichloride of mercury, we can only repeat what was said last week, namely, that it should only be used in conjunction with very thorough and careful washing, and even then, for various reasons, the solution of chloride or bromide of copper is to be preferred. For one reason the cuprous salt formed along with the silver chloride in bleaching the image appears to interfere less with the subsequent action of the developer than does the corresponding mercurous salt, and the films, both before and after treatment, require less washing than is the case with mercury.

Our reason for expressing a preference for cupric bromide over chloride was that the image is thereby converted into silver bromide, which exhibits a far less tendency to revert under development to the old colour of the untoned but fixed print. Bromide of silver, too, gives with greater readiness than chloride the rich blacks and neutral greys that are now so popular; and, as one method is as easy as the other, we give the preference to bromide on the ground stated, more especially as it requires the exercise of no precautions that are not necessary with the chloride.

With regard to the employment of the improvised solutions described by us, formed by the double decomposition of sulphate of copper and chloride of sodium, or bromide of potassium, and recommended, on the score not only of economy but also of convenience, our correspondent appears to think it unwise on our part to recommend an "impure solution" in preference to the real thing when the latter is so easily obtained. In reply, we can only say that, if he is in a position so easily to obtain cupric chloride and bromide, by all means let him use whichever he prefers; but all our readers, especially those residing in small provincial towns, will not find it so easy to obtain the salts named, especially the bromide, whereas the ingredients of the solutions mentioned by us can be obtained wherever a chemist's shop exists, or even where there is a veterinary or other surgeon within reach.

Again, so far from the "impure solution" being a disadvantage, it is, in fact, if anything a benefit, since the sulphate of soda or potash formed in the solution along with the copper salt will tend to prevent the softening of the gelatine film, and thus facilitate the manipulations. It is perhaps worth our careful correspondent's while to go to the little extra trouble of preparing the "impure solution" instead of the easier but more expensive plan of using the pure salts.

Turning next to the solution of bichromate of potash and hydrochloric acid, which for all-round purposes we prefer to those already mentioned, because, if properly applied, it leaves a bleached image consisting of pure silver chloride, we can assure our other correspondent that his failure is entirely due to his own eagerness to improve the formula given. Hydrochloric acid, with the aid of the loose atom of chromic acid in the bichromate, converts the image into chloride of silver; so also does chloride of sodium under the same conditions, but the latter goes further, and, if in excess, dissolves the silver chloride so formed. Our correspondent has evidently employed a solution of salt of sufficient strength to *fix* the image—or rather to remove it; after bleaching it so, it is little wonder that little or nothing remained for redevelopment. Perhaps he will recognise that his solution is *not* practically identical with ours.

We may add to our remarks of last week that where hydrobromic acid is available it is to be preferred to hydrochloric, for precisely the same reason as that given in the case of bromide of copper. In fact, the image bleached with bichromate and hydrochloric acid, if properly washed and treated throughout, behaves precisely as any of the slow bromide papers. If hydrobromic acid is not obtainable, a substitute is found by adding sulphuric acid to a strong solution of bromide of potassium, or by cautiously pouring a few drops of the strong acid on to some crystals, and then adding sufficient water to remove the red-brown colour. It is not necessary to adhere to any strict equivalent proportion; the potassium salt may be in excess, and, if the compound solution be employed in a sufficiently dilute state to ensure that the silver bromide is not dissolved by any excess of soluble bromide present, that will be all that is needful.

We may perhaps lay some further stress than we did last week on the importance of employing the solution of bichromate and acid in as dilute a condition as possible, on account of its physical action on the gelatine. So far as the chromium salt itself is concerned, its strength would be quite immaterial if it were not for the risk of staining that a strong solution entails. It is the halogen that does the bleaching, and so long as there is sufficient present to convert the whole of the silver in the image it cannot be employed too sparingly, that is to say, in too dilute a solution. The best plan is to use a solution of bichromate of fixed strength—say, ten ounces, five grains to the ounce—and to add the halogen solution in small quantities sufficient to bleach the print with moderate rapidity.

If from prolonged contact with the bichromate solution a

permanent or persistent yellow or brown stain should remain in spite of washing, it may be removed by means of very dilute sulphuric or aqueous sulphurous acid; but this operation is better left until after redevelopment.

Some of our correspondents inquire whether it is necessary to expose the prints to light before redevelopment, to which we can only reply that, in the case of bleaching with mercury or copper, the redevelopment would most probably take place under any circumstances without exposure to light; and, also, when hydrochloric acid is used with bichromate, if a sufficiently strong developer were afterwards employed; but, working as we have done by lamplight or diffused daylight, more or less exposure does not appear to exercise any influence on the result. If a strong light be allowed to act, especially on an image bleached with bichromate, then, no doubt, the conditions are identical with those existing in the case of ordinary emulsion paper, but the minute traces of chromic salt left behind render the bleached images very insensitive to light.

The mercury-bleached image is probably quite insensitive to light, as witness specimens of the old "alabastine" pictures, which retain their pristine whiteness in spite of light. The image bleached with copper is also practically insensitive, perhaps quite so, though it does change in time, but possibly from other causes than light.

So far as the redevelopment of the image is concerned, we cannot, in the space at our command, add anything useful to what we have already said. The circumstances are so variable, and the choice of developers so great, that we must leave individual experimenters to select their own particular course, assuring them, however, that they will experience little difficulty if they work on the lines we have indicated.

Reducing Action of Sulphite of Soda.—The question of the ability of sulphite of soda, in conjunction with pyro, to develop a dry plate without any addition of alkali, has often been raised, and it has been assumed occasionally that the development obtained by such means was due to the presence of a small quantity of carbonate of soda in the sulphite employed. But that sulphite alone may act as a reducing agent is known to chemists, and quite recently we may note in this connexion an important chemical process has been founded on that property. Messrs. Augustus Lumière and A. Seyewetz have succeeded in isolating several amido-phenols in a pure state by utilising for the decomposition of their salts neutral sulphite of soda, which, in consequence of its reducing properties, prevents the oxidation of the base formed. When this reducing action is thoroughly understood, it is capable of explaining many of the little-understood properties of sulphite, which is now a chemical absolutely necessary in many photographic processes. Yet it seems only the other day that the late Mr. Herbert Berkeley called attention to its value, and this he had to do repeatedly before its use became at all general.

Metallic Spots in Paper.—One of the first properties needful to be possessed by a paper for photographic purposes is that it should be free from contamination by metallic particles. It is difficult, even with a microscope, to detect such spots, and in last week's *Chemical News* Mr. Clayton Beadle has given a very simple and excellent method of testing paper for the presence of these deleterious matters. Strips of the suspected paper are floated in a one per cent. solution of ferrocyanide of potassium acidified with a few drops of nitric acid. After three hours' treatment, particles of iron will be rendered evident by the production of deep blue spots, and brass by chocolate-coloured spots. The former are of a very marked and certain character, but the latter may easily be mistaken for other foreign matter contained in the paper. To confirm the presence of brass particles, Mr. Beadle places a bead of nitrate of silver solution on the suspected spots and examines them by reflected light under the microscope. If any brass is present, clusters of crystals of metallic silver will soon be seen forming themselves on the surface of the paper. After the solution has nearly dried into the paper a drop of the ferrocyanide solution is placed close to the margin. On diffusion it produces a chocolate colouration about the margin. Other metallic particles, he states, are rarely met with.

Microscope Projection.—At a recent meeting of the Royal Microscopic Society, Sir David L. Salomons gave an exhibition of his projection microscope, which was spoken of in very high terms by the President of the Society, who remarked upon the unusual flatness of the field. We have, however, some difficulty in following the meaning of the brief account which appeared in *Nature* of the course of the succeeding discussion. The President said there was one point on which he should like to ask for information: "It sometimes happened that great concentrations of light produced also a great concentration of heat, and that, consequently, objects in balsam, if exposed for too long a time, were apt to get spoilt through the softening of the medium. Was this difficulty got over in the present instance by using the electric arc light as an illuminant?" Sir David Salomons said he obviated it very much by using lenses cemented with balsam. The customary alum and water he found to be rather a trouble, so he used simple distilled water, and found that it answered all the necessities of the case. It is difficult to see how the action of the balsam cement comes in, but there can be little doubt that plain water will answer as well as the time-honoured alum solution. It is not very long ago we published the result of an exhaustive scientific investigation of the relative diathermancy of several liquids, one of the results of which was to show the uselessness of adding alum.

A New Disinfectant.—Substances for preventing the decomposition of gelatines, paste, &c., are of perennial interest in photographic technics, hence an account of the latest introduction of the kind will be of interest to most of our readers, especially as the new chemical possesses most remarkable qualities. Mr. Worrell, chemist to the Thorncliffe Collieries, while investigating the nature of some bye-products, has discovered a hitherto unknown oil, intermediate in properties between the benzine series and its derivatives, on the one hand, and the paraffin series on the other. From this oil he extracted a body which he found to possess greater antiseptic properties than even pure crystallised carbolic acid. It is insoluble in water, though readily made into a permanent emulsion with it. Further, it has a high boiling point, which gives it a persistency of antiseptic action. A great advantage the new substance, which has been named "Izal," exhibits is its absolutely non-poisonous character. It produces no detrimental effect when taken internally or applied externally, in striking contrast to carbolic acid, as those who have inadvertently spilled it on their hands know too well, while the poisonous quality of "carbolic" is painfully and frequently shown by newspaper reports. It is no part of our work to show its wonderful effects on the pathological forms; but a substance such as Izal is described to be should be simply invaluable in all gelatines and pastes when used under circumstances likely to induce decomposition.

