THE DOUBLE ANASTIGMAT OF C. P. GOERZ.

To the Editor.

Sir,—In The British Journal of Photography of June 23, page 396, Dr. P. Rudolph, of Jena, makes an attempt to submit to an unfavourable criticism the comparison prints published by Mr. C. P. Goerz. At the outset of his critique, hints are thrown out as to the validity of the patent, with the evident intention of favouring misconceptions by suppressing the true facts of the case.

The type of construction which forms the basis of the double anastigmat had already been made the subject of an application for patent in England on December 19, 1892, a fact which was well know to Dr. Rudolph. The latter had made experiments in March, 1892, with the object of obtaining landscape lenses of good illuminating power, and claims to have, in the course of these experiments, arrived at the form of the separate lenses on which the double anastigmat is based. These trials have, however, not led to satisfactory results. Dr. Rudolph has not only admitted this fact in private conversation, but has also stated it in public. In his lecture, given on March 18, 1892, before the Freie Photographische Vereinigung in Berlin, on the subject of the Zeisa anastigmats, the elements of which he had calculated, he has made the following *verbatim* statement:—"The doublet type invented by me, is doubtless the only one by means of which anastigmatic flatness of field can be obtained without injury to the other properties expected from a good photographic objective." (See *Photographisches Wochenblatt*, Berlin, 1892, page 153, *a. f.*)

If, therefore, Dr. Rudolph in his letter says that already in 1892—the time of his lecture—experimental objectives of the type of the double anastigmat had been made, I can only understand from that statement that such trials have produced negative results.

I find my assumption confirmed in the work, *Theory of Optical Instruments after Abbe*, by Dr. S. Czapski, scientific co-operator at the optical works of Carl Zeiss. Breslau, 1893. Dr. Czapski writes in this work, after commenting upon the most important types of construction of photographic objectives, page 205, the following:—"At length endeavours have been made, after abandoning restriction to two single component parts, to obtain improved effects by a combination of three lenses, single or cemented. These attempts, made in various quarters, have, however, not yet been rewarded with undoubted success."

In his specification for the British patent, dated March 3, 1893, Dr. Rudolph certainly says: "The practical question as to whether in a combination of the above description it is possible to obtain a sufficient anastigmatic correction, and at the same time to comply with the other conditions required in photographic objectives, has been answered in the affirmative by theoretical and practical investigation of both types of the new triple lens." But nothing is mentioned about the time when this affirmation took place, and only a sufficient astigmatic correction is spoken of—a rather elastic term.

By calculating the elements of construction given by Dr. Rudolph in his specification for patent, I have been able to ascertain that both the detailed constructions show inaufficient astigmatic and spherical correction.

I have only closed my investigations, which have led to the construction of the double anastigmat, at the end of last year, after years of preliminary labour, which, as far as I can show, takes me back to the middle of 1889, and after correction of astigmatism of the radial lines and of spherical aberration, I have found not only that there exist kinds of glass which induce achromatism, but also that these kinds of glass possess the property of reducing the secondary spectrum, and further, that astigmatism is not only eliminated from the radial lines which come first into consideration, but from the whole surface of the image, and

finally that up to an angle of seventy-two degrees absolute flatness of field has been obtained.

Not until I had safely recognised all these advantages did I feel myself at liberty to declare that I stood before an important invention, of which I do not intend to allow my priority to be removed by the incomplete labours of others.

Lastly, I feel it my duty to make the following statement:—

When we entered the double anastigmat at the Patent Office, neither I nor Mr. Goerz had the slightest notion of similar labours in this direction on the part of Dr. Rudolph. We did not gain cognisance of this fact until we paid a visit to Jena at the end of December last. On that occasion we were informed that it had then been resolved to apply for a patent on the basis of Dr. Rudolph's investigations.

The circumstance, therefore, that Dr. Rudolph, nevertheless, postponed his application until March 3 last, requires further explanation.

I did not think myself justified to omit this remark, and the less so because the communication on the part of Dr. Rudolph opens the widest field to misconceptions.

As regards the critique on the comparison prints published by Mr. C. P. Goerz, I will now show that Dr. Rudolph, though laying claim to the construction of the double anastigmat, has not even conceived the important advantages of the same.

Dr. Rudolph asserts that the antiplanat and euryscope had not had a fair chance on account of the free aperture of *f*-6. What on earth has free aperture to do with astigmatism? That with objectives possessed of unavoidable astigmatism the effect of the latter can be diminished by a judicious arrangement of aperture and distance of lenses, whereby through timely vignetting a large portion of disturbing rays is cut off, was undoubtedly known to the constructor of the lynkeioscope; he well knew how to successfully utilise this experience, and attained thereby that his aplanat, by employing larger stops, gives much better results than other objectives of a similar kind with the same size diaphragm. And that this is so the photographic prints are intended to show—nothing else.

While, on the one hand, according to Dr. Rudolph, the antiplanat and euryscope are at a disadvantge by reason of their free apertures being too large, the anastigmat of *f*-7·2 on the other hand is at a disadvantage on account of not being corrected for a larger aperture.

There could be, surely, nothing more natural than to select from the price lists of the various makers objectives intended for the same purpose, and which in aperture and focal length approach as nearly as possible the double anastigmat; and of the Zeiss anastigmats No. 3 of series III. is that which in the just mentioned conditions almost completely harmonises with the double anastigmat, while Series II. of the Zeiss anastigmats does not include a suitable focal length.

Now, Dr. Rudolph asserts that no disadvantages would have resulted to the Zeiss anastigmat against the double anastigmat, if instead of a Zeiss anastigmat of *f*-7·2 one of *f*-6·3 had been drawn into competition. But instead of supplementing the published comparison prints by a corresponding photograph taken with a Zeiss anastigmat of *f*-6·3, which would at once have decided the correctness of his assertion, if founded, Dr. Rudolph produces in evidence of his statement certain prints which have been obtained under chosen conditions of disadvantage to the double anastigmat.

Even though stopping down to *f*-15·5 cannot be admitted as a measure for the examinations of syatems of strong illuminating power, the result in favour of the Zeiss anastigmat is still further removed by the circumstance that Dr. Rudolph approaches the object to the short distance of 1·2 meter with an objective lens corrected to an infinite distance. Of what worth such manipulations are I leave to the judgment of any unprejudiced person.

I am prepared to repeat the photographic exposures as represented by the prints with a Zeiss anastigmat of Series II., under the assistance of Dr. Rudolph or his representative, and declare emphatically that such exposure can only lead to further confirm the superiority of the double anastigmat.

The reproach that the two first objectives of the photographs have a shorter focus than the three others may have some justification, but as only specimens of this focal length are in commerce, nothing remained for Mr. Goerz than to use them. Moreover, any one with a technical knowledge can easily appraise and take into account the amount of the defect which may arise from the slight difference of the focal lengths, from the data given with each of the prints.

From the unequal definition of the two sides of the photographs, Dr. Rudolph infers that not the centre, but one of the sides, of the plate had been focussed. This assumption is erroneous. The unequal sharpness has much more its cause in the fact that the iron rails by which the Stegmann apparatus for reproduction used for the production of the originals was guided, though accurately directed upon the centre of the trial plates, were placed, as I could ascertain after closer scrutiny, not completely vertical to the plate. This circumstance, which affected uniformly all the exposures, cannot, however, in any way be considered a fault which might induce erroneous conclusions. On the contrary, it is particularly well adapted to demonstrate the difference in the lateral want of definition with objectives more or less corrected for astigmatism.

Finally, Dr. Rudolph objects to the omission of the author's name on the prints.

In producing the originals for the photographs, we have been assisted in a most amiable manner by Professor Dr. Gustave Tritsch, privy medical counsellor in Berlin, for which assistance we acknowledge ourselves to be greatly indebted to him. Professor Dr. Tritsch, to whom the prominent qualities of the double anastigmat at once became evident, exhibited such lively interest in this new objective, that he has sacrificed several days in testing them, and was not only present at the production of the originals, but also at most of the extremely painstaking, and sometimes tedious, preliminary labours.

The placing of the plates was separately executed by all persons present, in order to render ourselves as much as possible independent of personal errors, and exposure was not made until the placing by all agreed.

Present were: 1, Privy Medical Counsellor Professor Dr. G. Titsch; 2, Mr. Paul Goerz; 3, the undersigned; 4, Mr. Riffarth; 5, the operator of the Institute for Reproduction of Messrs. Meissenbach, Riffarth, & Co., who developed the plates.

With each of the objectives taken for trial at least two exposures were made, and the best only used for the prints.

If Mr. Goerz has omitted to attach to the prints the name of Professor Dr. Tritsch as author—this Dr. Rudolph no doubt has meant—it was done chiefly for this reason, that such a notification could only produce the impression of an advertisement, which in my opinion our double anastigmats are not in need of.

With a subject of such importance it cannot fail that, very soon, scientific authorities who have no interest in either side will comment fully upon the questions which here come into consideration. I can only welcome this in the interest of my good cause.

Asking you, Sir, to kindly admit the contents of this letter to your esteemed JOURNAL,—I am, yours, &c., EMIL VON HÖEGH.

Berlin.

THE CONCENTRIC LENS.

To the EDITOR.

SIR,—I had not intended troubling you further in this matter until some reliable independent testimony was obtained, but I am unwilling to let Mr. Stillman's letter of June 8 remain so long unanswered in face of the unfair charge he makes against me in his postscript.

Mr. Stillman is no ordinary controversialist. I was provoked, in the first instance, to lodge an emphatic protest against a statement that seemed to me inaccurate and misleading, twice repeated—a claim for the lens that is repudiated by the makers and has no foundation in fact. That so insignificant individual as myself should presume to question Mr. Stillman's accuracy, and suggest that his facts are fancies, seems to have roused his indignation, but we Yorkshire folks are a plain, practical lot, and have a habit of sticking to a point until proved right or wrong. No amount of indignation will crush us, and if we get into a dispute we accept the responsibility.

Just note how Mr. Stillman has performed the operation known as "climbing down." At first he contended that the concentric defined as sharply at *f*-16 as at *f*-64 over a plate as large as the focal length of lens. Then he changed to "any given object," and now he has watered that down to "such definition as meets his requirements." Had he said this at first, this controversy would not have arisen.

Then Mr. Stillman's style of argument—a long letter, not to me, but certainly at me, in which he commiserates other users of the lens for not achieving the impossible because we have not a nice delicacy of touch, or our cameras are not sufficiently well made, while Mr. Stillman proves his superiority by admittedly sending you a partially developed negative taken in a camera with a cracked front. Our cameras must be very bad.

Mr. Stillman's own interpretation of my protest was, that if I was right his contention was "brag, or worse." Now, he says I may take any course I like to prove my case, as "it does not concern him in the least." This is the same gentleman who contended that the instructions sent out by Messrs. Ross with the concentric were "illogical" because they did not support his views. Mr. Stillman is an excellent judge of what is illogical.

In conclusion, I regret I am unable to accept any advice from Mr. Stillman in the matter of courtesy. My letters have been very much on the same lines as his, and if I have sinned in this respect he is not entitled to reproach me. I take it as a little ruse to cover his retreat. I will send a concentric to Kew, and submit the report to you in due course. Whether for or against, we will have proof, which will be the one grain of wheat in this mountain of chaff.

Thanking you in anticipation,—I am, yours, &c., F. H. BURTON.

Roundhay, near Leeds, June 27, 1893.

IMPROVEMENTS IN PHOTOGRAPHIC LENSES OR OBJECTIVES.

To the EDITOR.

SIR,—*Apropos* of new lenses that are now being issued, permit me to say that in Patent No. 1261, of 1889, it was not my intention to place upon the market a new lens of such formation and advantages as that existent objectives, single or double, rapid rectilinear or wide-angle, should thereby become obsolete, but, on the contrary, by the use with

them of my patented combinations of greater public utility, that this end should be attained by simple, yet *correct*, means, and, at the same time, that a great saving to the photographic artist should be effected. That these desired results have been, and can be, obtained by the series of combinations specified in my patent cannot truthfully be denied. They are partially placed on the market in the French goods of F. Darlot & Co., and brilliant results are secured when, in workshops of British experts, the lenses are carefully centred and ground or selected exact to specification. That such combinations are absolutely corrected is proved by the fact that in the proportions specified no alteration can be made without detriment to their symmetrical definition, either in the centre or in the outer edge.

Owing to the facilities afforded by such a formation for obtaining a deep globular field (with the smaller stops in use), or, reversed, a flatter field (with the larger stops in use); or for obtaining an exceptionally deep, long narrow field, such as the cabin of a steamer or a long corridor (when, in such case, they can be placed one in front of the other in the space between the plane of the diaphragm and the front collecting objective of a half-plate rapid rectilinear doublet, or of an Optimus 10 × 8 rectilinear, wide angle, or other doublet); or, again, a narrow angle for obtaining a view of a distant subject (when, in such case, they may be placed at point, so called, of principal focus, outside and at rear of any photographic doublet, or single ordinary achromatic lens, and whereby, also, "instanto" effects may be obtained); the combinations, by preference, consist of four parts or pieces, two positive and two negative lenses, after a manner described in my specification, and divided into two separate cells, which whole combinations can, as aforesaid, "be applied *in* or *with* any photographic achromatic lens; astigmatism being corrected for, it follows that a correct media being added to any correct media the whole is correct, whilst a symmetrical and "the most accurate resemblance between the object and the image is secured," as shown in copies of finest engravings.

Consequently, as before written, it was no point of mine to interfere with the construction of an outer front collecting, or, in doublets, rear dispersing objective on lines as made previous to date of my patent, but to provide combinations to become, as it were, handmaids to render them increasingly effective and useful. Such being my case, it becomes my duty to, on the foregoing and on other grounds hereinafter stated, again present the claims of my Patent, No. 1261, of January 21, 1889, befor the public photographic world.

I. It would be superfluous to correct that which is correct, and these absolutely correct media are found specified in the first series mentioned in Patent No. 1261; they form the key to guide the construction of equivalents, as mentioned in following series, which were purposely inserted by me to prevent infringements. British opticians do not, of necessity, require the aid of other experts to calculate in two or three part the equivalents of the said series of four parts (as, for convenience, placed in plane of diaphragm front and rear of a doublet, with an air space between such, as is afforded by the stop-slot, width of angle being attained and retained, together with increased or decreased size of object, at will of the operator). To many the various series quoted in my patent seemed to be superfluous; but, upon examination with the first key-guide series, they will be found, I am well assured, to cover all needful ground.

Some months back a Resident Barrister mentioned to me that, in experimenting with an ordinary achromatic lens, instead of a stop, he placed behind it a piece of tinfoil, and, no matter in what part of that piece of tinfoil he pricked a minute pin-point hole, he found a perfect picture delineated on the screen or ground glass behind. This, in the minds of most people, will argue ill for the correctness of calculations dogmatically describing the formation of *two* partial focal points, formed by rays passing through "the meridional and sagittal sections respectively (why so called, one ray shoots as much like an arrow as does another wherever it gets through?). It follows, then, that that form of lens, or combination of lenses, which in practical work gives the best all-round results, will commend itself for use.

II. Correction for "astigmatism" will, in the rapid rectilinear doublet, be found to be a correction for "residual error," lying between the points A (at top-slot) called "principal focus," and *other* points between it and the points B (at rear-objective), called "conjugate foci;" this, in a very complete measure, is got rid of by insertion of my combinations at A, making these combinations principal to the front collecting objective, and transmittents to the rays passing through it; and B, the rear objective, become principal to the combinations at A, whereby "residual error" is so removed. This will be found to be the case with any rapid rectilinear doublet by a conscientious maker of repute; and is proved, by the interior (15 × 12) of the Crystal Palace, taken by Negretti & Zambra with my whole-plate, eleven and three-quarter inch focus, rapid rectilinear doublet (Fallowfield), the focus being increased by my combinations to fourteen and a quarter inches equivalent focus, stop of a quarter inch orifice. Lines—of the multiplicity of iron pillars of the vast building—rectilinear; and girders sharp to outer edge of circle of the image, received through the front collecting objective, and whereby great width of angle is obtained, to manifest advantage.

III. By placing the combination of four parts, contained in the two separate cells, in the plane of the diaphragm, they act either as a collecting or dispersing lens to the front or rear lens of a photographic doublet. Used singly with them, as may be desired by the operator, rectilinear lines being in marked measure still secured, and with a comparatively small stop, objects from twenty feet to over three miles are delineated in good definition or focus. Again, the "compensating" part of my combination in cell by itself may be allowed to remain in its position in the plane of the diaphragm, and the other portion, in a cell by itself, be placed at the point previously occupied by the front or rear lens (of the doublet), which had been unscrewed and removed for that purpose, and the correction for "residual error," mentioned above in Section II., becomes distinctly marked and observable. Therefore it appears clear that the position at point called principal focus, in which the combinations are placed in their connexion with "an ordinary achromatic lens," has to be considered rather than a fixed system of calculations as to "radii of curvature of the surfaces of the lenses," and "central thickness of the lenses." As, again, as a general rule, the radii of curvature of combinations must perforce have that relation to the radii of curvature of the "ordinary achromatic lens," or lenses, in conjunction with which they may be used—as have the various inner skins of an ordinary Spanish onion in varying "radii of curvature" to meet the requirements of the radii of curvature of each outer skin to which it is adapted, be that onion of what size or shape it may. But the shape of the human eye might, under the same conditions, be followed to advantage, and Professor George Butler Bradshaw (Gold Medallist in Science) informs me that the eye of the sparrow sees the hawk before the hawk's eye discerns the sparrow. The variation of radii of curvature of positive and negative meniscus lenses of from three and a half inches to seventy-two inches focus has been offered to be done for me by a London maker of such lenses, whilst it will scarcely be disputed that *no* optician would rightly be considered as an "expert" who was not *au fait* as to the methodical fulfilment of such requirements with the "ordinary achromatic lens," or lenses of any diameter with which he purposed to use combinations of lenses.

IV. The question, then, of correction for the astigmatic aberration of simple ordinary single meniscus lenses may be tested by taking any pair of positive meniscus lenses of, say, sixteen inches focus, either of which, viewed through by a person of normal sight, will "neutralise" a negative ordinary single meniscus lens of same focus, in such a manner as that a series of parallel lines, a quarter of an inch apart, will be found of exactly the same distance apart whether seen through the two neutralising lenses or on either side of them. Similarly, this pair of positives of sixteen inches focus—placed one on either side of a negative meniscus lens of eight inches focus, and found to neutralise it in such measure as that the same series of parallel lines will also still appear equidistant, whether viewed through the three neutralising lenses, or on either side of them (at points of impact and epact, so to speak, respectively); then either one of those two positive lenses may be used with that eight-inch negative as its corrector for astigmatism, subject to (after a similar process of testing) a positive ordinary single meniscus lens of forty inches focus, placed with a negative meniscus corrector lens of eighty inches focus, being together used with the previous mentioned pair as a compensator. These four parts, inserted in two separate cells (or cemented together or in pairs), as described in Patent No. 1261; the curvatures regulated as mentioned in Sec. III. herein; used in or with an ordinary achromatic lens or doublet, "with a single or divided objective tube," and placed at the point called principal focus, which may be either in the plane of the diaphragm, or in front, or at rear of either a single ordinary achromatic lens, or rapid rectilinear, or wide-angle doublet. It will be found that no one of these four parts can be replaced by any other lens of a different focus, even a slight variation showing a tendency to introduce spherical or other aberration. It will also be found that the positive may be separated from the negative at certain varying distances, if what are called "tele-photo" results are required with a short-focus camera.

To borrow, then, a simile from Lord Salisbury's speech at Derry:—Should "Infringerites" attempt to introduce into the British land of Canaan improvements in lenses which are already effected under a British patent of January, 1889—now that these plain facts in connexion with the patent (No. 1261) are again pressed upon British opticians and the scientific world, specifying a *mathematically exact* principle of construction and correction, I hold that a syndicate of experts behind Patent No. 1261, as a rampart, would be unassailable before any court. Be this as it may, my desires have never extended beyond requiring absolutely customary British "fair play."—I am, yours, &c., HUGH BLACKWOOD.

Beckenham, Kent, June 20, 1893.

"A FEW MORE WORDS."

To the EDITOR.

SIR,—That considerable opposition will be evinced towards the scheme as mooted in "Darkest Photography" on the score of "Free Trade," *cela va sans dire*. But where, it may be remarked, has free trade landed us? As pointed out in the previous article on this subject, it has caused a tremendous influx into the ranks of the profession without a corresponding degree of excellence. You are asked now to protect yourselves against this great incursion, which has exercised such damaging effects on your prosperity. The remedy, as suggested, is, to a great extent, in

your own hands. Be united! Act with a greater spirit of unanimity! Show to your fellow-men that this great art-science of photography, of which you are, or ought to be, so justly proud, and which you, as the professional exponents of, have brought its varied works to such a high state of perfection, shall no longer be invaded by a mob, sometimes composed of only the merest tyros, and henceforth only tested and proved men shall remain in, or find a welcome, in your ranks.

With regard to the licensing of photographers, there is one very great point to be urged in its favour, and that is, What body possesses such powerful influence within itself for its own trade's benefit as that of the "Licensed Victuallers?" and why should not such a happy state of affairs exist for the "Licensed Photographer?"

Another point is almost entirely overlooked in connexion with photography, and that is, the vast army of persons who are employed, either directly or indirectly, in the various manufactures and kindred trades required for the production of only a dozen cabinet photographs. This is again a matter for serious thought and reflection in connexion with the political economy of this vast kingdom. As the Government of the country has, by the introduction of photography some fifty years ago, been relieved of a terrible incubus in providing, or finding the means of support for the many thousands which our art-science has found good and remunerative employment, possibly no industry has ever cropped up so quickly, or made such rapid strides within so short a period, and therefore it behoves us to do all that lays in our power to protect this gigantic industry, and not let its vitality be choked, as seems probable it will, unless some decisive steps are speedily taken whereby to remedy the present state of affairs.

It is therefore suggested that a quick and easy means of obtaining the voice of the profession on the proposed scheme is this: All photographers to be invited to send a post-card, with their names and addresses thereon, and just these words, "*In favour*," to THE EDITOR, at the office of THE BRITISH JOURNAL OF PHOTOGRAPHY, 2, York-street, Covent Garden, London, W.C., and these post-cards would go far to simplify matters, and assist in initiating the necessary proceedings, so as to push forward the project of "Registered and Licensed Photographers."—I am, yours, &c.,

June 30, 1893. PIONEER.

AMATEURS AND PROFESSIONALS.

To the EDITOR.

SIR,—I beg to express my thanks for permitting me in your issue of June 30, to defend the occupation of shop-keeping from the imputation of degradation made against it by one of your contributors. I would further like to make a few remarks on the vexed question of amateurs and professionals.

One of your correspondents suggests that amateurs would be wiped out if they had to pay a tax of ten or twelve guineas a year; undoubtedly they would. Seeing, therefore, the remedy is admittedly potent, why is it not applied?

Well, in the first place, photography was not invented for the purpose of giving a body of professionals a monopoly of the art, and one man has as much right to practise it as an amusement as another has to practise it as a business. Can your correspondents be so childish as to suppose that Parliament will pass such an absurd law—they are surely joking?

Only a short time ago a Lancashire County Council or Local Board proposed to the Chancellor of the Exchequer that cyclists should be taxed five shillings per year. The proposal was not entertained for a moment.

Undoubtedly there is much to be said on the professional side. The amateur does, to a small extent, affect the trade, but the remedy is not Acts of Parliament.

The only way in which amateurs can unfairly compete with professionals is in the line of underselling them, or in giving photos away free. We must appeal to the good feeling of amateurs not to act so thoughtlessly.

If they must take photos for money let them charge the proper price, and if they can afford to do them without receiving pay let them carry round a subscription card for some hospital or charitable institution.

Then, when a person wants a portrait doing, do it on condition that a subscription for its value be given to the charity. Of course there will be exceptions to this rule; there are times when it would be correct and proper to make presents of photos to our friends, such as views, and special subjects of a like nature.

But let no amateur practise the indiscriminate free giving of photos. It will only tend to make them common and unappreciated, and when a charge is made let it be the usual professional charge for the same class of work, whether the amateur keeps it himself or devotes it to charity.

Then, in my opinion, professionals will have no need to complain of the amateur, and the problem will be solved. They have just cause to complain of the amateur who undersells them or gives away his work for nothing without discrimination.

Could an association be formed of amateur photographers binding each member to those terms, it would help to bring about the result so much desired.—I am, yours, &c., WILLIAM JAMES FARMER.

68, *Blackburn-street, London-road, Blackburn, July* 1, 1893.

To the EDITOR.

SIR,—I am sorry to see so many foolish utterances in the JOURNAL on this question.

It is as evidently impossible to restrain amateurs from the use of the camera, or from selling their productions if they find buyers, that it is the veriest waste of time and material to print the absurdities which have lately been written on these matters.

As well might the professional bakers seek to restrain home-made bread, dressmakers to prevent unlicensed infringement of their sphere, authors to tax the unprofessional essayist, and so on with every trade in the country! Is it not true that most trades are at present depressed, and people of all mercantile pursuits complaining?

There are causes for the depression in photography which are very plain to be seen do we but look for them.

"To him that hath more shall be given." Yes, if he does good work, and spends largely in advertising.

Nay, sometimes it is bad work that pays best; the flattering retouching, the untruthful effect of unnatural lighting, possible only in a studio furnished at great cost with an elaborate system of blinds and reflectors; these, and the magnificent "get-up" of the studio of the monied man, take a large slice from the general run of photographers.

A little lower in the scale commences the system of price cutting, of taking small orders and making up for it in number of sitters, overworking and underpaying assistants, running a number of branch studios for the profit which should be obtainable from one.

Panic fear of each other is a large factor in the present crisis. If it happens that the next stand, however unpromising, is working at lower prices than, say, mine, down must go my prices, however inferior his work.

Grabbing at one another's business, competing for estimates where the lowest tender is always accepted, and other things not so patent to the public, all combine to make our position what it is. We are largely paying the penalty for our own sins, and it is purblind folly to lay the blame on the amateur.

A certain man took transfers for 3*s.* 6*d.* minimum. Being one day asked for a block, he took the transfer, paid 2*s.* 6*d.* for etching, and furnished the block for 3*s.* 6*d.* Why? Because he heard that somebody in that trade was doing them for so much. (I generally publish my name, but wish not to do so in the present instance.)

Some of the very best work I have ever seen has been done by amateurs, and some of the most valuable discoveries of photography have been made by amateurs. To deny it is to plead ignorance of the history of photography.