A New Photometer.—Before the Physical Society, on June 9, Mr. A. P. Trotter read a paper on "A New Photometer." The author has modified his "illumination photometer," described *Proc. I. C. E.*, vol. cx., paper No. 2619, so as to adapt it to the measurement of candle power. The principle employed is to view a screen illuminated by one source through an aperture in a second screen illuminated by the other light, the aperture becoming invisible when the illuminations are equal. After using perforations of various patterns, a series of narrow slots cut in thin paper were found to give the best results. The plain screen is mounted behind the slotted one in a box sliding on the photometer bench, and they are arranged so that the light falls on them at equal angles. The screens are viewed from a distance of six or seven feet through an opening in the front of the box, cords being provided for producing the transversing

motion. Two "sights," set respectively at the middle of the length of the plain screen and on the lower edge of the front opening, serve to show when the middle of the band of equal illumination is vertically above the pointer on the carriage. The photometer is found to be particularly valuable when it is desired to determine the maximum power of a variable source. When lights of different colour are being compared—say, a gas flame and an arc—one end of the screen shows blue strips on a yellow ground, and the other end yellow strips on a blue ground; at the centre the colours seem to blend. To facilitate the comparison of such lights, Mr. Crompton, who has been working at the subject simultaneously with the author, uses one screen tinted pale yellow and the other pale blue. Details of construction of the new photometer are given in the paper, and the accuracy attainable when comparing two equal lights of about eight candles is stated to be about one per cent.

PHOTOGRAPHIC CONVENTION OF THE UNITED KINGDOM.

PLYMOUTH MEETING.

The seventh annual Photographic Convention of the United Kingdom was inaugurated at Plymouth on Monday evening, when the Mayor (Mr. W. Law) held a reception in the Athenæum, and the President (Mr. George Mason, of Glasgow) delivered his address. The attendance is not so large as at Edinburgh last year, owing to Plymouth's great distance from Scotland and the Midlands, and to the Royal wedding festivities falling in the same week. Still, there is a fairly large gathering, which not inadequately represents the scientific, artistic, and commercial aspects of photography. Among those present were Messrs. George Mason (President), Andrew Pringle, F. P. Cembrano (Hon. Sec.), F. York, J. Traill Taylor, A. Haddon, F. W. Hindley, J. Guardia, C. H. Bothamley, H. M. Smith, Phipps Lucas, Cornthwaite, W. D. Welford, Seaman, R. L. Kidd, Major Lysaght (Cork), H. Sturmey, R. Keene, W. Scorer, E. A. Leblanc, J. Birtles, Col. Barrington Baker, R. Hansford Worth (Local Hon. Sec.), W. G. Tweedy, R. F. Yeo, R. Rugg Monk, S. Weekes, Lethbridge, G. F. Treleaven, and others. Many ladies also graced the proceedings with their presence.

The Mayor, who wore his gown of office, tendered a hearty welcome to the Convention, and congratulated the members on the prospect of fine weather. They would, he was sure, find an abundance to delight them in the district, with its wealth and variety of foliage and flowers, hills and dales, woods and moors, tors and rivers, and a sea-coast of great beauty. They would, he was sure, feel amply repaid for the long journeys they had undertaken. Of the historic associations of Plymouth and its famous Hoe all had heard, and, with Dartmoor at its back, they would find much to interest and to admire, and especially in the neighhourhood of Tavistock and Ivybridge, both of which the Local Committee, he was glad to see, had included in the week's programme. Again, he would say he felt it an honour to receive the Convention in such numbers, and would add the hope that they would be so impressed with the beauty of the place and the heartiness of the people that it would not be long before they came again.

Mr. Bothamley said, in the absence of Mr. George Davison, last year's President, he had two duties to perform. The first was to acknowledge the Mayor's most hearty welcome. Plymouth they all associated with those great sailors who had made England what it is to-day; and they recollected that in Penzance, still further west, was born one of the greatest chemists that ever lived—Sir Humphry Davy—who was associated with Wedgwood in some of the very earliest photographic experiments ever made. It was, however, the feeling of good fellowship so characteristic of photographers that had brought them so far west to enjoy and make pictures from some of the finest scenery the United Kingdom could boast of; and he was sure the Local Committee would do its best to make their visit pleasant and profitable. His second duty was to introduce to them, as President, Mr. George Mason, a good photographer, an active supporter of the Convention from the very beginning, and a very good fellow. The President then delivered his annual address as follows:—

PRESIDENT'S ADDRESS.

At the Bath Photographic Convention meeting, Mr. Traill Taylor said that, up to that point in the history of the Convention, the presidential chair had been filled consecutively by representatives of the following departments of the art science, viz., the literary, the scientific, the chemical, the professional, and last year the chair was most ably filled by Mr. Davison, who might, with every confidence, be termed the artistic. And now come we this year to what is known as the commercial element, for you all know that the commerce of photography is what fills up the most of my time and study, and in this phase of the art-science I am most at home. The commerce of photography may seem at first sight the most commonplace and least attractive of all its various branches; but this is not so, for more or less it embraces all, and it will be found to be the most essential element in the whole, it is the leaven that leaveneth the whole lump. Only in so far as any profession is found to be for the general good, so is it essential, and by its claims proving good or bad so will it succeed or fail. All our introductions, experiments, discoveries, and inventions—and their name is legion—are but means to an end, and the end is commercial.

I fancy I can hear the enthusiast exclaim, "Oh, no, that is not so. The glory of discovery is the reward. The love of the work is ample repayment." That's all very well, and I believe that he who says so has perfect confidence in his statement. Yet, "What is it worth?" is really the point to be solved on the introduction of any new thing. It may seem a very poor platform on which to place the work of the enthusiast and the investigator, embracing as it does years of experiment and labour that on which is marked "What is it worth?" but I fear that with but few exceptions it comes down to that at last.

There are exceptions to every rule, and all of us have met the enthusiast who, for the love of the thing only, goes on working untiringly in one groove or another, using both time and money for the advancement of the art-science, anticipating no profit from his labour, the pleasure of overcoming difficulties and the joy of "finding out" being his end and aim. But, even in such a case, what has been discovered, if to spread and flow, it must come to the river of commerce. If one happen to have income enough so as to render his position independent of any thought of repayment, he may sneer at the position herein taken up; but, nevertheless, it is a fact that commerce is the stream into which all the tributaries flow. Looking back to the beginning, we find Niepce straying along the country roads trying to gather stones suitable for his photo-lithographic experiments; his correspondence with the Paris lithographer and his partnership with Daguerre all have a commercial leaning. We also find his brother, who, in his own time, was as great a scientific enthusiast as himself, determine to leave his home, and resolve to come to England, feeling sure that it was a better field for the success of his inventions. And have we not the notable cases of Daguerre and of Mr. Fox Talbot protecting their inventions? What for? For a profit, of course!

Whether we agree regarding the position I take up, that the end and aim of all our work tends to commerce, I have no doubt we will be at one on the various items that I intend to touch upon to-night, for they are in their very essence the work of the business. And, first, I would make a few remarks upon the Convention itself and its membership.

Last year was the most successful of all our meetings; but the Convention meetings, since the very start, whether large or small, have ever shown great vitality. Still, the professional has not given it either the attention or the support that I feel it was his duty to do, and that the institution deserves.

The greater part of the success of our meetings is due to the support and enthusiasm of the amateur element, and why should this be? Surely there ought to be some equality of representation. The profession, as a body, is large enough and influential enough to at least treble its present representation; but I fear that it is the spirit that lacks energy and enterprise. At first there was a considerable outcry about the time the meeting was held being unsuitable for many in the profession. To meet this objection, the date has been changed two or three times, I think; this with some little advantage perhaps, but not much.

Taking professional photographers collectively, I feel that if they tried they could make this meeting for themselves the most pleasant and profitable outing of the year. Every one that has been with us knows that this is an honest statement, and, if they would only gather round in numbers, they would find it a gain both in health and business. The lines on which our Convention is run commend themselves, and are better, in my opinion, than those adopted by our American friends. To a great extent the American Convention is a dealers' show, a good enough thing in its way, but the platform upon which we meet is more inde-

pendent, and the principal business of our gathering is educational and social, the dealers' part being a mere detail, and never interfering with the more salient points for which we meet.

The professional who joins us in this week's outing, by personal contact and general interchange of ideas and experiences alone, is bound to learn more than he would in very much more time spent in less congenial and less favourable circumstances, so that, even as a paying speculation, I look upon the Convention as a profitable investment to any member with his eyes and his ears open. Hence I would that the professionals bestir themselves, and make a fairly representative turn out. If they but did this, the institution would be, beyond doubt, an assured success for all the coming years, a centre where the representatives of all the various societies might meet in a broad union once a year.