But what is the cause of these causes? How comes it that we find ourselves in the toils of advertising monopolies, price-cutting, falsifying, labour-sweating, seven-day working, neighbour besting, toiling for nothing? The answer is to be found, but it has nothing to do with photography; therefore, unless at special request, and by special licence of the Editor, I shall not divulge it. Indeed, to many correspondents on the subject, it would, I fear, be unintelligible.—I am, yours, &c.,

June 29, 1893. INDIVIDUAL.

To the EDITOR.

SIR,—No one can fail to sympathise with the unfortunate professional photographers who, while suffering through the laws of political economy, lay all or most of the blame on the amateurs.

The recent suggestion that the latter class should pay a heavy licence for the privilege of carrying a camera points out the most practical way of dealing with the matter.

There may, however, be a good deal of conservatism to overcome before such a tax could be imposed, and as the ranks of our legislators include a number of amateur photographers it is to be feared that a certain amount of class prejudice will oppose the scheme.

The suppression of the amateur will, doubtless, seriously damage the manufacturers of plates, cameras, &c. The latter will find it to their interest to pay the tax for the amateurs so as not to lose such good customers.

If this happens the National Association of Professional Photographers will, of course, have to buy off the opposition of the manufacturers. The financial results may prove complicated.

The principle of taxing those who amuse themselves with any occupation outside their own trade or business is too good to be applied only to photographers. As soon as the public have been educated up to it, we shall of course tax amateur carpenters, gardeners, soldiers, *et hoc genus omne*. They all interfere with those engaged in the corresponding trades.

The Chancellor of the Exchequer would be only too delighted, and many vexatious duties (including perhaps the income tax) could then be taken off.

I would only suggest that the snap-shottist be exempted from the proposed licence. Such a large proportion of his shots are failures that he greatly benefits plate-makers, without doing any appreciable harm to the professional photographer.—I am, yours, &c., ECONOMIST.

July 1, 1893.

LEYTONSTONE CAMERA CLUB, SECOND ANNUAL EXHIBITION

To the EDITOR.

SIR,—Owing to the great success and overcrowding attending our First Annual Exhibition held on last November 10, 11, and 12, the Council of this Club have decided to extend the time this year to a week. The date is also fixed, and it will be held at the Masonic Hall, High-road, Leytonstone, opening on Monday November, 20, and closing on Saturday, November 25. Further particulars will be duly announced, and it is earnestly hoped that our numerous photographic friends who supported us so well last year will do so again this year, when we hope to eclipse our previous efforts.—Yours faithfully, ALBERT E. BAILEY,

Rose Bank, South West-road, Leytonstone. *Hon Sec.*

"MUSIC HATH CHARMS."

To the EDITOR.

SIR,—My attention was lately attracted by an advertisement which appeared in a popular photographic journal demanding the services of a "musical retoucher," the particular quality of voice required being soprano. This appears a novelty in the way of orders, but one which, I am sure, will be readily filled. In the mean time "wonderment guesses" why is such a combination desired, and to what more or less useful purpose will it be applied when found? Perhaps the best way to satisfy my curiosity would be to wait until a retoucher with a tenor voice is applied for, when, perhaps, it will be my good fortune to be selected to take part in a "retoucher's madrigal" or a "stripper's roundelay." Whether or not such happiness will ever be mine, this idea of combining two hitherto widely separated vocations seems a happy one, and is rich in suggestions. Attending, first, to such as are quite utilitarian, and therefore business-like, one might suppose that the system of having a retouching department conducted on harmonic principles would answer very well. I know by experience that singing is a great relief to the nervous tension caused by prolonged application to such tedious and monotonous work as retouching. I knew a surgeon who had a habit of whistling softly the air of some old ditty—a cross between a jig and a country dance—when performing the most skilful and perilous operations; doubtless he did so in order to keep himself cool and his hand steady. Many employers think that you cannot do two things at once, and discountenance talking and singing whilst at work. Talking may be bad, as it is apt to become controversial and take up too much attention; but there is not the same objection to singing, as long as it is not of that class which requires the accompaniment of gestures and poses, or too many "runs" and "shakes." Singing acts beneficially on the circulation, remedying in some measure the ill effects of sitting; moreover, the energies receive that stimulus which the work cannot give, activity is sustained, one is prevented from falling asleep, or quarrelling with his neighbour, unless it be over a question of "tempo" or "pitch," the work receives less begrudging attention, and the result is—progress.

Shakespeare says, "The man who has not music in his soul is fit for treasons, stratagems, and spoils." He does not particularly allude to retouching, unless in the last part of the sentence he refers to spoilt negatives.

In connexion with this notion of employing stippling songsters, or singing stipplers, many amusing thoughts present themselves. One can picture the spectacle of an energetic foreman wielding the bâton, which might in this case consist of a retouching pencil, and seeing that the bows—I mean the other pencils—keep time with the music. He prefers pieces that have an "allegretto" movement, deprecates anything like "adagio," but has a partiality for "accelerando al presto."

A "photographic establishment choral society" might do double duty, so many birds might hit two objects with one stone—by being placed in proximity to the studio their harmonious breathings would serve to evoke that lively and amiable expression of countenance in the sitters which it is the aim and endeavour of all good operators to obtain. Experience would soon show whether the best singers turned out the most artistic retouching, which we might expect them to do by dint of their mental faculties being elevated and quickened to a perception of the beautiful, whether it be found in the graduated tones of a negative or in a modulated scale. Certain it is that amateur vocalists are so fond of exercising their voices and their talents that many would be found anxious to acquire the art of retouching in order to gain admission to such musical salons as the retouching-rooms of the future promise to become.

Finally, we can imagine the fashion extending to other departments, until at last it becomes a *sine-quâ-non* in an operator that he be also operatic, and it may even lead to a solution of our present "Depression in photography" problem, for if once the public takes to the new photo-musical fad it will only patronise those establishments which are ready to add to the allurements presented by a system of rendering the harshest and plainest of features soft and agreeable, the further attraction of being dissolved into ecstasies by strains of the sweetest music, vocal—and it may come to this—instrumental whilst waiting one's turn in the reception-room or undergoing the process, which will no longer be stigmatised as the "ordeal" of being photographed. The subject is so charming; but I must tear myself away from it, sufficient to say that by the time that the last-named state of things shall be *un fait accompli*, the profession shall have been subjected to such complete and remorseless action of the laws of natural selection and the survival of the fittest, that the unmusical among them will have disappeared, leaving the fiddling photographer more elbow-room for his scrapings and the photographic flautist freer space and air as he "softly purling glides on the even tenor of his way." Simultaneously another vexed question will be settled, the last element of discord will be eliminated, and all photographers henceforth will hold the undeniable and inestimable privilege of calling themselves artistes, with or without the "e."—Yours, &c.,

July 1, 1893. THE PIPING BULFINCH.

COLOURED LANTERN SLIDES.

To the EDITOR.

SIR,—We notice in the June issue of "Supplement" to THE BRITISH JOURNAL OF PHOTOGRAPHY an article taken from the *Photographic Times*, written by Mr. L. C. Laudy, and must say we fully endorse what he says about "the need of more trained artists in the slide-colouring line." He very properly denounces the "rubbishy painting extant—harsh, wild, and sensational colouring, and that those who are induced to try their hand may avoid the above, and restrain that childish appetite for lurid and glaring effects, and be guided by a *chaste* and *educated* taste." He then adds, "The field of lantern-slide colouring is an excellent and tempting one . . . . will be delightful and *lucrative* in its results." (The italics are ours.)

Now, we wish to add a few remarks, the result of nearly half a century's experience in painting slides by hand, and colouring photographic slides. The majority of the public refuse to pay a fair price nowadays for the colouring; the cheap 18*s.* a dozen complete (photograph and all) have done it. Our dealers say they "*cannot sell the true artistic work*, and *that a good slide by an educated artist* would be passed by as tame and poor, &c." Really, what inducement is there to be found for educated men to compete, receiving, as they would (from the dealers), from 3*d.* to 6*d.* per slide for their work? Then, again, the glaring and vulgar colouring by the trade workers (as shown in all our opticians' and chemists' shops) that are turned out by the thousand, are done by girls and children, in stuffy rooms in or near London—mostly by people who never knew anything of art or taste. Poor things, they cannot afford the time to improve themselves or their work, and, as to *reading up a subject*, that is out of the question. What art training do you suppose any of the people have had that are regularly advertising in yours and other papers? It is the *quantity* of cheaply daubed trash that pay them best and real sweating out of girls and children. How different it was twenty or thirty years ago, before the advent of the present grade of "artists!" Very different it must be with the true artist! He wants good pay, with leisure to do his work conscientiously and well. He cannot afford to advertise, because he could not work for enough to pay the expense. And, lastly, if a man of ability *must* spend half his earnings in advertising for work, he will turn to better-paying methods of earning a livelihood We know of several clever artists who have left slide-painting in disgust. A man of ability is worth 3*l.* to 5*l.* a week at the very least; can any of the "sixpenny art" pay that sum? What number must he do per week?—We are, yours, &c., WILKINSON & Co.,

Holmeside, Sunderland. *Dissolving View Slide-painters.*

Exchange Column.

*** *No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance. The full name of the advertiser must in all cases be given for publication, otherwise the Exchanges will not be inserted.*

Will exchange ratchet safety bicycle, ball bearings all over, for good hand camera (¼ or 5×4). Facile or Kodak preferred.—Address, G. M. MILLER, 15, Cambridge-terrace, Belgravia, London.

Wanted, 12×10 camera, three double slides, globe enameller, good hand camera, or accessories. Exchange Singer tricycle, as new, cost 26*l.* nét, or 24×18 hot rolling press. Address, J. ASTON BRIGGS, Whitby.

Wanted whole-plate studio camera, with two double backs and carriers. Will exchange a 15×12 enlarging, &c., camera, with full set carriers for same.—Address, H. WILKINSON, 2, Church-green, Harpendsu, Herts.

Will exchange THE BRITISH JOURNAL OF PHOTOGRAPHY from 1889 to 1892 (inclusive) and a few odd numbers of *Photography* for graduated background or interior.—Address, FREDK. HURD, Photographer, Shepton Mallet.

Will exchange a 15×12 reversible camera, long extension, with two double and one single slides, for a 10×8 folding bellows camera, with three slides, double.—Address, JOHN BROOKS, Photographer, 40, Parliament-street, Burnley, Lancs.

Answers to Correspondents.

*** *All matters intended for the text portion of this* JOURNAL, *including queries and Exchanges, must be addressed to* "THE EDITOR, THE BRITISH JOURNAL OF PHOTOGRAPHY," 2, *York-street, Covent Garden, London. Inattention to this ensures delay.*

*** *Correspondents are informed that we cannot undertake to answer communications through the post.*

*** *Communications relating to Advertisements and general business affairs should be addressed to Messrs.* HENRY GREENWOOD & CO., 2 *York-street, Covent Garden, London.*

*** *It would be convenient if friends desiring advice respecting apparatus, failures in practice, or other information, would call at the Editorial Office either on Wednesdays from* 4 *to* 6, *or Thursdays from* 9 *to* 12 *noon, when some one of the Editorial staff will be present.*

CONSTANT READER.—You omitted to give your name.

KNOWLEDGE IS POWER; A. J.; and others, in our next.

ACCESSORIES.—Mr. W. H. Redshaw, of Bourne, Lincolnshire.

G. WRIGHT & CO.—Why not advertise the solution for that purpose?

EBOR.—Apply to Mr. W. I. Chadwick, St. Mary's-street, Manchester.

LUX.—The simplest and, in the end, the cheapest plan will be to purchase a new dish.

W. M.—It is doubtful if the stains can be removed. Try the effect of very dilute hydrochloric acid, or, failing that, oxalic acid.

G. REYNOLDS.—Yes; the chemicals are measured out by avoirdupois weight—sixteen drachms, of twenty-seven and a half grains each, to the ounce.

T. RAYMENT.—So far as we are aware the collodion transfer for the so-called "Club Picture" is extinct. Therefore, if you must have them, we suspect you will have to learn how to make them for yourself.

SPOTS.—We know several ways by which the stains may be taken out, but none that will remove them without also removing or changing the colour of the fabric, so that the remedy would probably prove much worse than the disease.

R. T. WATSON.—The best way will be to obtain instruction from a practical worker of the process. If you desire to work the process as a business, the best way will be to "article" or apprentice yourself to some of the firms who take apprentices, and many do.

E. HOPPER.—A portable studio such as you desire will be constructed by any of the horticultural builders in your neighbourhood. If you require one second-hand, no doubt an advertisement in the columns devoted to such purposes will secure what you desire.

E. R. NEWMAN.—Whether the emulsion was defective or not we, of course, cannot say. The negative sent (which arrived in fragments) was not sharply focussed, which may in some measure account for its apparent lack of detail. Its appearance is not inconsistent with over-exposure.

E. WALTON.—Your friend is quite right, the boiling point of water is 100°, but that is on the Centigrade scale. On the Fahrenheit scale, with which you are familiar, it is, of course, 212°. On the Reaumur scale, the boiling point of water is 80°. The latter is the scale most used in Germany and Austria.

H. R. P. asks: "Can I, as an amateur photographer, let photographs of mine be sold for a charitable purpose, thereby receiving no benefit for myself, without infringing the laws for exhibiting as an amateur. Kindly answer this."—This query is on all fours with that put by C. Moore, and the reply will apply in both cases. Each of these correspondents appears to be anxious not to lose the privilege of being *bonâ-fide* amateurs.

C. E. COE writes: "Will you please answer the following: What is the best way to vignette bromide paper and opals, by artificial light, when printing in contact? I have tried several dodges, but up to the present cannot get a reliable result."—Mask the negative as in silver printing—that is, with it placed some distance from the negative—and keep the frame moving during the exposure, so that the light is diffused between the mask and the negative.

BROMIDE.—1. If the manipulations as described were carefully carried out, there ought not to be any spots at all. Obtain a fresh batch of paper and compare with the old. 2. If the glasses be clean, and are in good contact, such appearances are generally present, but we have never found them show in a print, by whatever process it was made. The markings complained of, we suspect, are due to other causes. 3. No work on ceramic photography in the English language is in print at the present time.

C. W.—Makers of dry plates do not publish the formulæ by which they make them. Therefore we cannot tell you how the particular brand you are so anxious about is produced. Probably others besides you would like to know. It is very unreasonable to expect that manufacturers should publish the various methods they employ, although some few amateurs may possibly desire to prepare the whole of the material they use themselves. It is possible, though scarcely probable, that some amateur Society might be induced to offer medals for pictures made entirely on material prepared by the exhibitor. C. W. had better take the initiative and see the result.

OILS puts the following queries. I shall feel greatly obliged to you if you can give me advice through your columns, as to the best way to clean and remove creases from an oil painting on canvas, which is badly cracked and soiled. The canvas has been taken off the stretcher and been carelessly rolled up? 2. Can you also tell me what preparation is the best for varnishing an oil painting?"—In reply, 1. To give the necessary information for it to be of any use would occupy several columns of the JOURNAL, and even then it is probable that an inexperienced hand would inevitably ruin valuable pictures in the first few essays. We advise that the work be put into the hands of an experienced picture-restorer. 2. Mastic varnish; but it should not be applied till the picture has been prepared for its reception. Many valuable pictures are ruined by injudicious treatment.

C. MOORE writes: "A gentleman, amateur in photography, has succeeded in taking some very fine views of the cathedral here, and I shall be glad to know if it will disqualify him from competing as an amateur if the photographs are exhibited at my shop, and sold by me on behalf of a local charity? None of the proceeds will go to the gentleman; in fact, he is in a position not to require or desire any. The photographs are placed unreservedly in my hands, and it is to prevent any possibility of disqualification that I hesitate to make a sale before hearing from you in your JOURNAL."—The question just now is very vexed as to what qualifies an amateur and what a professional in photography. We know that a considerable number who are looked upon strictly as amateurs, and pose themselves as such, allow their pictures to be published, and take a liberal commission on the sale of them. We should like to have the opinion of some of our readers on the question raised by our correspondents.

G. A. writes as follows: "We have moved into fresh premises, and in them cannot get a toning bath to act. The print, on immersion, refuses to change colour. After twenty minutes it tones in the high lights, but the shadows absolutely refuse to put on any gold whatsoever, so come from hypo quite yellow. We have made up quite a dozen new baths, buying fresh chemicals. Bottles, dishes, &c., have been thoroughly washed so as there to be nothing to cause precipitation of gold. Fresh paper has been tried; the same results exactly with P.O.P. and sulphocyanide, so it cannot be due to paper. The failure is due, we think, to precipitation of gold; but how it comes about we should feel obliged for you to tell us. We use acetate and P.O.P. baths. On some acetate baths we have noticed the gold deposited a day after, but P.O.P. refuses to tone directly, so the gold must be reduced simultaneously."—If the facts be as stated, and all the vessels are chemically clean, we should suspect either the water with which the toning baths were prepared, or the water with which the prints were washed prior to toning. If the latter be the regular supply to the district in which our correspondent resides, we quite imagine the trouble does not arise from that. We surmise that the difficulty is due to some trifling manipulatory detail, which, of course, we cannot localise.

RECEIVED.—T. N. Armstrong; J. Pike; E. Dunmore; H. Dennis Taylor; and W. T. Wilkinson.

PHOTOGRAPHIC CLUB.—July 12, Members' Open Night; 15, Outing to Burnham-on-Crouch.

*** Several interesting communications, answers to correspondents, &c., are unavoidably held over.

RATIO OF GRADATION.

Mr. Bothamley did good service at the Convention in endeavouring to remove what might not inaptly be termed the deadlock on this question between highly skilful scientific theorists and skilful practical workers. He disclaimed any intention to introduce new facts into his lecturette, but led his hearers into paths from which they could look at old facts from different standpoints. He pointed out that, while it was patent that in this gradation question photographers appeared not to agree, it yet might turn out they were talking really of different things when they imagined they were discussing the aspects of one only; and he did not hesitate to point out the folly of using loose nomenclature in discussing scientific results. He strongly accentuated the fact that nothing that Messrs. Hurter & Driffield had written was contrary to the contention of practical men that the printing value of a negative was greatly under control. Messrs. Hurter & Driffield, in their valuable researches, required to discover the relation that existed between the amount of silver deposited and the amount of light to which it was owing. Put into simple language, their experiments, in their view, go to prove that, if a certain amount of light results in a certain amount of silver being reduced, twice as much light will give twice as much silver, and so on. By means of two simple diagrams, representing a set of four gradations, Mr. Bothamley showed how the printing value of a negative might be vastly improved by altered development, and yet the proportion or ratio existing between the highest, the lowest, and the medium tints remain the same. Some difficulty was felt in accepting to the full his valuation of the important position as regards the ratios held by fog. Fog, he pointed out, was rarely, if ever, absent from a negative. The typical perfect one, with "absolutely clear glass in the shadows," rarely, if ever, *was* absolutely clear glass in the shadows, and this would be readily seen by placing the plate upon a piece of white paper.

To every one conversant with mathematics it is a truism to state that, by adding to each term of a geometrical ratio, the ratio is altered. If fog deposit be added to the light deposit, the ratio that would be obtained by a fog-free plate is interfered with, and the printing value may positively be a function of actual fog. When a plate is over-exposed, and it is said that the ratios are altered by the usual mode of counteracting over-exposure, Mr. Bothamley pointed out that what happened was that all the alterations worked for less fog, while with under-exposure the correcting methods introduced fog.

A great part of the interesting discussion that followed turned upon this view. Mr. Cowan, while quite ready to believe that he was not really at issue with the lecturer, claimed that fog had not the influence claimed for it. Dr. Mitchell, Mr. R. H. Worth, and Mr. Watmough Webster joined in the discussion, the latter gentleman introducing to notice what he considered a neglected factor in fog valuation. Messrs. Hurter & Driffield always experiment with an unexposed portion of the same plate when estimating the light reduction, and subtract the fog value exhibited on the non-exposed plate from the total value. Mr. Webster considered that in counting fog reduction as a constant in estimating the value of two portions of one plate placed in a given solution, a mistake was made. He contended that it was then a variable quantity, and said that the experience of practical men would show that it was possible to expose half of a plate to the image of a light object varied by the presence of a few actual blocks, lines, or spots, and obtain those lines or spots almost clear glass, although the unexposed half be decidedly fogged. Mr. Cowan considered this to be a mistake. It is a matter, however, that any one could settle for himself by a simple experiment or two.

We make no excuse for thus attempting to bring before our readers the salient points of an interesting discourse, if for no other reason than to accentuate the fact that the important and valuable experiments of Messrs. Hurter & Driffield have been performed in such a systematic manner, and estimated on a basis of scientific principles in a way in which the use of mathematics was unavoidable, that a really fruitful discussion cannot be carried out on any other basis. The majority of photographers have no use for mathematics, and may presumably be little acquainted with them; hence if a small committee were elected from our leading Society, instructed to examine and report on the much-vexed question, their verdict would stand a chance of being received as final.

We would conclude by adding a further contribution to the fog question, which, nevertheless, may possibly increase to fog. Not one of the speakers at the Convention said one word as to where the fog deposit was to be placed in the negative. For aught they said, it might be indifferent whether the fog deposit was between film and glass, on the outside of the film, or evenly distributed through it. In other words, so far as the argument went, the added piece of tissue paper Mr. Cowan instanced might be placed between negative and printing paper, or outside the printing frame, without altering the scale of gradations in the print. Would this be the case?

VIGNETTING BY ARTIFICIAL LIGHT.

The operation of vignetting is one that requires a great amount of care in order to produce the best results under the ordinary circumstances of daylight, but when artificial light is in question the difficulties are very materially increased. Whatever may be the method employed for masking and softening the image, it is of course of the utmost importance that the light be as diffused as possible, and it is the production of the necessary diffusion that renders the task of vignetting by gas or other artificial light so much more difficult than by daylight.

Of the unknown devices in use for daylight vignetting, none answer practically with artificial light without very considerable variation in the mode of use. We may perhaps make exception in favour of the mechanically graduated screens of glass or paper sold for vignetting purposes, but these are comparatively little used, and far from perfect in their performance. If a perfectly graduated vignette glass or screen for use in contact with the negative can be secured, then all the difficulty at once disappears, but the provision of one such for each separate negative is a practical impossibility. Failing that, we can only do our best to imitate the diffusion obtainable in daylight.

Of the mechanical methods employed for masking the negative, there is a sufficient choice, and probably each individual will have his favourite, though, if properly used, nothing is simpler or more efficient than a plain aperture with serrated edges, and covered with tissue paper. Such a screen placed at a distance of from three-eighths to half an inch from the negative will, in diffused daylight, produce the most delicate gradation, and if the position of the printing frame be frequently changed, or, better still, if it be kept in constant motion, the evenness of action will be still further promoted.

It must be borne in mind that the securing of gradation is not the only difficulty in vignetting; to be perfect it must be uniform, and this can only be obtained when the light falls equally in all directions upon the negative. In vignetting in daylight, should the light be stronger from one side of the negative than the other, the inevitable result will be that the shading on one side of the picture will be deeper or more extended than on the other; and, if this be true of diffused light, it is even more so when sunlight or artificial sources of illumination are concerned, and the necessity for softening the action of the light by every possible means becomes greater.

It is not our intention to describe the numerous varieties of screens employed in vignetting, but rather to show how they may best be utilised in connexion with artificial light, and we shall therefore assume that such a one is employed as would give a satisfactory result if employed in ordinary diffused daylight. The question, then, is how best to imitate the diffusion of light from a clear sky.

The simplest and most natural plan is to utilise reflected light, that is, to expose the negative, not directly to the source of illumination whatever it may be, but to allow the light to fall on an extended surface of suitable colour, such as the wall or ceiling of a room, and to expose the negative to that. If the printing frame be held above the head in such a position that no light reaches it directly from the chandelier or lamp, but only that reflected from the ceiling, a very satisfactory gradation will be secured, and, if at the same time the frame be slowly rotated, additional uniformity will be assured.

Another plan consists in suspending a board by its four corners in a perfectly horizontal plane, and causing it to rotate, the moving board being used as the table on which to expose the vignetting frame. If this be fixed in such a position with regard to the source of light that the latter falls on it at an angle of from 30° to 40°, and the board be set in even motion, the gradation will be as perfect as in diffused light. But it must be borne in mind that any irregularity of motion or departure from the horizontal will, with a fixed light at close quarters, produce a corresponding want of uniformity in the gradation.

A further means of softening and equalising the gradation by whatever means obtained consists in interposing a sheet of tissue paper or ground glass midway between the vignetting screen and the negative in such a manner that the intervening screen itself becomes, in a measure, the illuminant. This, of course, gives much greater softness, though it necessarily increases the exposure. A simple frame of three-eighths of an inch in thickness, to fit in to the front of the printing frame, will suffice to carry the tissue paper on one side and the vignetting screen on the other, and can be made attachable to any frame.

Some little more attention might well be given by dealers in this country, as is the case in America, to the provision of special frames and appliances for vignetting, and more especially for vignetting bromide and other films that necessitate the use of artificial light.

The Chicago Exhibition.—We learn by a telegram just received that the Judges appointed to make the awards to the exhibitors are to commence their labours to-morrow (Saturday). It is to be hoped that they will prove satisfactory to all concerned. Anyhow, exhibitors must be better satisfied to have their works adjudicated upon by a jury than reported upon by any single individual. Had this system been adopted in the first instance, much unpleasant friction would have been avoided.

The "Benevolent."—During the outings of the Convention last week, especially when these took place on a steamer, Mr. Hedley Smith rendered excellent service to the Photographers' Benevolent Association by going frequently round with the contribution box. After a song, say by Mrs. Mason, W. D. Welford, Birt Acres, or others, off on his rounds among the passengers would start Mr. Smith, whose appeal for the "smallest donation" was seldom disregarded. In this way the goodly sum of five pounds was collected and handed over to the President of the "Benevolent."

Gold.—A great many professional photographers prefer to make their own chloride of gold, and usually, notwithstanding it is illegal, employ the current coin of the realm for the purpose. From a return just made, it appears that no less than 16,000,000*l.* worth of worn gold was withdrawn from circulation last year. In making the chloride new coins should always be selected. This should be manifest to every one; but we recently saw some about to be used which, upon being weighed, showed a deficiency in weight of several grains in the bulk. New sovereigns cost no more than worn ones, and they yield more chloride.

An Incomplete Novelty.—The *Literary World*, alluding to an American work, *Titled Americans*, which gives a list of American ladies who have married titled Englishmen, and some of those who have married titled foreigners, says: "The most remarkable feature of the book is the list appended of the unmarried scions of our nobility, with their estimated incomes—a sort of *vade mecum* for Chicago millionaires." Surely, such a work would be far more complete if it were illustrated with the portraits of the titled bachelors and widowers. We imagine there would, in some instances, at least, be no difficulty in obtaining them if the object were explained. Here is a hint to further "American enterprise."