The National Association of Professional Photographers should find the time and places of the Convention a fitting opportunity for their meetings. There they could be in numbers, and could easily arrange to hold their own special meetings during the week, to suit themselves without in any way interfering with the general arrangements of the Convention.

All being in one town at one time, more meetings could be held, larger audiences could be got, and they would be far more likely to command attendance than where they have to travel, in many cases, long distances for single meetings.

Last year Messrs. Fall, Whitlock, and O'Neill made a move in this direction, and I have no doubt that their endeavours then tended to the growth and influence of the Society. This Association, worked on broad lines, should be a power for good to the whole profession, there are so many questions of importance, such as insurance, copyright, holidays legal defence, prices, and many other subjects that are of great commercial interest to the whole profession alike.

One thing might here be noted: that the obtaining of a closer union between the individual members of the profession is what should be aimed at if success is to be the result in this as well as all other like institutions; and this is the greatest difficulty to be overcome, for the photographer does not take so kindly to unity as most other professions do.

Here I would say a few words on behalf of the Photographers' Benevolent Association. This Society should have much more consideration and sympathy from the photographic worker. On investigation, I find that most of the funds and the greater proportion of interest and work is undertaken by the kindly well-wisher, and that don't-care-about-it apathy still belongs to the working photographer. As I have elsewhere said, every *employé* in the photographic trade in the United Kingdom holds a special interest in this Society, and half-a-crown a year is all that is necessary to be paid up by any one to place himself in the position of membership, which, in cases of need, gives him the advantage of becoming a participator in the funds of the Society. About a halfpenny per week! just think of it; and for this fraction, if paid by the body of employers, the income of the Society would be raised to 400*l.* a year, and, if the employers also joined, the return shown could not be less than 500*l.*, at the very minimum, of our outlay. Look at the power for good this would place in the hands of the Executive. If every employer would interest himself to induce his *employés* so to assist themselves, the feat would be accomplished, for they could not fail to be successful, and thus the many rivulets would swell the greater river.

For the promotion of union in the profession, I think that the institution of the "Central Photographic Club" is no mean factor.

It opens up an avenue of social intercourse and information, and anything of such a nature must help to advance a man in his business; it gives him the opportunity of being up to date, and that is one of the essentials of successful trading.

A place of meeting where, at all times, the country member comes in contact with his compatriots in the city, and where he at once gets into the centre of that which most interests him—and the friends from the provinces will also keep the city members acquainted with what is going on in the country districts—and these advantages are to be obtained at a merely nominal outlay. This Institution should have the fullest support of the profession.

The Affiliation scheme of the Society of Great Britain is also a march in photographic progress that should help to draw photographic societies together, and, if taken up with a will, must result in an intercourse that is bound to be beneficial to all, the interchange of papers and slides alone being of great moment and importance, especially where societies are too small or too young to be able to produce new subjects or original matter without help from wider fields.

The progress of the year shows steady advancement; nothing startlingly new, but there's not a week passes without the introduction of some ingenious device or discovery which tends to save labour or to perfect results.

It has been stated that there are more patents taken out in connexion with photography than in any other trade of like dimensions, and, looking at the continuous stream of applications for protection, it is easy to believe.

Printing-out papers is one phase of photographic work that has made a marked advance in the currency of the year. Gelatino-chloride paper has come into almost universal use, the beauty of the finished results secured by the use of this paper tending greatly to its growing popularity. Collodio-chloride paper has also grown considerably in demand, as it is considered by many to allow of a greater variety of tone, and also that it is more permanent than the gelatino-chloride, but to prove the latter requires the test of time. The new cold-bath-process paper introduced by the Platinotype Company has also made a rapid stride to the front, and is now almost universally adopted. The advantage of local development by its use being rendered sure and easy was a great recommendation to its success, and, where it has been fairly tested, the hot bath has been laid aside for this more perfected process.

Stereoscopic photography, which, like the sleeping beauty, has been lying dormant for so many years, lives and breathes again. A great advance has been made, and considerable work has been done in this department during this last year, and it still goes on increasing. A big future may be anticipated for it.

The hand-camera competition still runs on without impediment. The originality and ingenuity displayed and expended on the construction of these little instruments is perfectly astonishing, and the excessive number of forms placed upon the market—each professing to be the best—is marvellous. By their results ye shall know them. The work produced by them is to be found broadcast in all sorts and conditions of illustrated papers, photographic and otherwise, ranging from very bad impressions up to charming productions. So much in favour has the hand camera become, that I have no doubt but that the larger proportion of the apparatus brought for use by the members of the Convention will be found of this description. If the advances during the year have not been made by leaps and bounds, they are at least sure.

In lenses, the Zeiss, the Dallmeyer Tele-photo, and the Ross Concentric are increasing in demand. Isochromatic plates are taking a firmer hold, and the Sandell has been adopted by many.

The journalism devoted to the profession seems to be out of all proportion to the extent of the trade it caters for, but I suppose time will try them, and the weakest will go to the wall.

Since last we met we have had to mourn the loss of one of our best friends—one of the most genial and gentle of men, foremost in every good work, an able artist, and thorough experimentalist—Mr. William Bedford. I pay this tribute to his memory as one of our previous presidents and the friend of all.

And now I will leave the various members, in their various classes, during the Convention, to thrash out their various themes, one by one, scientific or chemical, each in his department, be it development, speed, light, colour, or optics, each of them needing its own specialists to do it justice.

I hope you will all spend a happy and enjoyable week.

On the motion of Mr. James Martin, the President was thanked for his able address, and the Mayor for his cordial welcome.

Light refreshments were then served, and the rest of the evening was devoted to the admirable exhibition arranged in the art gallery, and to views shown by the optical lantern. The exhibition, a fuller notice of which we will give next week, contains much that, in the estimation of the *Western Morning News*, is a revelation for the west. Eastman has a grand and tastefully displayed exhibit illustrative of the capabilities of their Solio paper and of their Nikko paper, a development paper which may run bromide paper very hard. Morgan & Kidd have remarkable bromide enlargements (one eight feet long in one piece), and specimens of the beautiful collotype process. Mr. W. Scorer, of Havant, has two direct landscape works, 36 × 20, and two of his very ingenious cameras with double eccentric fronts. Elliott & Sons have a splendid portrait of a lady from a direct negative five feet by three. Mr. E. H. Micklewood has works illustrative of his shutter for securing clouds naturally; and Messrs. R. W. Thomas of the Sandell plate. O. Sichel & Co. have a fine collection of moulds and mounts and elegant studio accessories, and a very complete studio camera. Byrne & Co.'s portrait of an infant Battenberg prince is one of the choicest things shown. Mr. W. G. Tweedy sends interesting results of panoramic photography, and J. Martin & Co., New Southgate, an ice picture. There is a very neat collection of

Dr. Andresen's chemicals, many of which are in handy cartridge form. Local photography is admirably represented. Mr. Heath, of Plymouth, includes a more than life-size autotype carbon print of the Prince of Wales, from a negative taken by command during his Royal Highness's recent visit at Admiralty House, Devonport; Mr. Hawke, of Plymouth, sends a score of photographs of the Duke of Edinburgh; Mr. R. F. Yeo, of Plymouth, has charming studies of children; and Cox & Durrant, Torquay, send a delightful portrait in sepia.

There was a lantern display at the close of the reception. Among the slides were several by Dr. Mitchell (of Philadelphia), Major Lysaght, Messrs. York, Cembrano, Bothamley, Welford, Hindley, Forsham, and Brier (of Bollington, near Macclesfield).

On Tuesday there were excursions to Tavistock and up the rivers Yealm and Tamar, landing to visit Mount Edgcumbe Park and Gardens, and Cothele, by the kind permission of the Earl of Mount Edgcumbe.

About seventy members with several ladies and local amateurs attended the invitation excursion of the Devon and Cornwall and Devonport camera clubs up the rivers Yealm and Tamar. A fine steamer had been chartered for the purpose, and an excellent luncheon was served. Col. Barrington Baker and Mr. R. H. Worth (local Hon. Sec.) were indefatigable in promoting the comfort of the visitors, who, early in the day, experienced heavy rain.

Wednesday.

The weather, which on Tuesday had been very rainy and had somewhat interfered with the excursions, improved as the forenoon of Wednesday wore on. A very large number of members had arrived to swell Tuesday's total, and more were expected, so that, numerically speaking, the meeting promises to be as successful as several of those that have preceded it. The group was to have been taken at mid-day in the Guildhall-square. The past President (Mr. George Davison) waa conspicuous by his absence from the Convention, for which no explanation was forthcoming.

Next Year's Convention.

At the committee meeting held on Wednesday morning it was decided that the Convention of 1894 shall be held in Dublin.

"ON A FAILURE OF THE LAW IN PHOTOGRAPHY THAT, WHEN THE PRODUCTS OF THE INTENSITY OF THE LIGHT ACTING AND OF THE TIME OF EXPOSURE ARE EQUAL, EQUAL AMOUNTS OF CHEMICAL ACTION WILL BE PRODUCED."

[A Communication to the Royal Society.]

It has been generally assumed that, when the products of the intensity of light acting on a sensitive surface and the time of exposure are equal, similar amounts of chemical action are produced, and, with the ordinary exposures and intensities of light employed, such, no doubt, is practically the case, and any methods of measurement hitherto practicable have been insufficiently delicate to discover any departure from this law, if such departure existed. In some recent experiments, however, I have discovered that this law breaks down under certain conditions, and I think the fact worthy the attention of those interested in the subject, since it is possible that these conditions may arise with other experimenters. Quite lately I have described the method of comparing the photographic value of sunlight with that of candle light (*Photographic Journal*, June, 1893), which was as follows:—A beam of sunlight, after three reflections from plain glass mirrors, was admitted through a narrow slit to sensitive bromide paper stretched round a drum of about four inches in diameter. The drum could be caused to rotate round its axis at any speed up to about sixty revolutions per second by means of an electro-motor. A small exposure with this light was given to the paper during the rotation of the cylinder. Subsequently an amyl-acetate lamp was placed in position at any convenient distance from the same slit, and a fresh portion of the same sensitive paper exposed to its action during a much longer period, the rotation being continued as before. The slit was next replaced by a small square aperture of some half-inch side, and further portions of the same paper exposed to the amyl-acetate light at the same distance, for varying or unknown exposures, with the drum at rest. On development the paper showed three images, a narrow band of deposit of the width of the slit caused by the sunlight, a second band of the same width due to the light from the amyl-acetate lamp, and a third row of squares of varying blackness of deposit due to the different exposures given with the drum at rest.

If the width of the slit be accurately measured, the band formed by the amyl-acetate lamp is evidently superfluous, supposing the usually accepted law to hold good under all circumstances, as by measuring the blackness, or rather want of whiteness, of the different squares, and using them as ordinates to the abscissæ which were the times of exposure, and drawing a curve through them, the blackness produced by the sunlight could be referred to that produced by the light of the amyl-acetate lamp, and its equivalent value in terms of the latter light be calculated. The band of deposit produced by the amyl-acetate lamp was introduced as a check, for its blackness could also be referred to the curve, and the width of the slit be calculated from it. On making such calculations I was surprised to find that in every case the calculated width of the slit was always considerably less than what it was in reality, the difference being far beyond that which would be caused by any error in the measurement. This led me to commence an investigation into the cause of this difference, and what has already been carried out is sufficient to show that there is a failure in the usually accepted law. It may be pointed out that, if it held good, the sum of any number of very short exposures should be equivalent to a single exposure for the same length of time.

The experiment which naturally suggested itself was to expose a sensitive surface to the action of the light of an amyl-acetate lamp passing through a slit as before, the drum on which it was stretched being caused to rotate at high and low speeds, and also to place on the same paper a scale of exposures with the drum at rest. These were all developed together. An example of one of many experiments is given as an illustration.

The circumference of the drum with the paper stretched round it was 12·25 in. The width of the slit was arranged to be 0·012 in. The amyl acetate lamp was placed 2 ft. from the slit, and a rotation of 30 per sec. was given to the drum for one exposure and 1 per sec. for a second exposure. In the first case the time of exposure during each revolution was $\frac{0{\cdot}012}{12{\cdot}25} \times \frac{1}{30}$ sec., or about 1/30,000 sec.

The sum of the exposures during 20 mins. was thus 1·176 sec.

In the other case the exposure was

$$\frac{0{\cdot}012}{12{\cdot}25}, \text{ or about } 1/1000 \text{ sec.},$$

and the sum of the exposures was, as before, 1·176 sec. Thus the first individual exposures had only $\frac{1}{30}$ of the duration of the second exposures, though in the aggregate they were the same.

A scale of blackness was made on the same paper, through a square aperture, without shifting the lamp, the exposures being $\frac{1}{8}$, $\frac{1}{4}$, $\frac{1}{2}$, 1, 2, 4, and 8 sec. On developing it was apparent to the eye that the first band was much lighter than the second. The scale and blackness of the bands were measured accurately, and the times of exposure which had been given to each band, on the assumption that the law enunciated held good, was calculated and found to be for the first band 0·6 sec., and for the second band 0·91 sec., instead of 1·176 sec., which was really given in all. Another example is where the slit was opened to 0·11 in., and the time of exposure reduced from 20 to 10 min. It was found that in this case the exposures given on the same assumption were 3·7 sec. and 5·28 sec., the real exposure given being 5·36 sec. The last experiment shows that if the slit had been slightly wider, or the rotation slower, the law would have been approximately obeyed.

Another experiment was made by throwing an image of the crater of the positive pole of the electric light on a hole bored in a plate about $\frac{1}{20}$ in. in diameter by means of a lens, and allowing the emergent beam to fall on the slit and paper, the drum being made to rotate as before. The same kind of results were obtained.

As it might be thought that this difference was caused by some action other than chemical, another series of experiments was undertaken. In these different sensitive surfaces were employed in order to eliminate any possibility of the effect being due to any phosphorescence of the paper, though none could be detected. Plates were held stationary and exposures made by admitting light to portions of them through slits of known angular aperture, cut in a disc which could be rotated at any desired speed. Similar results were obtained to those already described. The quickest rotation gave the least density. It may be remarked that the more sensitive a surface is to radiation the less marked are the differences observable for the same speeds of rotation. This is what might be expected.

As an outcome of the experiments so far made, it seems that, when exposures less than $\frac{1}{1000}$ sec. are made on a sensitive surface, and the source of illumination is an amyl-acetate lamp (Von Altneck's) placed 1 ft. from the sensitive surface, the law quoted *ante* fails.

The question of a very low intensity of light acting and of the sensitiveness to different spectrum colours is now occupying my attention.

Captain W. de W. Abney, C.B., F.R.S.

MY FIRST DAGUERREOTYPE.

THE interesting demonstration, by Mr. William England, of an almost forgotten process, but of which he was a most distinguished exponent about forty years ago, surely must have been very attractive to those who were fortunate enough to witness it. At least, I know it would have been to me, and, indeed, to any one who had ever marred the pure surface of the silver plate by a failure; for I never knew any one who had ever attained any proficiency in the Daguerreotype process who did not retain a lingering yearning for the revival of this lost art.

In the recent editorial remarks on "Daguerreotyping," the editor said that "unlike all other systems of photography, the personal skill of the operator is the sole factor in the achievement of success." How true this is will be seen by the narrative of my early struggles with this difficult process; indeed, I might, with justice, use stronger terms, and say obstinate and refractory process, for so it proved in my hands just thirty-nine years ago.

During the latter years of my apprenticeship, I had passed through the cigar-box-and-sixpenny-lens struggles with photography, and was rewarded by most complete and entire failure, but was more fortunate, however, in my printing efforts. Some paper negatives were given me by an amateur—who was, by the way, the instructor of Buckle, of brush fame—and I showed him my very imperfect results. A few hints helped me on, but the fearful price of the chemicals cleaned out the shallow pocket of the apprentice, and there were long and serious waits until sufficient funds enabled me to replenish my photographic stores. In those days hypo was sold by the country chemist at sixpence per ounce: but, to encourage me, he let me have it at threepence! Even at that price, however, the cost, from my point of view, was simply ruinous.

In a very short time the serious business of life was before me, and I went to London to face the unknown. Of course, photography had to go overboard to lighten the ship; in fact, the ship became too light, for frequently a biscuit, eaten in the National Gallery, was the sole furniture of my mid-day meal. The eye was fed, however, and that was something.

I read every scrap relating to photography that came in my way, and thus theoretically got to know a great deal more about it, and patiently waited for happier times when I might hope to ripen theory into practice. About eighteen months after my arrival in London I made a new friend, who absolutely had a practical knowledge of the Daguerreotype process. He had just returned from America, where he had taken lessons in the art, and was looking about for premises in order to commence business. When he finally got to work and put out his specimens, I am compelled to say there was a marked difference between the examples of the art brought from America and those produced by himself, the artistic merit being most evident in the foreign productions. As time went on his work improved, and his *clientèle* rapidly increased. We lodged in the same house, and therefore I daily heard of his photographic doings, and I determined the moment I could get together sufficient money to make a start. I would take lessons of him, and try my luck also.

After patient waiting the long-looked-for day came, and I took my first lesson in "Daguerreotyping." I need scarcely say this was a memorable day for me. After eagerly watching the whole process through, from the polishing of the silver plate to the final gilding operation, so well described in the article in this JOURNAL, already referred to, I saw that all I had read and done—or rather had not done—in photography would avail me nothing, and I had to completely start afresh.