The Royal Academy.—A resolution has been submitted to the Council of this body, and has been discussed by it, according to which Academicians and Associates will have to limit the number of their exhibits at the annual show to six, while outsiders are not to send in more than four. This, if the resolution be adopted, will considerably lighten the labours of the committees of selection, while it may induce some artists to concentrate their energy on fewer works instead of expending them on a larger number, sometimes at the expense of execution. Would not some such regulation with regard to photographic exhibitions be an advantage, particularly some of those held in provincial towns and the suburbs of London? In many instances an exhibitor would figure to better advantage by showing half-a-dozen pictures than he does by exhibiting twice or thrice that number.

The Silver Market.—Photographers are less directly interested in the value of silver now than they were formerly when the nitrate was required for baths in the collodion process and for sensitising paper. Now the silver nitrate is rarely required, if at all, by many photographers. Still, the market value of the metal largely concerns dry-plate makers and those who supply ready-sensitised paper. Silver has been depreciating in value for many years past, and the announcement of the lowest record has often been made. The record has, however, again been broken, for a fortnight ago it was quoted at 29½*d.* per ounce. About five-and-twenty years ago it stood at something over 60*d.* per ounce. The market has recovered somewhat, but is still in a very excited condition, and the value of the metal has fluctuated as much as several pence an ounce from day to day. Unless the new regulation with regard to the Indian mint be relaxed, or more mines are closed, it is clear that even the present price of silver will not be maintained for any great length of time.

Show Cases.—In connexion with the lack of enterprise shown by some portrait photographers, we have on more than one occasion commented upon the small attention given to the specimens exhibited in the show cases and shop windows. These are shown to attract sitters, and therefore, one would think, should be in keeping with the times. To exhibit portraits in summer attire when the snow is upon the ground, or in heavy winter attire during the dog days, is certainly a mistake from a business point of view. We were forcibly reminded of this one day last week, when the thermometer was registering over 80° in the shade. While admiring some excellent pictures in a show case in one of our fashionable West-end thoroughfares, we overheard one young lady remark to two others, "Just look at those people in furs! Ugh! how horrid!" Furs in photographs are always effective, and there is little doubt that the same pictures would be looked at by these same people with admiration a few months hence. With ladies the immediate style and fashion tell for much.

Royal Cornwall Polytechnic Society's Exhibition.—The sixty-first annual Exhibition of this Society will open at Falmouth on Tuesday, September 5, 1893. As heretofore, medals and prizes are offered in various departments, including photography, the class being open to professionals and amateurs, and a section being devoted to photographic apparatus. List of prizes and all further information may be obtained from the Secretary, Mr. Edward Kitto, F.R.Met.S., the Observatory, Falmouth. Information respecting the photographic department may be obtained from Mr. W. Brooks, Laurel Villa, Wray Park, Reigate (member of the General Committee). Medals are offered by the Society for meritorious productions in the following subjects:—Outdoor photography (professional): 1. Landscape, not less than 20×16 inches. 2. Landscape, 12×10 inches, and under. 3. *Genre.* 4. Architectural (exterior). 5. Instantaneous, including marine. 6. Animals. 7. Enlargements. Indoor photography: 1. Portraits, not less than 20×16 inches. 2. Portraits, 15×12 inches, and under. 3. Home portraiture. 4. Still life, flowers, &c. 5. Interiors, architectural or otherwise. 6. Photo-micrographs. 7. Enlargements. Amateur: 1. Landscapes. 2. Architectural, exterior or interior. 3. Hand-camera work, not less than twelve examples. 4. Instantaneous, including marine. 5. Still life. 6. Enlargements.

The Royal Wedding.—Probably on no previous occasion in a single day were so many plates exposed, and with so little result, as on the day of the marriage of the Duke of York and the Princess May. We are told by dealers that, at the beginning of last week, there was quite a run on the most rapid brand of plates of the various makers of the quarter-plate size. The day, as far as light was concerned, was all that could be desired, and hand cameras were to be seen at all points on the routes of the processions. Yet how disappointingly small is the proportion of really good pictures that were secured as compared with the attempts made! A large number of novices have by now realised the fact that obtaining even fairly good negatives of events, such as that referred to, in the streets of London is by no means easy of accomplishment. Where there is a large crowd of people packing a thoroughfare, with high buildings on either side, there is always a considerable amount of haze and dust, which brilliant sunlight makes painfully conspicuous, that quite obliterates distance, though that may not be far off, unless there is a strong wind blowing. It is this that has caused so many of the negatives to appear fogged when developed. However, many of the negatives obtained, though they may not be good photographically, will serve as interesting souvenirs of the occasion in time to come to those who took them.

PHOTOGRAPHIC CONVENTION OF THE UNITED KINGDOM.*

On Wednesday morning the General Meeting was held at 10 a.m., the President in the chair. Mr. Cembrano read the minutes of the last meeting, which were approved. He then read a list of societies which had sent delegates. These included the following: — *The Photographic Club*, J. Guardia and S. H. Fry; *Richmond Camera Club*, R. L. Kidd and P. Ennis; *North London Photographic Society*, J. Traill Taylor; *Leicester Club*, J. Porritt; *Munster Club*, Major J. D. Lysaght; *Manchester Society*, J. Brier and E. Woodward; *Tooting Club*, Mr. L. E. Morgan; *London and Provincial Association*, W. D. Welford and S. H. Fry; *The Photographic Society of Ireland*, A. Warner. There were also a large number of other ladies and gentlemen present from all parts of the kingdom, among the latter, not members of the council, being Messrs. J. W. Webber, Bromley; A. Haddon, Greenwich; Birt Acres, Barnet; W. M. Ashman, Bath; J. S. Hawke, Plymouth; E. J. Humphery, London; F. W. Hindley, London; and E. Marlow, Birmingham.

On the proposition of Mr. C. H. Bothamley, the General Committee with the addition of a few fresh names were re-elected.

Invitations from the Photographic Society of Ireland to hold the next meeting in Dublin, and from the Shropshire Camera Club to meet in Shrewsbury were submitted to the meeting. A vote having been taken, it was declared that a large majority was in favour of Dublin.

The President then asked the meeting to accord a very hearty vote of thanks to the Mayor of Plymouth for his most generous reception of the Convention, to the Plymouth Institution for the loan of their premises, to the Local Committee for all they had done to make the meeting pleasant, and to the leaders of the excursions. If Tuesday's excursion might be taken as a sample, then they had a store of interest and beauty to come. Of course, the weather could not be commanded, but, in spite of the thunder and lightning and the torrents of rain, all managed to enjoy themselves, and the little sing-song in the saloon was by no means the least enjoyable feature.

A cordial vote of thanks was given Mr. Cembrano, the Hon Secretary; and Mr. C. H. Bothamley, in proposing it, said the prospects of the Convention had never been so bright, and that was due largely to the efforts and tact of their Hon. Secretary.

Mr. Cembrano, in acknowledging the compliment, said with this meeting his first year's service came to an end, and he was pleased to say that, for the first time in the history of the Convention, there was

* Continued from last number.

a balance on the right side. (Applause.) It amounted to 15*l.* 19*s.* 9*d.*, and next year he hoped it would be doubled, although the number of members was certainly a good deal less. So far he had received subscriptions from 173, which was a good deal more than he expected, considering the great attractions in other parts of the country this week.

Messrs. John Howson and S. B. Webber were elected auditors.

The following motion, submitted by Messrs. H. Snowden Ward and E. J. Wall, was recommended by the Council for adoption:—"Resolved, that the Photographic Convention of the United Kingdom acknowledges the courtesy of the Photographers' Association of America in inviting British photographers to attend its Conference this year as honorary members, and this Convention wishes its Committee to add to its rules one to the following effect:—That all members of the Photographers' Association of America be considered honorary members of the Photographic Convention of the United Kingdom, and, if travelling in the United Kingdom at the time of the Convention, are invited to take part in its proceedings."

Mr. Wall, in proposing the adoption of the motion, regarded it as a first step towards a Photographic International Union.

The Hon. Secretary seconded the motion, remarking that he had received courteous and encouraging messages from the Photographers Association of America.

The motion was carried unanimously.

Mr. J. Traill Taylor, whilst in full accord with the desire to cultivate brotherhood with their American brethren, would point out that some of their brethren at home had a feeling of soreness towards the Convention, and that others regarded it with apathy. When the Convention was at Birmingham a debt was incurred, not perhaps wisely, and doubtless without due authorisation, by the brethren there, but in the interests of the Convention. Some, and he himself among them, looked upon this as a debt of honour, and he would suggest that, now the Convention had funds in hands, the Council should try to defray that debt as soon as possible, and thus remove the feeling of soreness, and also to overcome the apathy of places like Manchester.

Mr. Taylor's suggestion was adopted.

It was moved by Mr. A. Werner, and seconded by Mr. H. M. Smith, that the following be elected members of Council for the ensuing year:—F. A. Bridge, Dalston; J. J. Briginshaw, London; C. H. Bothamley, Taunton; A. A. Carnell, Plymouth; A. Cowan, Southgate; J. P. Gibson, Hexham; M. J. Harding, Shrewsbury; H. M. Hastings, West Kensington; A. L. Henderson, London; T. C. Hepworth, London; R. Keene, Derby; J. A. King, Bath; W. Lang, jun., Glasgow; P. Lange, Liverpool; A. Levy, London; C. Phipps Lucas, Kent; A. Mackie, London; W. W. Naunton, Shrewsbury; J. Porritt, Leicester; A. Pringle, Bexley Heath; B. J. Sayce, Liverpool; A. Seaman, Chesterfield; H. M. Smith, Stroud Green; J. Stuart, Glasgow; H. Sturmey, Coventry; J. Traill Taylor, London; A. Tate, Belfast; L. Warnerke, London; G. W. Webster, Chester; J. B. B. Wellington, London; A. Werner, Dublin; R. H. Worth, Plymouth; F. P. Cembrano, Richmond; E. Appleby, Bath; J. L. Lyell, London; E. G. Humphery, London; J. Fergus, Largs; W. Taylor, Leicester; R. L. Kidd, Hampton; T. Mayne, Dublin; and Major Lysaght, Queenstown.

At noon the official Convention group was taken in the Guildhall-square by Mr. Heath, of George-street, Plymouth, and the President announced, in the course of the afternoon, that the negative had turned out very satisfactorily. Mr. Scorer, of Havant, also took a group on a plate 28×20 with a camera that would take a plate 30×24. Numerous other "shots" were had at the group, one by Mr. Kidd, giving a fine picture which will be presented to our readers next week.

Wednesday Evening.

This evening the Mayor of Devonport (Mr. Alderman W. Waycott), along with some of the Aldermen and Councillors, together with Mr. Croydon, the Vice-President, Mr. C. H. Moore, the Secretary, and with other members of the Devonport Camera Club, received the members of the Convention. The President of the Club, Colonel Stewart, was unavoidably absent on duty in another part of the country.

The Mayor said it gave him much pleasure to offer the Convention a hearty welcome, especially in their Council Chamber, whose walls were adorned with interesting examples of the photographic art taken by a former official of the Corporation, Mr. C. R. Rowe, their late borough librarian. It was with regret that he saw that the Convention excursion up the River Tamar on Tuesday was sadly interfered with by the rain, but he hoped fair skies would favour them during the rest of their sojourn, so that they might see in their fullest glory the beauties of the district of which the residents were so proud. They would, doubtless, be interested in knowing that at Devonport was born Robert Hunt, one of the earliest and most painstaking investigators of the principles and chemistry of photographic operations. He apologised for the absence of the Town Clerk, who was on a holiday, and of several members of the Council, who were busy preparing for the Royal wedding celebration on the morrow.

The President, in a genial speech, acknowledged the heartiness of the Mayor's welcome, and said it was an added pleasure to know that they were assembled in the birthplace of Robert Hunt, to whom photographers owed so much.

Mr. C. Croydon then, in the absence of Colonel Stewart, the President, offered the Convention a hearty welcome on behalf of the Devonport Camera Club, paying a tribute to the memory of Robert Hunt, with whom was associated John Towson, another Devonport man, so well known as the originator of great circle sailing, mentioning that Colonel Stewart was the inventor of the Panoram camera, and graphically illustrated the great uses of photography in astronomy, microscopy, and natural history.

Mr. A. Tate, J.P., of Belfast, acknowledged the Club's welcome of the Convention, remarking that everywhere in the district they had been received with kindness and cordiality, and, in allusion to Mr. Croydon's remark, said photography was now the trusty handmaid of every science, seeing more than the eye of the astronomer, the physician, and the naturalist.

Wines, tea and coffee, and other light refreshments were then served, and an adjournment was made to the Town Hall, where a most interesting optical lantern exhibition was enjoyed.

Following this was a lecture, copiously illustrated by the lantern, by Mr. J. T. Cunningham, M.A., of the Marine Biological Laboratory, Plymouth, descriptive of the developments of soles, crabs, jelly-fish, and of the habits of the angler fish and the hermit crab.

A paper on the *Special Properties of the Zeiss Anastigmatic Lenses*, by Dr. Paul Rudolph, with diagrams and specimens, was taken as read.

A lecture on *Photography in Relation to Medical Record and Demonstration* was down on the programme to have been delivered by Mr. Andrew Pringle; but, owing to the absence of that gentleman from illness, it was not given.

Thursday.

This day was devoted to a most enjoyable excursion to the ancient town of Totnes, and thence down the Dart to Dartmouth. The party, nearly seventy in number, started from Plymouth shortly after nine o'clock in the morning, and Totnes was reached about ten o'clock. The town looked gay with many flags, while in the streets were people, young and old, in holiday dress, making ready for the festivities. The keep of the old castle was ascended for the view, and many pictures were taken of the gate in Fore-street and of the church, whilst a score of photographers all in a row were seen intent on making pictures of the well-wooded island. Ere Totnes was left the children assembled on the Plains and sang the National Anthem, and some snap-shots of the scene were taken from the pedestal of the monument to Wills, the Australian explorer. Most enjoyable was the trip down the River Dart. It was made in a steam launch, and a roomy boat and two smaller ones towed by the launch. The English Rhine, with its grand woods sloping down to the water's edge, and with its many windings, was seen at its best. Little could be done photographically on the way down, but the hand camera was in constant use as soon as Dartmouth Harbour was reached. By H.M.S. *Britannia*, naval cadet training ship, the launch went slowly, that photographs might be taken; then at greater speed the party proceeded to the harbour's mouth, to view the castle so picturesquely situated on the shore. Yachts, some dressed rainbow fashion and others in full sail, the Kingswear horse ferry boat, and the high banks, with beautiful residences nestling among woods and gardens, and the castle itself were the constant objects of members' attention. Returning

from the harbour mouth, the party landed on the quay, and, proceeding to Bodley's Hotel, enjoyed a substantial luncheon, after which the President, in sympathy with the feelings of the company, gave expression to the hope that the Duke of York and his bride would be blessed with a long and happy life, and heartily thanked Mr. Barnston for acting as leader of so interesting an excursion. Then the party separated to photograph the Butter Walk (in one of the quaint houses of which King Charles II. held court), the Church of St. Saviour, scenes in the harbour, and the softening effect of a sea fog which drove over the hills above the town was seen. All were agreed that the borough and its land-locked harbour was truthfully described by the Queen on one of her visits as "Beautiful Dartmouth." The return to Plymouth was by train, *viâ* Kingswear and Newton, Torbay and Torquay affording charming views in the bright sunlight.

In the evening there was a fair gathering at the Plymouth Athenæum, when Mr. Bothamley gave an address on *Some Points in Connexion with Development*, on which Mr. G. W. Webster, Mr. A. Cowan, and others made remarks.

Other papers, on *The Power of Compensating in Development for Variation in Exposure*, by Professor W. K. Burton; *Latitude of Exposure and Speed of Plates*, by Dr. F. Hurter; and *Our Pictorial Failures*, by the Rev. F. C. Lambert, M.A., were taken as read.

The members then adjourned to the Hoe, to witness the great pyrotechnic display (including the burning of a ship) in connexion with the Royal Wedding celebration.

Friday.

There were three excursions this day, respectively to Lydford, Bickleigh Vale, and Dockyard and Keyham, Cattewater.

The annual dinner was held in the evening, and was numerously attended, many ladies, as usual, being present.

The toast list, which was laudably limited, comprised the Queen and the Royal Family; and The Convention, proposed by the President, was responded to by Mr. R. H. Worth, local Hon. Secretary, and Colonel Barrington Baker, who then, in the name of the Plymouth Club and in a few fitting remarks, presented the Club's medals to Mr. Mason, President, and Mr. Cembrano, Secretary, as a memento of the Plymouth meeting, both of whom acknowledged the graceful gift.

Songs, speeches, and recitations were contributed by Mrs. Mason, Mrs. (Dr.) Mitchell, Messrs. A. Cowan, S. H. Fry, A. Werner, C. H. Bothamley, G. W. Webster, A. Tate, Fuerst, Laurence, Welford Newman, and Mowll. The dinner, taken all in all, was a great success.

Saturday.

A meeting of the Council was held this morning to elect a president.

Mr. J. Traill Taylor said that, as the meeting next year was to be held in Dublin, it was fitting that a representative Irish gentleman should be elected. The name of Grubb had for a long course of years been honourably connected with photography, both through the father, the late Thomas Grubb, and the son, Sir Howard. He therefore begged to propose that Sir Howard Grubb, F.R.S., be elected president for the next year. This was seconded by Mr. Alfred Werner, who observed that Sir Howard's high position in Dublin would ensure the success of the Convention.

This was carried by acclamation. A telegram was received from Sir Howard, accepting the position.

This terminated the proceedings.

THE CONVENTION EXHIBITION.

We now give a more detailed account of the exhibits:—

Messrs. Morgan & Kidd.—We have referred to the large portrait of the lady which occupied the place of honour in the room. It was trimmed down to 8 ft. by 4 ft., having been taken 6 ins. larger both ways. It was supported by two large portraits of a lady and cavalier, somewhat inferior in dimensions, but equally excellent in technique. Pictorially speaking, Mr. Kidd's *Misty Morning*, an enlargement from a hand-camera view taken on the return journey from the Edinburgh Convention last year, was probably the best landscape in the room. Their works in carbon challenged attention, especially a portrait of a lady seated in an ornate chair. Several of these were nicely coloured. They had also a fine exhibition of works in collotype, a department into which this firm is now going extensively.

Mr. Heath, Plymouth.—Among this artist's exhibits was an "At Home" portrait of H.R.H. the Prince of Wales; also portraits of their R.H. Princesses Marie Victoria and Alexandra of Edinburgh. There were also various carbon prints.

Messrs. Elliott & Son, Barnet.—A singularly fine portrait of a lady, enlarged from a negative by Werner & Son. This was a direct print in carbon, produced from a plate of the large dimensions of 64 × 38 inches.

Mr. John Hawke, Plymouth. — This artist's exhibit consisted of a frame of eighteen portraits of H.R.H. the Duke of Edinburgh, which bore the announcement that they were from part of a series of thirty-one negatives taken in forty-two minutes.

Mr. W. C. Tweedy, Plymouth. — This exhibit consisted of a number of views, some of them embracing an exceedingly wide angle They are entitled "Experiments in Panoramic Photography."

Mr. H. Yeo, Union-street, Plymouth. — Mr. Yeo is evidently a master as regards the taking of children, of which this formed one of the most charming collections to be met with. Some are enlarged and are skilfully coloured.

The Eastman Photographic Materials Company had an imposing exhibit which occupied one entire side of the room. The leading feature in their exhibits was soliotypes, plain, burnished, and enamelled, mainly in rich purple and black tones, and in every size from twenty-two inches downwards. The capabilities of solio paper have never before been so well illustrated. This firm exhibited for the first time specimens on their new Nikko paper. The tones of these are of a peculiarly warm and brilliant character. The various exhibits are from negatives by Lafayette, Dublin; Brown, Leicester; Yeo, Plymouth; and several by American photographers.

M. & T. Scott, Edinburgh.—Several excellent enlargements from negatives by Warneuke, Glasgow; Hawke, Plymouth; Ellis, London; Heath & Bradnee, Exeter; and Villiers & Quick, Bristol.

O. Sichel & Co., London.—Two good enlargements from negatives respectively by Byrne & Co., Richmond; and Cox & Durrant, Torquay.

W. Scorer, Havant.—Direct prints of Netley Abbey and Portsmouth Town Hall, taken on plates 30 × 24 inches.

The Sandell Plates were well represented by numerous scenes, groups, interiors, and other subjects, prominent among them being *St. Mark's, Venice; A Royal Vinery; Frogmore; Dean Stanley's Tomb*, &c.

Messrs. Benthall & Co. exhibited their ingenious simplex camera stand, of which we gave an account a few weeks since.

Messrs. Geo. Houghton & Sons showed Clement & Gilmer's telephoto lens in brass and aluminium, together with the well-known shuttle hand camera.

Beale's Non-Actinine had a prominent place on the table, and the albums, frames, mouldings, backgrounds, and other exhibits of Sichel & Co. were well to the front. This last firm also exhibited a portrait camera for 15 × 15 plates, and an outdoor camera expanding to fifty inches.

Messrs. Taylor, Taylor, & Hobson had appliances in the shape of a camera front fitted with flanges and lens mount showing their system of perfect screw attachments.

The new developers were in good display. Messrs. Fuerst, Leblanc, Morgan, and Haussmann were present to impart information when required.

Messrs. Geo. Mason & Co. showed a model of a singularly compact projection lantern, believed to be the smallest practical lantern that has yet been seen. The catalogue of this firm now forms quite a thick volume.

The following are the papers that were read:—

RECENT DEVELOPERS.

By E. J. Wall.

A writer in one of the journals lately said, "On what grounds and to what purpose this eternal puff of the most recent? Is there a 'fashion' in photography that we must all betake ourselves to the last *haute nouveauté* or proclaim ourselves slovens? Amidol! metol! glycin! These are 'the only wear,' and the old clothes are gone to the ragman! But suppose that the old should be better?" I think possibly in the last sentence we may find the reason why we have "this eternal puff," or, I would rather say, this eternal experimenting with new things. I take it

that there is a general feeling of a desire for progress, whether in technique or art, and that to this desire we must put down the craze for the last new developer, the latest lens, and the latest printing process. If some such healthy feeling did not exist, photography would not have made the progress it has done in the last fifty years.

To our professional brethren who, when working in the studio, may be said to work practically under given conditions, not the least of which is to turn out good work which shall remunerate him suitably for his skill, his time, and outlay, there is possibly not so much temptation to experiment, especially when experimenting may mean increased expense without any increase of revenue; but to the amateur, to whom expense is possibly not so much an object, and who firmly believes that he may yet discover a panacea for all ills of under or over-exposure, or careless or ignorant working, there is a very strong temptation to exchange "old lamps for new."

One of the subjects which has claimed no small amount of attention since our last happy meeting in Edinburgh is that of the new developing agents—amidol, metol, and glycin—and I propose to summarise the results of a few experiments which I have made.

The number tablet of Warnerke's sensitometer was used as a convenient subject to expose with. The light chosen was a Welsbach or incandescent gas burner, the supply of gas being passed through two governors to regulate as far as possible the supply. Commercial plates marked with one batch number and one speed number were bought, and exposed one after the other as quickly as possible, and then treated with the various developers.

Mr. Bothamley's standard pyro-soda developer was used for the pyro to obtain a standard. The other developers were modified to try what was the effect of modifying the proportion of the constituents of the various chemicals.

Amidol is a salt of di-amido-phenol, and is fairly soluble in water, forming a slightly acid solution. It is far more soluble in solution of sodium sulphite, and with a saturated solution it is possible to get as much as sixteen grains of amidol dissolved in every ounce.

The distinctive feature of amidol is that it forms a very energetic developer in conjunction with sulphite without the addition of an alkali, and for this reason alone I think it is worthy of consideration as obviating any chance of frilling, which was not unknown with eikonogen and hydroquinone when used with caustic alkalies.

The first method of using this developer, suggested by the makers, was to prepare a stock solution of sulphite and amidol, and dilute as required. Such a solution, however, has, I think, given rise to some of the contradictory statements we have heard about this developer, but it is now generally accepted that keeping it in this form is certainly not the best way of using it, and I have here a negative which fully bears out this idea. A plate exposed in a studio was cut in two, and part developed with a freshly made solution, the other part developed with a similar solution three weeks old. The difference is so striking as to need no comment to those who see it: the one part, that developed with fresh solution, is dense; the other, developed with old solution, a veritable ghost. As amidol is readily soluble in water or sodium sulphite, there is not the slightest difficulty about making a solution up as required.

Coming now to practical tests, I have tried the addition of varying quantities of sulphite, amidol, and bromide, and I will summarise the results I have obtained.

The normal developer used was amidol, 1; sulphite, 10; water, 100. In this the image appeared in 10 seconds, and development was complete in 5 minutes. Increase of sulphite in the proportion of 15, 20, 30 merely reduced the time before the appearance of the image and the time of development, but when over 20 parts of sulphite were used the plates fogged very quickly. Increase of amidol also accelerates the appearance of the image, and enables one to obtain density very readily, and I may here state that, with some plates I have tried, the amidol has to be increased to the extent of 10 to 15 grains per ounce before sufficient printing density could be obtained. Dilution of the developer with water delayed the appearance of the image, and tended to thinness of image, though this, of course, can be compensated for by developing longer.

The addition of bromide in small quantities—that is, up to about 1 grain per ounce of developer, seemed to have little or no influence, but in larger quantities to the extent of 8, 10, and 20 grains per ounce, the appearance of the image was enormously delayed, and, notwithstanding a development protracted to over six hours, neither density nor as many numbers could be brought out. So far, I think that a more certain and reliable restrainer will be found in the use of a weak acid, such as citric or acetic.

The influence of the temperature of the developer was tried as follows: A developer was cooled by means of ice till it registered 35° Fahr. In this the image appeared in ten minutes, and took one and a half hours to gain anything like reasonable density, and was then finally too thin. A developer of the same constitution was heated to 70° Fahr., and the image appeared almost the instant the developer touched the plate, and development was finished in two minutes, the plate being slightly fogged.

I have here two negatives developed with amidol, kindly made for me by Mr. Beckett, of Hackney, as examples of ordinary studio work, and he says that negatives developed with amidol or metol do not require so much retouching as pyro-developed negatives, and, as he does the best part of his own work, he ought to know. I hand these round specially for the benefit of our professional brethren.

Finally, it has been said that plates for development with amidol require less exposure than for pyro. This I cannot believe; I have made a series of very careful tests, cutting exposures down, and I have not found that amidol will fetch more out of the plate, it will not fetch out what is not there, but what it will do is to flash the image up and give far softer results, which are more amenable to after-treatment than the harsh negatives so often yielded by pyro with under-exposed plates.