The first business was to completely master the by no means easy art of buffing the plate, for upon the perfect doing of this depended the success of the final result. An absolutely "black" polish was necessary, and the faintest visible scratches, therefore, made the attainment of this impossible, and, in consequence, weakened the force of the shadows. It will be seen by this that, unlike most of the other photographic processes, black shadows were necessary in order to obtain a brilliant as well as delicate Daguerreotype. Day after day I worked at "buffing," and found it hard work, and, though it was winter-time, the coat had to come off in order to lighten the labour. The rubbing up and down on the plate with the long piece of wood, covered with buckskin, and treated with the finest rouge, seemed easy work enough at the start: but, as the hours went on, the operation became tedious, as well as tiring, and I decided that buffing could not be the most interesting part of Daguerreotyping. I suspected that my friendly instructor found this irksome part of his business quite as well done by proxy. At any rate, as time went on, with no change of employment, I mildly suggested that I wished to be something more than a photographic "buffer," and that the number of lessons agreed upon were rapidly coming to an end, and that only one stage on the photographic journey had been reached. I was assured that, when I had fully mastered this most difficult operation, I had little else to learn, as all the rest was comparatively simple. I thought of the master who kept his pupil at scales for seven years when teaching him to sing, and, in reply to remonstrance, said, "Go forth, thou art the finest singer in Europe!" Perhaps, when I became an absolutely perfect buffer, I should astonish the world with my unrivalled Daguerreotoype productions, so I worked on patiently. I think, if the truth were told, my friend was so busy, that not only was I useful, but I was less in the way when occupied by this necessary operation.

My friend had brought all his apparatus with him from America, and, as he had several surplus articles, he sold them to me. Amongst them was a camera of American make, and I must say that, though it would be regarded as clumsy now, it was far in advance of the English cabinet work of that period. It was a bellows camera, and the woodwork was rosewood. The focussing screen was inserted some distance in the camera, and was protected from the light, so that a focussing cloth was not necessary. A little trap-door admitted the former as well as the dark slide. When the latter was in position ready for operation, the shutter, which was of sheet iron, was pulled entirely out, and the lid of the camera shut down until the exposure was over. In those days a little extraneous light was not heeded, and the small amount that could get down the groove during the opening or shutting of the camera lid did not appear to affect the plate. The bellows portion of the camera was beautifully made; indeed, the whole instrument was a marvellous contrast to the clumsy wooden boxes made in England and sold as cameras. It would be interesting to learn when the first bellows instruments were made in this country. I can simply say that in 1854 I had never seen one of English make.

All the American silvered plates were slightly bevelled downward, and in appearance were not unlike miniature reproductions of the Venetian bevelled looking-glasses. They were lighter and cheaper than the Birmingham electro plates at first employed in England, and in consequence the name of Scovell—the American manufacturer of these plates—became known all over the world. This slight bending downward of the edges prevented any cutting of the fine leather surface of the buff, and also enabled them to be more readily fixed in the slight groove of the screw block to which they were attached in order to hold them tight during the process of buffing.

The American arrangement for holding these blocks of various sizes was very ingenious. The instrument was of cast iron, and in general appearance was not unlike the modern American burnishers. There was a broadish flat bar, slightly tapered and bevelled on the under side, so that the block carrier of the plate, which had a corresponding tapered groove, could be pushed along it until it was held tightly. The ends of this bar were bent upwards at right angles, and were furnished with pivots which fitted into sockets provided for them in two uprights, which formed portions of the more solid part of the apparatus, and which had to be screwed down to a solid bench in order to secure the necessary rigidity.

When the pressure of the buff came on to the plate, the socketed bar took the necessary angle to ensure even contact between the buff and plate, and thus the friction was even all over its surface. A moment's consideration will show the use of this arrangement. Had the plate been rigid during the process of buffing, the silver surface would very soon have been scrubbed away from the copper support at the edges. In those days there were *some* failures, even as now, and the cost of these plates made it imperatively necessary to use them over and over again as long as possible, for replating was nearly as costly as new plates.

The American coating boxes as they were called were far superior to the English apparatus for applying the iodine and bromine vapour to the silver plate. As the constant inhaling of the iodine and bromine vapours would have in a very short time seriously affected the health of the operator, it was necessary to devise some efficient way to keep them imprisoned, and get always ready for work. The Americans employed two square shallow porcelain pans with the edges ground perfectly true. These were placed side by side in a box that was provided with a framed top which fitted closely on to ground tops of the pans. A sliding carrier with inner frames for the various-sized plates travelled from pan to pan along grooves in the wood work, but there was plenty of wood at each end of the carrier, so that, when the plate was over the iodine pan, the bromine one was tightly covered, and *vice versâ*. This American contrivance was so much superior to all others that it finally drove all the rest out of the market.

I wish I could speak with equal praise of the American mercury bath, but I cannot, and for reasons which will appear later on. My friend had not one to spare so I proceeded to get one made on the

American model. The matter seemed so simple that I did not apprehend any difficulty. All that was needed was a hollow cast-iron pyramid which had to be fitted on a retort stand, and made to slide up and down so as to adjust the flame of the spirit lamp in order to get the correct temperature of the mercury. Of course, the pyramid was fixed with its hollow base upwards, and on this was fitted the carrier with the silver plate downwards, to receive the fumes of the mercury which was placed at the bottom of the well thus formed. A thermometer with metal index plate was attached to one of the outer sides of the inverted pyramid so as to record the right temperature of the mercury necessary for the development of the latent image.

VALENTINE BLANCHARD.

(To be concluded.)

DODGES.*

THE PRINTING FRAME.

A QUARTER-PLATE picture can be vignetted into cabinet or half-plate size by using a half-plate printing frame with a piece of cardboard, the same size with an aperture cut out for the quarter-plate negative, covering the join with yellow or black paper, as in the example I show you; the same arrangement applies to larger sizes.

PLAIN AND FANCY BORDERS.

At times you may wish to have a margin round a print, perhaps a plain one round a landscape, or a fancy one for a portrait. For that purpose a mask must be provided of opaque paper, cutting out an oval, square, or any other shape desired; place the outer portion on the negative in its proper position, then the sensitised paper, and print. By using a larger frame, and filling up the space round negative with cardboard, a much wider border can be obtained; a plain white border gives, I think, a neat and bold appearance to a print. It may, on other occasions, be desirable to print a fancy border, and it will be necessary then to make a negative of the design required, marbled paper or imitation morocco paper will answer the purpose. After printing with the plain border, the part already printed must be covered with the piece of opaque paper cut out of the mask; slightly stick it in its place on the print, and print the border from the border negative provided for the purpose. There are several modifications of this style of double-printing which will, no doubt, suggest themselves as occasion requires.

THE NEGATIVE.

I now come to dodges in printing from the negative, and will suppose that, on examination of the negative, unpleasing defects are observed. There may be shadows too intense, one side thicker than the other, the foreground too thin, &c. All these matters want attention and correction, and for these and similar faults I prefer simple to more elaborate means, and I don't think there are many faults but what can be corrected by means of semi-transparent material, tissue paper, and the like. Use it in this manner: suppose the lens does not cover the plate sufficiently, the corners of the negative are then thin and print dark; in such a case, gum pieces of paper on the corners of the frame, to shade off the corners and so prevent any unpleasant appearance. A road is perhaps too dense: cover all except the road with tissue or yellow paper, one side of negative thinner than the other, and so print quicker, paste tissue paper over one side. Perhaps a central portion of the negative is thin, cover the whole of the negative with tissue, and a second or third piece of the centre, and so on—in fact, I know nothing more generally useful than tissue paper. It is also invaluable for thin negatives; use one, two, or more thicknesses; in fact, any negative is better for printing under it. As an example, I show you a print from a negative of an interior, about the worst I can find, another print from the same negative dodged with tissue and yellow paper; I think the superiority of the latter over the former is apparent. Another example is of a workshop; the light at the window is rather strong; consequently, printed as usual, it is unsatisfactory, but, if after printing to usual depth a piece of opaque paper is taken with an aperture cut the shape of the window, and the window is printed deeper, a great improvement is made.

For landscapes a bent cardboard shade is very useful, and is a simple means to dodge a negative with a thin foreground. If any clouds are in the negative, it will help, if not entirely bring them out. I show you an instance of a print from a negative without a shade, and another using a shade, and I recommend you to try it. I first saw this idea mentioned in a paper by Mr. Blanchard, and I consider it a valuable dodge.

* Continued from page 410.

Negatives are further dodged by working on the back. In the case of a group some of the faces may print too dark, in which case a light touch of pale blue paint on the back of the negative will improve the print; also, tissue paper can be pasted on the back or gummed by the edges, and worked on with a pencil or crayon to increase the high lights, cutting away parts of the paper to increase shadows. I show you a portrait which I think treatment of this kind has improved. It is from the negative of one of our members, who kindly lent it me to experiment with. No. 1 is a print from the negative in its first state; No. 2 the same after intensification with mercury and ammonia; No. 3 is after the negative had been backed with tissue paper and worked on roughly with pencil to take out the brick marks, also vignetted. The cabinet is from the same negative, printed in a half-plate frame as before described.

Matt varnish on the back of the negative is also another means of improving a print; but, unfortunately, it is a dodge of itself how to get the varnish on the plate, and I do not think it will be out of place to describe how it is done. When you first try it, you will perhaps get the varnish on the under side of the plate, or over your fingers, up your sleeve, and on the carpet; in fact, anywhere except the right side of the plate.

To practise the trick, I can recommend you thin gum water; it does not cost much if wasted, and it will flow in about the same manner as varnish if not too thick.