It has also been recommended to use amidol in conjunction with metabisulphite of potash and an alkali. So far my experiments have only enabled me to obtain a filthy mess of a developer, and magnificent examples of dichroic fog, but I intend to try it with other plates, because all plates do not require or stand exactly the same method of working.

It seems to me to be absurd to suggest the use of an alkali when we can get such excellent results without it; but Dr. Stolze suggests keeping a stock solution of amidol and metabisulphite, and then at the moment of using neutralising with bicarbonate, not carbonate of potash, but so far I have not been able to obtain better results with this than by dissolving the amidol in plain sulphite just before use.

Metol is the sulphate of methyl-para-amido-meta-cresol, and is a glistening powder of faint buff tinge. It is soluble in water to the extent of two and a half parts—100 of water. In solution with sulphite, it forms a colourless solution, which keeps its developing power, so far as I can see, unchanged, thus having the advantage of amidol in this respect. Like amidol, it develops without the addition of alkali when used with sulphite, but the images are extremely thin and weak. The alkaline carbonates of potassium and sodium may be used, and of the two potash gives a quicker developer and rather more density, soda having a tendency to a slower development and softer results. Bromides act in small quantities merely by delaying the appearance of the image and prolonging development. I developed some plates with eight to sixteen grains of bromide to the ounce of developer, and with the latter quantity the image was twenty minutes in making its appearance, and, after six hours' development, only four numbers were rendered visible. In small quantities, however, bromides seem to have far less action than with pyro and some of the other developers.

A normal developer may be considered to be one containing metol three grains, sodium sulphite thirty grains, carbonate of potash or carbonate of soda fifteen grains to every ounce. If distilled water be used, there is no necessity to use so much sulphite, and I have not been able to detect that the omission of the sulphite has any ill effect on development beyond a slight tinge given to the gelatine. Increase of the alkali tends to produce harder results, that is, the higher lights are denser than the lower. Dilution with water produces greater softness, whilst increase of metol causes again greater density.

Testing as to the influence of temperature, I found that at 35° Fahr. development was unduly protracted, and only thin images obtained, but in no case could I get a lower number, whilst heating the developer caused fog. I again tried with metol to see whether it brought out more than pyro, or, in other words, whether it permitted of a reduction of exposure, and I am compelled to say that my results were distinctly contradictory to this statement. The main advantage of these two new developers is that within reasonable limits, in fact, I do not think I should be far out if I said it was impossible to obtain that hardness which is so easy to obtain with pyro and slight under-exposure.

Glycin is oxyphenyl-glycin, and is a pinky, salmon powder, smelling strongly of carbolic acid, not very soluble in water, and more soluble in sulphite solution or an alkali, when it forms a colourless solution, which seems to keep well as a normal developer. I have used glycin five grains, carbonate of potash twenty-five grains, water one ounce, and find that diluted with water or addition of bromide gives far more transparent

negatives. It is characteristic of glycin that it requires no addition of bromide in order to give negatives absolutely free from fog under conditions and with plates, that with amidol, metol, and pyro invariably gave fog. It is, in its action, I think, more like ferrous oxalate than any other developer, and should be useful for black-and-white work, and I have used it for this purpose with excellent results. I have not used it so much as metol and amidol, but am inclined to think it is less useful for landscape and portrait work than the others, though for plates overexposed in the field I have obtained some capital results by using a very weak glycin developer, in the proportion of glycin one and a half grains, potash carbonate twelve grains to the ounce, and allowing plenty of time for development.

Of these three new developers, I think the one that will find most favour is metol, because it is more akin to the older developers, in that it is used in two solutions with an alkali. All of them are applicable to bromide paper and transparency work, but I must confess that so far my use of them for this purpose has been so small that I am loth to say anything about them.

Within the last two months yet another developer, reducin, has been announced, which, like amidol, requires no alkali, and it is quite possible that we are by no means at the end of our list yet, and that thanks to the energy and researches of our German friends, we may be blessed with still more tools to play with.

I have, of course, condensed my remarks, and I have not brought down any experimental plates, though I had intended to do so, but I thought it would hardly interest you to look through between 150 and 200 negatives. Nor have I in any case tried for what Messrs. Hurter & Driffield have defined as a perfect negative. I have tried these developers from the same standpoint as a man in practice would use them, but I hope I have said sufficient to prove that it is worth while giving the new-comers a fair trial, even if it is not found that they will oust our dirty old friend pyro.

Since the above was written, Messrs. A. & L. Lumière's paper, read before the Société Française on June 2, has been published, and I briefly summarise it. They suggest the use of the oxalate of di-amido-phenol as preferable to the chlorhydrate, which is one of the commercial forms of amidol, and the oxalate is formed by them by double decomposition of potassium oxalate and chlorhydrate of di-amido-phenol. The one is, of course, well known to you all, and the latter is amidol Hauff; 20 parts of this dissolved in 200 parts of water, and mixed with 19 parts of oxalate of potash dissolved in 200 parts of water gives a solution containing 21·5 parts of oxalate of di-amido-phenol. This salt is sparingly soluble in water 1 in 2000, but far more soluble in sodium sulphite solution, and by means of this it is possible to get a concentrated solution. A 2 per cent. solution of sulphite will dissolve 1½ per cent. of oxalate of di-amido-phenol, a 5 per cent. sulphite solution dissolves 3 per cent., a 10 per cent. 5½ per cent., and a saturated solution 7 per cent.

Messrs. Lumière state that increase of the strength of the di-amido-phenol above 3 per cent. gives no increase of energy of the developer. A very few drops of 10 per cent. solution of ammonia accelerates very much without giving any fog, but that with larger quantities of ammonia a general black fog is produced. A few drops of 10 per cent. solution of acetic acid is the best restrainer, small traces of bromide having but little effect.

Finally, they suggest the following formula for instantaneous work:—

Oxalate of di-amido-phenol		5 parts.
Anhydrous sodium sulphite	30 to 40	,,
Distilled water	1000	,,

For time exposures reduce the quantity of sulphite to ten to twenty parts.

The advantages of the oxalate salt are that both in the solid and liquid state it is more stable, considerably less sulphite is required, which, from an economical point of view, is not to be despised, and, finally, it will not stain the skin.

I only received the number of the *Bulletin* containing this paper last Tuesday, and have not, therefore, had much opportunity of doing more than try the method suggested by Messrs. Lumière, but I have tried it both with amidol-Hauff and amidol-Andresen, and find it certainly workable, and I think it will prove to be in practice an advantage, and for those who would like to try it I suggest the following rough-and-ready formula:—

Dissolve 20 grains of amidol in ½ ounce of distilled water, add 80 minims of the normal 1 in 4 oxalate solution as used for ferrous oxalate developer, then add from 1 to 2 ounces of 1 : 3 solution of sodium sulphite, decant or filter from any precipitate, and the developer is made.

I had hoped to have been able also to make some mention of the method of developing plates with gelatino-silver emulsions, as suggested by Dr. Jenney, which has appeared in several photographic journals during this last month; but, whilst I have only just had time to concoct the awful mixtures suggested, and try them for about a dozen plates, I am unable to say anything for or against because of such few experiments; but it is certainly a promising field for experimentalists, and the process may prove yet another valuable assistant in practical work for obtaining pictures.

Mr. L. E. Morgan did not agree with the statements as to the reduction of exposure by means of amidol. If they were going to use amidol, the exposure must be reduced very much. Taking pyro as a standard, the reduction must be one half.

Mr. Birt Acres found that with a very weak pyro developer he could get everything he desired. The negatives just shown appeared to him to be flat.

Mr. Cembrano thought that they could get a softer picture with pyro than with anything else.

Dr. Mitchell said his impression was that the new developers at present offered no advantages over pyro. He felt there was a strong reducing power in them, however; but, as yet, it was like the task of chaining lightning to bring them down to the practical uses of photography.

Mr. A. F. Mowll thought they could not judge as to the printing qualities of the old and new developers, as one had to be made more dense than the other.

Mr. Sturmey considered that amidol should be used rather as an assistant to pyro than to its exclusion. The two combined had given him the best results he wished for.

Mr. Henderson thought they were simply working in the dark with regard to new developers.

The President was inclined to the belief that pyro negatives, if well worked, were to be preferred to any other.

In replying to the discussion, Mr. Wall said the new developers had the advantage, that was much as it required a great deal of training and experience to get good results with pyro, anybody could succeed with the former.

LANTERN-SLIDE MAKING.

By Charles L. Mitchell, M.D.

The preparation of lantern slides is a subject upon which so much has been both said and written within the past few years, that it would seem almost impossible to say anything new. And yet, notwithstanding this, the number of really *good* lantern slides made bears but a small proportion to the entire amount produced, or to the large quantities of plates, &c., used for their preparation. So that it seems, perhaps, after all, something might be still said on such a trite and commonplace subject. Having, during the past few years, occupied much of my time in lantern-slide making, I have acquired considerable familiarity with the different methods usually employed in America, and also made some modifications of my own, so that, while not pretending, in the limits of the present paper, to give a complete *résumé* of the subject, it may be of interest if I detail, in a general way, the methods mostly in use by American lantern-slide makers.

The vast majority of lantern slides made in America by amateurs are prepared from gelatine plates, collodion emulsion being very little used, and wet collodion being employed by but few outside the regular commercial slide manufacturers. Perhaps this may be partly explained by a prevailing fondness for the black and grey tones, so easily obtained with gelatino-bromide emulsions. There is, however, a rapidly growing taste for warmer tints in brown, and even sepia, or Bartolozzi red. Quite a number of different brands of lantern-slide plates are found in our market, and of varied excellence. Of these, those prepared by the Eastman Company are probably the most popular. I have always used gelatine dry plates for preparing my own slides, and I am a firm believer that, all things being equal, it is quite possible to prepare as good, if not, perhaps, even a better slide upon a gelatine plate than can be obtained by any other procedure, while its convenience and readiness for immediate use render it much to be preferred.

The size of the American lantern-slide plate is always $3\frac{1}{4} \times 4$ inches, thus differing from the English size, which is usually square, and $3\frac{1}{4} \times 3\frac{1}{4}$ inches. We in America think the oblong shape the best, as it allows of a rather larger picture, gives ample room for the label, and also for taking hold of the slide when placing it in the lantern. We can hardly expect in a country like England, where customs are firmly established, that a change of size would readily be adopted. And yet it is highly desirable, in view of the growing interchange of slides between not only England and America but also with other countries, that some one standard and uniform size for all should be adopted. The present difference often leads to considerable annoyance on account of fitting the

varying sizes into the carriers generally used for the lantern. This difficulty is less in America, however, than in England, for it is always easier to put a small slide into a large carrier than it is a large slide into a small carrier. I notice, indeed, that one English photographic periodical has announced that in future it will receive no slides for competition unless made of the uniform size of $3\frac{1}{4} \times 3\frac{1}{4}$ inches. This is much to be regretted, for it would seem possible in such cases to use an ordinary "push through" carrier, and I hope the example will not prove contagious, for it will tend to check these international exchanges and competitions, and prevent many on each side of the water from becoming acquainted with the best examples of well-known workers.

In the preparation of lantern slides I believe that the majority of our best workers in America prepare their slides by reduction in the camera. I have been informed that in England the reverse is true, the larger number being prepared by contact. I think this difference may partly be ascribed to the fact that the sizes of negatives adapted for contact printing ($3\frac{1}{4} \times 3\frac{1}{4}$ and $3\frac{1}{4} \times 4\frac{1}{4}$ inches) are not as popular in America as they are in England. We do not use the $3\frac{1}{4} \times 3\frac{1}{4}$ size at all, and for all small work the most popular size is 4×5 inches. This does not lend itself so well for contact work, and hence the reducing camera is more frequently brought into requisition. My own preference is unquestionably for reduction by the camera, even when preparing slides from small negatives. There seems to be a certain quality gained which is sometimes missing in contact work, and, in addition, the process affords many facilities for shading or vignetting different parts of the negative which may need either holding back or prolonged exposure.

The character of the light used is also another prime factor. In my own experience I use two different lights—a south light, where full sunlight falls directly upon a ground-glass window; and a north light, where the window is of clear glass and at an angle of about 45° to the horizon, thus securing an even, soft illumination all over the negative. I use one or the other of these lights, according to the character of the negative, as will be detailed later.

Returning again to the subject of lantern-slide plates, I may say that I do not believe it possible, when using all varieties of negatives, dense or thin, to obtain uniform excellence with one grade of plate. This would stand to reason, for a slow landscape plate will give a different negative from one made with an emulsion of high rapidity. I therefore use two grades of plates, one quite slow, giving great contrast, the other several times as rapid. In the former I use the Eastman plate, for the latter the transparency plate made by the Cramer Dry Plate Works, of St. Louis, Mo. These two varieties are used as follows:—Given a very strong, perhaps even harsh, negative, quite dense, and yet with plenty of detail. In order to bring out all the best points of the negative, a strong, intense light is required, and nothing but sunlight seems to answer the requirement. A weaker light will not penetrate the dense portions of the negative, and the corresponding parts of the positive will lack detail. Furthermore, the negative probably possesses too much contrast already, and the endeavour should be to reduce this contrast, and at the same time obtain all the detail possible. I therefore use here the fast lantern-slide plate, and fully time the exposure, using a diluted developer. The harshness of the negative is thus materially reduced in the positive, and the rapidity of the plate makes it more susceptible to the weak light coming through the dense portions of the negative, and thus renders the detail properly. Lantern slides made in this manner are usually quite warm in tone.