To coat a plate with matt varnish, the plate must be cold; with spirit varnish, warm. Take the plate at the left-hand near corner by the thumb and finger of the left hand, hold it in a horizontal position, supporting it by the tips of the extended second finger. Pour the varnish in a pool in the middle of plate, then gently tilt the plate so that the varnish slowly runs to the corner held between the thumb and finger; then tilt it to the other left-hand corner, then to the right outside corner; finally, with one gentle sweep, pour the surplus off at the corner nearest you on the right-hand side, gently rocking the plate at the same time, to prevent lines forming. The plate must now be laid at one side to dry, and, when dry and hard, can be worked upon with pencil and brush, and parts scraped away with the knife to increase the shadows if necessary. This mode of dodging is useful to put clouds in a weak sky. Get a suitable cloud negative as a guide, and, with pencil or crayon and stump to shade off, copy as well as you can the cloud negative. With a little practice it is easy to get passable results. A blue pencil is also one of the easiest articles to work with I have ever tried.

When thinking over this matter, it occurred to me to try ground glass itself, and I think (after trial) that it has some advantages. It is remarkably easy to work upon, and can be used over and over again. To use it, take a piece of ground glass and place it, ground side up, on the top of negative, film side up. Work on it to increase high lights as usual with black and blue pencil, blue for medium effects. To increase the shadows it is not possible, of course, to scrape away the matt, but the same effect can be obtained by thin gum water. Put it on lightly with a small brush, the thinner the better (this is important, because, if thick, it will have a diminished effect), and let it dry. After doing what you think necessary, place the ground glass at the back of negative, the ground side next back of negative, then print as usual. A softer effect will be produced by placing the ground glass on the back of the negative, working on it and printing in the same position. In the former case only one thickness of glass intervenes between the ground side of glass and the film of negative, in the latter case there are two thicknesses. If you wish to use ground glass again, the work can easily be removed by that useful kind of soap that "won't wash clothes." Matt varnish is very inferior to ground glass in its liability to damage.

VIGNETTING.

There are many ways of doing this, and many effects to be produced. A good plan is to make a cardboard screen for the purpose to go on top of printing frame, leaving a space between negative and cardboard. Cut a hole half an inch smaller than you wish your vignette to be, then gum tissue paper round the edges, also a piece of tissue paper over the whole aperture. This softens the effect to a large degree. It is also advisable—in fact, with gelatino-chloride paper, necessary—to stuff wool between the cardboard and glass to prevent the light unduly spreading over the whole print.

DOUBLE PRINTING.

I give you an example of this. On looking through my negatives I selected one with a cow, and decided to transfer her from Chingford to Hampstead Heath. I then printed the cow on a piece of sensitised paper, cut out the animal with a penknife on a piece of glass, and stuck the piece cut out on the Hampstead negative in the position in which I

wished the cow to appear. The other part of the print was stuck on the negative of the cow, so that the cow could be seen exactly in the aperture; the other part of the negative was then covered with opaque paper. The cow was then printed on a piece of sensitised paper in the position required, then a second print from the other negative, taking care that the cow already printed was exactly behind the mask, and the trick is done, more or less cleverly according to the care and skill exercised. There are other ways of doing this, but the example is as good as any.

C. O. GREGORY.

(*To be concluded.*)

News and Notes.

MESSRS. WORMALD & COS. new address is Rodney-road, New Malden, Surrey.

MANCHESTER AMATEUR PHOTOGRAPHIC SOCIETY.—July 8, Monsal Dale and Ashford. Leader, Mr. J. T. Lees.

HACKNEY PHOTOGRAPHIC SOCIETY.—July 8, Excursion to London Colney. 11, *Lantern Slide Reduction*, by Mr. A. G. Nunn.

RECEIVED.—*Traite de Photo-lithographie.* By Leon Vidal. (Paris: Gauthier-Villars et Fils, 55, Quai des Grands Augustins.) *The Great Barrier Reef of Australia.* By W. Saville-Kent, F.L.S., F.Z.S. (W. H. Allen & Co., 13, Waterloo-place). These and others in our next.

AN AMATEUR PHOTOGRAPHER'S CAMERA PARTY.—Mr. G. A. T. Middleton, of 42, Bolingbroke-grove, Wandsworth-common, is organizing an amateur photographers' camera party to Belgium for the week commencing August 2, 1893. Full particulars and itinerary may be obtained from him at the address given.

BIRMINGHAM PHOTOGRAPHIC SOCIETY.—July 8, Last day for sending in photographs for the Stoneleigh Excursion Competition. 11, Social Evening. 12, Whole-day Excursion to Charlecote, Hampton Lucy, Wellesbourne, Sherborne, and Compton Verney. Leader, Mr. W. Jones. Train leaves Snow Hill for Warwick at thirty-two minutes past eight.

J. H. STEWARD'S PHOTOGRAPHIC CATALOGUE.—Mr. J. H. Steward, of 7, Gracechurch-street, and 406, Strand, has just issued a new photographic catalogue, which is devoted to particulars and prices of cameras in considerable variety, lenses, stands, shutters, and other accessories. The Omni and Standard cameras appear to be particularly well adapted for those requiring a strongly made, serviceable instrument, having all desirable movements.

"SUMMER TRIPS ON THE RIVER THAMES."—Bearing this title Messrs. Salter Brothers, the well-known boat builders, of Folly Bridge, Oxford, have sent us a capital little pamphlet, illustrated, containing complete guide-matter as to fares and times for their steamers plying between Oxford and Kingston. An account of the trip is also given. With photographers especially, these trips should be popular, an unequalled field for camera work being afforded by the lovely scenery encountered. The pamphlet may be obtained from Messrs. Salter, price one penny.

ASSOCIATED FOREIGN TOURS FOR AMATEUR PHOTOGRAPHERS.—The Association for the Promotion of Home and Foreign Travel, of 41, Eastcheap, E.C., inform us that special arrangements have been made for associated tours to districts which are particularly rich in features of attraction to amateur photographers, as well as to all who take an interest in architecture. One of the tours is arranged to visit the finest cathedrals and chateaux of northern France and the course of the beautiful French and Belgian Meuse. The other tour takes in the Central Pyrenees and the ancient Republic of Andorra, a district which at present is practically unknown, but which is one of the most interesting in Europe. Fuller details of both tours are given in a pamphlet supplied by the Association.

MR. HENRY BLACKBURN'S STUDIO FOR INSTRUCTION IN DRAWING FOR THE PRESS.—The well-known art critic and journalist, Mr. Henry Blackburn, has opened a studio devoted to this purpose at 123, Victoria-street, S.W., which we hope to have the pleasure of visiting shortly. From an *Educational Review* reprint on the subject, by Mr. Arthur Montefiore, we learn that Mr. Blackburn is meeting with considerable success in teaching artists the requirements of work for photographic reproduction. We cull the following passage from Mr. Montefiore's *brochure* with much pleasure:—"This brings me to a question on which Mr. Blackburn is properly emphatic. Critics are continually inveighing against these 'cheap and nasty' processes, entirely forgetful or ignorant of the fact that it is *not the process but the draughtsman who is generally in fault.* Men will continue to draw what the public call 'pretty pictures,' ignoring entirely the question whether the process can reproduce them or not. Some men won't—others, apparently, can't—learn the simple rules of drawing for photographic reproduction. I know of a sketch by an R.A. in which the stars came out a beautiful black on a white sky! Now, if the draughtsman has a reasonable amount of knowledge, the result may be so beautiful (for the fidelity of photography in line-work can be exquisite), that I have known the reproduction mistaken for the original drawing, and that by an expert. I cannot add a stronger argument in favour of the study of drawing for the processes so largely used in the press." We have before now noted that Mr. Blackburn has shown a great appreciation of photography as an aid to artists, and we are glad to have his testimony on a point in connexion with which half-educated newspaper art critics are constantly denouncing photo-mechanical work, namely, its unsuitability for reproducing artists' drawings.

CHECK PATTERNS ON HALF-TONE PRINTS.—"A good many process workers" (says *Process Work*) "have no doubt puzzled their heads over the fact that when they attempt to reproduce a print from a half-tone block by the half-tone process, there is a peculiar chequered appearance all over the picture. This has been variously ascribed to the grain of the paper, to the print on the back of the paper, and, in fact, anything but the right cause. It is really due to the superimposing of one set of parallel lines upon another, and so producing the effect of the magic-lantern chromotrope. Any one who has a screen and a half-tone negative, can soon test the matter by putting the screen and the negative together, and holding them up to the light. You will then see the check pattern that has troubled you; or again, if you lay your screen over a half-tone print, the same thing will be visible. But observe further, if you turn the screen circularly, the pattern will gradually become smaller, and when the lines of the screen cross the picture at right angles, the pattern has disappeared altogether, and a rather pretty mezzotint appears. The application is obvious."

NEW FORMULA FOR SILVER BROMIDE PAPER WITH METOL-HAUFF.—Messrs. Fuerst Bros., say:—"For bromide paper the normal metol developer requires much less exposure than ferrous oxalate. The best plan is to use the metol-potash carbonate developer in concentrated form. The developer should be kept up to strength, and exposure made to suit that strength, so as to obtain results which cannot be distinguished from results by ferrous oxalate. A little bromide solution (1:10) say half to one grain per ounce of developer, should be used, which allows more latitude of exposure than ferrous oxalate. If these instructions be carried out, the best tones will be obtained. If the developer, as a whole, is much diluted, or if the alkali is much reduced in proportion, or if too much bromide be added, the tones will be more grey and black than is usually desired. When soft greyish prints are required, as for after-toning or intensification, the plan is to dilute the developer. The process of development is speedy, and there will never result any discolouration of any kind, even if the prints are kept long in the developer, as when a large quantity of bromide has been added. The gain of time in exposure and development for enlarging is considerable, and will commend itself to all who enlarge on this paper. No clearing bath is needed; the prints are extremely amenable to the processes of toning after fixing.

EMOTIONS OF THE HEART IN PHOTOGRAPHY.—"Recently," says Mr. George Davison, in the *Photographic Gazette*, "addressing some art students, Mr. W. F. Yeames, R.A., sought to give photography its proper place in the training and work of the draughtsman. It is something to find a painter admitting the actual use made of photography by draughtsmen. Almost without exception they get practical assistance in their drawing from it, and, in most instances, at the same time abuse and misrepresent it. Mr. Yeames admitted that photography lightened the labour of the draughtsman and *extended the range of his subjects;* but, he averred, 'in no photograph did one see any expression of the emotion of the heart, which were qualities artists had to deal with.' How far a painter may legitimately or with advantage use photography will always be a matter of personal opinion. The tendency of all photography is to educate the eye of the public as well as that of the artist, and to raise the standard of excellence and correctness. As to expressions of the emotions, Mr. Yeames would probably find considerable difficulty in so defining his meaning as to exclude photography from getting such qualities into its productions. The character of a worker may be shown in his photographs, and the more he learns of his technique the more subtle may be the signs of his individuality and perception. Photography, as Mr. Yeames stated, deals in facts, and expression of emotion is one of these facts. The kind of emotion one sees in ninety-nine out of a hundred of our Royal Academy pictures is certainly not out of the range of the susceptible and capable photographer. Mr. Yeames may not know so much about 'emotions' as about the use of mechanical photography. The brush will do mechanical work as well as the camera. When painters discuss such subjects, they generally find it convenient to use terms vaguely and without definition."

PHOTOGRAPHING IN NORWAY.—Mr. Edward J. Smith, of Park Royd, Halifax, writes: "I have not sooner responded to your invitation for information on the above subject, hoping that some one having a wider experience would reply, but, a fortnight having elapsed without response, perhaps my limited knowledge will be better than none. Writing, then, from personal experience, extending only so far north as Sogne Fjord, I should decidedly say there is not much scope for a stand camera placed upon the deck of a steamer. In the first place the Fjords, though exceedingly grand as viewed with the eyes, do not lend themselves well in a general view to picture-making; and, secondly, the deck of a steamer is about the worst place that could be chosen upon which to erect a tripod, unless the camera is pointed directly at right angles to the side of the vessel, which is the most trying position from which to take moving objects; it is almost impossible to get the field of view free from ropes or spars, and, if the deck be at all crowded, one's fellow-passengers vote the sprawling legs a decided nuisance. There are a few 'bits' that may be taken from deck, such as passing vessels, and the little landing-stages with their picturesque groups of natives, &c., but these are far more easily secured with a hand camera, which may be either rested upon, or held right over, the side of the vessel. When, however, there is opportunity of going ashore, by all means take the tripod, and give as long exposure as possible. The special features of the barren hills are entirely lost with snap exposures, whereas time exposures give in beautiful detail the bare limestone rocks and dwarf herbage. Trees in our sense of the word are unknown on the west coast. In August, I found that a Ross R.S., used at *f*-11, gave good drop-shutter exposures, but in Norway, as everywhere else, the only good exposure meter is 'brains.' My best results were with *f*-64, and exposures from three to twenty seconds, according to light, Ilford ordinary. In passing, I may just mention I took two makes of plates; every Ilford exposed gave a good result, my failures were entirely confined to the other make. Some steamers are fitted with dark rooms; but, if there is not this accommodation, a changing bag of some sort is necessary, as for some months there is not any night."

FRAUD BY A "PHOTOGRAPHER."—On Friday, June 30, John Wilson, 48, described as a photographer, and formerly of Ipswich, was charged with having obtained by false pretences 4s., the moneys of the Rev. W. R. Tate, at Walpole; 2s. 6d., the moneys of Harry Sallows, at Halesworth, and Annie Booth, at Huntingfield. Mr. Blofeld appeared for the prosecution, and detailed the facts in the first case. The prisoner drove up with a horse and cart, and boy, to Walpole Vicarage, and told Mr. Tate that he had taken a photograph of the church, and should like to take one of the house. At the same time he handed the Vicar a card, giving an address, 5 Tintern-terrace, St. John's, Ipswich, and stated that all photographs must be paid for when ordered. Witness gave the man 4s., and he went through the form of photographing the house, but no photograph was ever received. Ultimately the prisoner was apprehended by Superintendent Andrews, of Halesworth, at Lynn. The superintendent, who understands photography, searched the house, and found some twenty-six negative plates, but none of them relating to Walpole. He also found a camera and lens, but they were in such a dilapidated state that he was of opinion they were incapable of being used for the taking of a photograph. The inspector afterwards visited Tintern-terrace, and found one table left on the premises, but that was all. There were no signs of photographic processes ever having been carried out there. In his evidence, the superintendent added that he found at prisoner's lodgings at Lynn a cigar box containing some chemicals in boxes, but not sufficient to take one plate. Prisoner, in defence, handed in a photograph of a country seat at Lynn, and said that, if his apparatus were dilapidated, he could not have taken that. The superintendent replied significantly that he saw those photographs on sale at Lynn. Prisoner emphatically declared the photograph was his own production, and handed in another of another kind that he had bought to prove a difference. Charging the jury, the Chairman said the prisoner seemed to think, or would have them believe, they were trying the question whether he could photograph; but that, of course, was not the issue. The real question was, whether he got the money by false pretences, and it appeared from the evidence that he had never supplied a photograph of the house as he had undertaken to do. The jury promptly returned a verdict of guilty. The prisoner mentioned that he had been locked up for three months. Mr. Blofeld did not proceed with the other two cases, but said he held in his hand a document showing that the prisoner had been carrying on the same practices in various parts of the county. The Chairman said he was aware of this, although, of course, he could not tell the jury. Complaints had been made about the prisoner in his (Lord Rendlesham's) neighbourhood. Taking into consideration his detention for three months, the Court now sentenced prisoner to a further term of three months' hard labour.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
July 10	Darlington	Trevelyan Hotel, Darlington.
„ 10	Dundee Amateur	Asso. Studio, Nethergate, Dundee.
„ 10	North Middlesex	Jubilee House, Hornsey-road, N.
„ 10	Richmond	Greyhound Hotel, Richmond.
„ 11	Birmingham Photo. Society	Club Room, Colonnade Hotel.
„ 11	Derby	Smith's Restaurant, Victoria-st.
„ 11	Great Britain	50, Great Russell-st. Bloomsbury.
„ 11	Hackney	206, Mare-street, Hackney.
„ 11	Manchester Amateur	Lecture Hall, Athenæum.
„ 11	Stockton	Mason's Court, High-street.
„ 12	Leicester and Leicestershire	Mayor's Parlour, Old Town Hall.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

JUNE 29,—Annual General Meeting,—Mr. Alexander Mackie in the chair.

Mr. T. E. FRESHWATER read the annual report of the Committee:—

ELEVENTH ANNUAL REPORT OF THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

In submitting this report the Committee have to congratulate the members on the very sound basis on which the Association stands. There is a good balance on the right side, though this balance would have been much greater but for the large sum spent on the binding of so many volumes of the photographic journals; but we have the value, though not the cash, and, if we go on increasing the library to the extent we have lately, we shall soon want another bookcase, so I will ask you to look around and see if you can find another kind friend to give us one. There have been large gatherings of members and visitors. Many valuable discussions have taken place, arising out of lectures given and papers read by members and others well known in the photographic world, amongst others being:—*Intensification*, by Mr. Teape, the discussion on which lasted three evenings; *On a Simple Apparatus for Testing Oxygen*, by Mr. Haddon, assisted by Mr. Grundy; *Photographing Paintings by Artificial Light*, by Mr. W. E. Debenham; *On the Calculation of the Angle of View*, by Mr. Everitt; *Retouching*, by Mr. Redmond Barrett; *Investigations in Spirit Photography*, by Mr. Traill Taylor, which has caused no small stir in the photographic world; *The Sandell Plate*, by Mr. Fry; *Determination of the Speed of Plates*, by Mr. Williams; *The Influence of the Hand Camera*, by Mr. W. D. Welford; *Is the Present Construction of the Photographic Studio Wrong in Principle?* by Mr. W. H. Harrison; *Development of Instantaneous Exposures*, by Mr. Parfitt; *Stereoscopic Photography*, by Mr. Dando; *Photographic Limits*, by Miss Catharine Weed Barnes; *Various Rapidities of Printing Processes*, by Mr. Foulkes Winks; *Flashlight Continuous Lamp*, by Mr. Hudson; *On the Difference in Bulk of Liquid Ammonia*, by Mr. Haddon; *The Hurter & Driffield System of Testing the Speed of Plates*, by Mr. A. Cowan; *The Toning of Chloride Papers*, by Mr. Welford. A course of Technical Lectures have been started, which at some future time it is hoped will be put together in book form. We have had one on *The Lens*, by Mr. Traill Taylor; *On Camera, Tripods, and Dark Slides*, by Mr. Clifton; *On Developers*, by Mr. E. J. Wall; and we hope this next year to get through a good many more.

The Lantern and Musical Evening was attended by nearly 350 members and their friends; in fact, the large room in the hotel was not big enough for the gathering.

The Lantern Evenings have been much appreciated, and when Mr. Hindley showed his Irish slides the room was over-crowded.

The Fortnightly Outings have not been so well attended as they might have been.

The Library has had many additions and valuable gifts of books from the friends of the Association, and they have been very carefully arranged by the Librarian, Mr. F. W. Pask.

The Affiliation scheme seems to be successful. The Association has been ably represented on the Committee of Delegates by Messrs. Everitt and Pask, and much good work has been done.

We have lost one of our most able members through death—that is Mr. William Bedford, and I think the last photographic meeting that he attended was that of this Association.

There have been a good many new members elected during the year and several resignations, and the Committee ask the members to do all they can to increase the number and look around to see who they can bring into the ranks of this Association; also, they ask the members to do a little more in way of getting papers to be read and subjects for discussion, and fifty-two meetings in the year are a great many and entail a large amount of work in this matter.

We cannot close this report without expressing our great regret that our late Secretary, Mr. Drage, has been compelled to leave us. The Association has grown and made great strides during his three years of office, and we can only say that we hope the long holiday that he is about to take will do him much good, and that we shall see him back again safe and well.

The report, together with the balance-sheet, which showed the Association to be in a healthy financial condition, were adopted.

Two or three alterations in the rules were made, and votes of thanks to the various officers for their services during the past year were adopted.

Mr. P. EVERITT proposed, and Mr. W. E. DEBENHAM seconded, a vote of thanks to Mr. R. P. Drage, for his services to the Association as Secretary during the past three years, in recognition of which the same gentlemen proposed a resolution that Mr. Drage be elected an honorary member of the Association. Both resolutions were carried by acclamation.

The election of officers for the ensuing year resulted as follows:—*Committee:* Messrs. G. W. Atkins, Thomas Bedding, J. Weir Brown, C. H. Cooke, P. Everitt, C. H. Oakden, J. S. Teape, W. D. Welford.—*Librarian:* Mr. F. W. Pask.—*Curator:* Mr. A. Haddon.—*Trustees:* Messrs. J. Traill Taylor and J. B. B. Wellington.—*Hon. Secretary and Treasurer:* Mr. T. E. Freshwater.

A vote of thanks to the Chairman concluded the proceedings.

North London Photographic Society.—June 20, Mr. A. E. Smith in the chair.—Mr. Oakley referred to the meeting of the Affiliation Committee on June 6, which he had attended as one of the delegates of the Society, and reported that, stated shortly, the business transacted consisted of a balance-sheet being presented, and two sub-committees, each consisting of two delegates, being appointed and respectively commissioned to tilt with the English railway companies on the subject of reduced fares for photographers, and to consider what the Affiliation rules meant. Mr. Oakley had no doubt that the affiliated 5000 awaited the reports of these sub-committees in nervous expectancy. Mr. Walker showed prints on gelatine paper, the toning results being unsatisfactory. Mr. Bishop advised the use with this paper of the combined toning and fixing bath, made according to the formula recommended for Solio paper. Mr Williams advised workers to make the chloride of gold they used, and, preferably to others, from Australian gold coins, as these contained no copper alloy. Mr. Morgan then gave a lecture and demonstration on the *Amidol, Metol, and Glycin-Hauff Developers*. He stated that amidol was essentially a developer for all-round work, whether for negatives, lantern plates, or bromide paper. He especially urged the formula in which the dry crystals were added to the solution of sodium sulphite immediately before use, and, in cases of over-exposure, adding water and bromide according to requirements—the last-mentioned even to the extent of three grains to the ounce of developer. He averred that a good printing negative could be made with amidol as a developer which had received only one-third of the exposure necessary to produce one when pyro was used. Metol was a developer to be used in two solutions, one being the free alkali. It was not so powerful as amidol, and any amount of tentative work could be done with it. For bromide prints it bid fair to supersede the ferrous-oxalate developer altogether. He had been experimenting at the works of a large photographic company that day, and, as a result, it was admitted that metol developed a print equally well with half the exposure required when ferrous oxalate was used as the developer. The lecturer did not enlarge much on glycin, it being a more recent introduction; but, from what he intimated, the audience concluded it would be a kind of automatic developer, such as the button-pressing fraternity would gladly hail if they ever dared on development. You only had to put the exposed film in the solution and take it out when it was reduced to a perfect negative.

Northern Photographic and Scientific Association.—On Saturday, July 1, through the kindness of Mr. George Murray, F.R.S.E., F.L.S., a visit was paid to the Natural History Museum at South Kensington, and a most enjoyable afternoon was spent. It has been arranged to have an excursion every Saturday afternoon throughout the summer. Next Saturday, July 8, there will be an outing to White Webbs Park and Enfield. Train leaves Broad-street at five minutes to three; Finsbury Park, twelve minutes past three; Harringay.

(G.N.R.), fifteen minutes past three; Hornsey, seventeen minutes past three; Wood Green, twenty minutes past three; and Bowes Park, twenty-two minutes past three.

East London Photographic Society.—June 27.—A question from the question box was read: "Wanted, a good formula for a borax bath. The Chairman recommended one ounce of borax to eighty ounces of water for stock, for use, take one ounce of stock and one grain of gold. Mr. E. M. Minns then read his paper upon *Subjects, and how to Find Them.* During the course of this most interesting paper, the lecturer strongly advocated the use of a view meter, and showed one of his own construction; he also advised the use of blue spectacles, so as to do away with the colouring effects in the view, and only to perceive the relative values of the high lights and shades; he further said that the "subject" was only a secondary consideration, the manner in which it was portrayed was everything.

Leytonstone Camera Club.—June 28, Second Annual General Meeting, the President (Dr. W. Pickett Turner, E.C.C.) in the chair.—Mr. Albert E. Bailey, Hon. Secretary, read the report for the past year, which was highly satisfactory, accounting for weekly meetings during the winter, and weekly outings during the summer; a brief *résumé* of the lectures, demonstrations, and public entertainments showed a very varied and interesting programme had been gone through, special reference being made to the great success attending the first annual exhibition, which had resulted in the satisfactory balance of 24*l.* being added to the revenue of the Club. The balance-sheet of the Club for the past year was next presented and adopted, showing an increase of receipts over expenditure of 38*l.* 2*s.* 10*d.* The election of Officers resulted as follows:—*President:* Dr. W. Pickett Turner.—*Vice-Presidents:* Messrs. E. Widdrington Byrne, Q.C., M.P.; W. B. Whittingham, J.P.; A. Horsley Hinton; D. J. Morgan; J. F. Sanderson.—*Council:* Messrs. G. H. Cricks, A. T. Cufley, H. E. Farmer, A. Frost, G. H. Hart, A. J. Newton, D. G. Riddick, F. W. Wates, A. P. Wire.—*Hon. Treasurer:* Mr. Tom Symmons.—*Hon. Secretary:* Mr. Albert E. Bailey.—*Assistant Hon. Secretary and Curator:* Mr. Montague Atkinson. The Hon. Secretary announced the number of members as 136, that the subscription for the new year would remain the same, 5*s.*, and that before the next winter season the Club hoped to be in their new hall and studio. The definite date for the 1893 exhibition had been fixed for November 20 to 25 inclusive. A vote of thanks was passed to the Chairman. The Hon. Secretary wishes particularly to call the attention of both amateur and professional photographers in the vast Epping Forest district in which they work to the many advantages of this Club, offering, as it does, throughout the year an almost weekly entertainment and use of dark room, and shortly a studio, for the annual sum of 5*s.* On the completion of the new premises, it is proposed to introduce an entrance fee, so there is no time like the present to join. The headquarters, the Assembly Rooms, are about three minutes' walk from Leytonstone Station, G.E.R., and the Hon. Secretary's address, Rose Bank, South West-road, Leytonstone.

Liverpool Amateur Photographic Association.—June 29, Mr. Paul Lange in the Chair.—Three new members were elected. Excursions to the following places were announced: Burton (Cheshire), for beginners, Saturday, July 8; leader, Mr. J. T. Norman-Thomas. Puddington, Saturday, July 22; leader, Mr. F. Anyon. Mr. W. T. Wilkinson gave a lecture and demonstration on photogravure. After describing the class of negative required for photogravures, a carbon positive was developed, then a ground was laid with resin on copper plate, and a carbon negative developed upon dusted copper plate, the image being afterwards etched in relief. After replying to a few questions of technical interest, the spectrum was projected from the lime-light through a prism, and various colour screens interposed to show the orthochromatic value of various aniline dyes, and also demonstrating the value of different screens, both for orthochromatic work and providing a safe light for the dark room.

FORTHCOMING EXHIBITIONS.