Now, on the contrary, suppose a soft, thin negative full of detail, but with comparatively little density. Here the advantage of the slow plate and the soft north light becomes apparent. This soft, even illumination is amply sufficient to penetrate any part of the negative, and yet, not being so intense as the sunlight, does not so rapidly overtime the plate. The slow lantern-slide emulsion is amply sensitive enough to render the detail perfectly in all parts of the negative, and with a moderately short exposure gives good contrast and brilliancy much exceeding that of the original. It is thus possible to obtain from an inferior negative quite a crisp and brilliant lantern slide. The tones obtained by this method are usually grey or black.

For a developer, I use a mixture of eikonogen and hydroquinone in the proportion of fifteen parts of hydroquinone to eighty-five of eikonogen. Eikonogen by itself does not always give the brilliancy or the density desired, but this is easily obtained when a small percentage of hydroquinone is added. The development of a lantern slide is an entirely different matter from that of a negative. In the latter, the time of exposure, and the intensity of the light, are always, to a certain extent, unknown factors, and the developer must be modified according to the necessities of the case. With the lantern-slide plate, the developer, as far as regards the proportion of reducer and alkali, is always the same, so also is the lighting of the negative. The developer should, therefore, be of a standard strength ascertained to give the best results with a normal exposure, and then, when making the exposure, it must be shortened or lengthened until the desired result is obtained. It will not do here to give a short exposure, and then push development by adding more alkali. The plate will soon fog, and an amount of fog which might perhaps be allowable in a negative would be fatal for a good lantern slide. Nor will it do to overtime, and then restrain development with a bromide, for we will be apt to get harshness, much density, and opacity in the shadows, all fatal defects for a good slide. What should be sought is a correct exposure, then a normal developer, and as the former is always under our control, it is better to reject a few plates and change the time of exposure until we have it just right, than it is to attempt to modify the developer.

The question of tone here comes in for consideration. This is a matter influenced, first, by the plate, next by the developer, next by the character of the light, next by the exposure, and, lastly, by the negative itself. As I have before remarked, the cool grey and black-and-white tones are preferred by many in America. There we use eikonogen, hydroquinone, ferrous oxalate, or pyro soda—all developers producing black or grey tones. The warmer tones in most of the slides made by English workers are, I am told, due largely to the use of pyro and ammonia as a developer. Still, for true warm tones gelatine can hardly be made to equal those obtained with collodion emulsion, either washed or dry. It is quite possible, however, with a strong negative, a sunlight exposure, a little over-timing, and a developer well diluted with water, to obtain quite warm tones with an ordinary gelatino-bromide emulsion.

As far as regards fixing, there is nothing superior to the acid fixing bath, now so well known. It prevents staining and clears the plate thoroughly.

The plate should always be varnished, to protect it from the effects of moisture. I use for this purpose the "Zapon" varnish, a solution of nitro-cellulose in amyl-acetate and wood alcohol.

As regards matting, the square opening, with rounded corners, is used by us for all commercial slides. Amateurs who make their own slides vary the opening, however, making it oblong, upright, oval, or round, according to the artistic treatment of the picture.

In labelling the slide, a thumb label is placed on the lower left-hand corner of the face of the slide, while the descriptive label is placed on the opposite end (right hand), sometimes on the face, but more usually on the back of the slide.

Much might yet be said regarding the arrangement of the negative, apparatus for varying its position (so that either the whole or but a portion can be used, the choice of lenses, varieties of cameras for reducing purposes, &c., but it would occupy too much time. The few extremely general remarks that I have made on the subject of lantern-slide making will, I trust, serve to indicate some of our most usual methods of working, and present, perhaps, one or two novel modifications of the orthodox and regular modes of procedure.

After some desultory observations respecting the relative advantages of the American and English sizes of lantern slides,

The President said that, on a commercial scale, the wet-collodion process was the only method by which uniform tones could be obtained.

ARTISTIC EXPRESSION WITH THE HAND CAMERA.

By J. Guardia.

At this period in the history of photography, when every user of a camera is sorely puzzled to know whether his work is fine art or not, it seems to me useful, now we are assembled here, to pause a few moments and conwhere we stand and whither we are drifting.

While some writers claim for photography the highest artistic possibilities, others quite as strenuously assert that it is but a mere mechanical process, admitting of no variation in the hands of different workers, and therefore unworthy to rank as an art at all. Now, I think that the truth here lies, as is so often the case, midway between the two extremes, and that we should rather say that, though photography as generally practised is not an art, yet artistic expression is not impossible to photography. Further, if we admit, as I am afraid we must, that photography has not as yet realised its proper sphere as an art, we may at least hope that the day is not far distant when, acknowledging its limitations and understanding its possibilities, photography will at last gain an honoured place among the fine arts.

But are we really doing anything towards this wished-for end? No, for the principles of art are order and culture, and in photography—in

the photographic world of to-day—nothing but disorder and confusion, yes, and ignorance too, prevail.

I am not now speaking of the great majority of people who "dabble in photography"—who go about the country securing pleasant mementoes of the places they visit, with the sole aim of amusing themselves and entertaining their friends. They are quite right in what they do, for, after all, they stick to what will always be the most popular side of photography—*photography as a mechanical process*, in which good apparatus and dexterity of hand are their own reward. Neither, of course, am I addressing myself to the select few (real artists at heart) who are, each for himself, earnestly trying to find a clear path out of the difficulties which photography is constantly setting before them. Their work bears the seal of their strong individuality, and is, therefore, truly artistic.

But I am speaking of the general body of photographers, whom you may see at our clubs, who often write in our papers, who cram our exhibitions with their worthless productions. There is not one of them but thinks himself a born artist. But look at their work, and you will see no art at all—merely a weak imitation of some other art by means of photography. And this work is turned out in cart-loads, and is bemedalled by omnisapient judges, and crushes out any real pictures that may have strayed amongst it. What wonder that in the end artists merely laugh at us!

Our photographic world is chaos. We are all authors, publishers, and readers; artists, critics, and judges. We elect scientists to decide weighty questions of art, and artists prattle about chemical problems. We all know so much that we are always quarrelling, and we only unite to howl down any man who shows a little originality, and who strives to rescue us from our slough of despond. There are men abroad who, before they bought a camera, had never even stopped to consider that there was such a thing as art in the world, and who, probably, have not seriously studied a single word about it since; but their fingers were deft, and they produced negatives beautiful to look at, and which earned them a goodly show of medals. And, lo! one day they issue forth past-masters in high art. Other foolish people, after years of deep study and constant work, hopelessly exclaim, "Art is long, and time is fleeting." Not so our facile photographer; he masters it all in a few months.

We clamour to be recognised as artists, but the bulk of the work at our exhibitions shows nothing but our absolute lack of taste. To select two samples only. Take first what we are pleased to call a "genre picture." How is it done? You begin by placing the cart before the horse, *i.e.*, by first selecting your title, and then looking around how to construct your work of art. Some figures are now more or less gaudily dressed and stuck in impossible attitudes before an impossible background, and the *chef-d'œuvre* is accomplished. The result is applauded by the general run of photographers as a marvellous feat—a wonderful inspiration. To a person of taste such productions seem eminently absurd; in fact, when they happen to represent historical subjects, the effect is often so incongruous that the authors themselves must at times feel ashamed of their own work.

A particularly mistaken class of *genre* pictures is that which results from "double printing." Although this has enjoyed the advantage of being practised by some exceedingly clever people, their very best results have only served to prove that such tricks are entirely out of place in photography, and that nothing will ever be gained by these efforts to mimic methods which are legitimate and admissible in painting and allied arts only.

Another proof, if one were needed, of the bad taste displayed by photographers is to be found in the mounts they use. We need not mention the wonderful green and chocolate bevel-edge enamelled cards on which the professional fixes his perishable productions. No one has ever called the ordinary portrait-taker an artist, except himself; but let us consider the mounts patronised by the "artistic amateur." Where could one find a more glaring proof of his incompetency to make photography a fine art than the "plate-sunk" mounts to which he consigns *his* efforts? What on earth a plate-mark has to do with a silver or platinum print, I presume, no one has asked himself. We have here a deliberate fraud—a confession on the part of the man that he distrusts the art he practises, and an attempt to make people believe that what he is showing them is not a photograph.

This affectation is not art, and can do us no good. If a plate-mark is essential for our work, let us have real one; let us print in photogravure.

Fault-finding is an unpleasant task, and I do not intend to continue in this strain. I think, however, that what I have said may account to some extent for the contempt which photography is experiencing from painters and other artists, who should be, and may yet prove, her best friends. It seems to me that artists have not taken photography seriously at all as yet, but how can we wonder at it when to the majority of photographers themselves a camera is only a plaything, and photography but a joke. My work of destruction having ended, I will attempt to explain the path which I think we shall have to follow when we clearly understand the nature of photography and her only true sphere of action as an art.

That photography, an invention little more than half a century old, should have so quickly spread throughout the world, and should be practised with equal enthusiasm by persons so different in temperament, position, or education, it must have something in its very essence which supplies a universal want, or gratifies some feeling which all civilised men share in common. The love of beauty in nature is more general than one is likely to suppose, and the very feeling which finds its loftiest expression in our great painters is but evolved from the unconscious efforts of primitive man, and, in fact, arises from tendencies inherited from our animal ancestors. As Professor Baldwin Brown so aptly explains:—"On every grade of his being man possesses an ideal self-determined life, existing side by side with, but apart from, his life as conditioned by material needs. This life expresses itself in, and is nourished by, various forms of free and spontaneous expression and action, which on the lower grades of being may be termed simply 'play,' but on the higher grades take the shape of that rational and *significant play* resulting in art." Now, I think we may readily admit that the success of photography is due to its having given us an easy means to satisfy that desire for "play," that wish to forget the troubles of our daily labours which, as we have seen, is natural to us; or to its having made it possible to everyone to express by his unaided efforts whatever artistic feelings he may have acquired through natural disposition or education.

The foregoing remarks, while explaining the wide popularity of photography as a *pastime*, give us no gauge of its merits as an *art*. That photography *can* be made an art we need not waste much time in asserting. As Nadar recently said:—"Why should photography not be an art, considering that, in copying nature, the painter, the draughtsman, the sculptor, and the photographer all aim at the same goal? Why should we trouble about the means employed if this reproduction of nature awakens in us the same impressions which we felt when looking at nature itself? The superiority of the painter, the draughtsmen, and the sculptor would seem to consist in their power to create. But the use of the palette gives of itself no more right to the title of work of art to any reproduction of visible objects than does the employment of a camera. Photography is in itself a science and an art, and, above all, a means to an end. Its results essentially depend from the taste, the artistic knowledge, and the temperament of the worker."

In forming an estimate of photography as a means of artistic expression, and in accounting for the unfavourable attitude which the general body of artists preserves against us, the enormous disadvantages which artistic photographers have had to contend, and are still contending with, should not be lost sight of. These are disadvantages which, in the nature of things, could scarcely be avoided in the early days of the new art, and which are now being rapidly overcome, and will, no doubt, soon entirely disappear. The principal difficulties which retarded photography in its progress as a fine art were—(1) The low sensitiveness to light of the materials employed, requiring long exposures, and (2) the inadequate nature and unmechanical construction of the apparatus used. The speed of plates has enormously increased within the last few years, and manufacturers are even now vying with each other to turn out plates of greater and greater sensitiveness. With regard to a more correct rendering of the different colours, however, much remains to be done. Celluloid films also promise considerable advantages over glass plates, though they are as yet scarcely perfect enough for the best work.

But it is the old apparatus which must bear the greater part of the blame for the low position which photography still occupies as an art. Lenses, it is true, have long been perfect enough, especially since the introduction of Jena glass. If the lenses generally used are of too short a focus, as undoubtedly is the case, the opticians are not to blame. In shutters, too, the photographer has been fortunate to secure the services of the highest mechanical skill, and though the modern shutter is a comparatively new creation (called into life by the increased sensitiveness of dry plates), it is already, both in speed and efficiency, well in advance of the present requirements of photography. With cameras, however, the case is very different. Designed originally by incompetent persons, they have remained to this day the evident production of cabinet-makers and carpenters, whose only improvements during fifty years may be said to be the substitution of the shaky bellows camera for its steady but ponderous sliding-box ancestor, and the addition of simple movements, like rising front and swing back. The same type of apparatus has been adhered to,

not by a few, but by all makers, and this, not only in the early days when the slow processes employed demanded nothing better, but long after plates had reached a high degree of sensitiveness. For fifty years photographers have had to carry about bulky implements, necessitating the use of a strong stand, and requiring long delays for setting them up ready for work. What wonder, then, that photography never reached its proper province among the fine arts—*the representation of life in nature*, with all its beautiful but evanescent phases and movement, which has only now become possible, thanks to the modern hand camera.

"Fine art," says Ruskin, "is that in which the hand, the head, and the heart of man go together." What chance has the hand, the head, or the heart with a 15 × 12 field camera, and a tripod weighing five pounds? Before hand cameras were invented, what was the aspect of nature as recorded by photography? A dead maze of trees, and fields, and buildings. The rivers and lakes showed no ripple; they were merely a mass of glaring white. The streets were deserted, and tenantless houses were but a mockery without reason. The beauty of cloud and atmosphere was unknown—was represented by acres of white paper. Here and there a group of soulless caricatures of human beings were, indeed, to be seen, all stuck up in constrained attitudes. Not breathing, and moving, and palpitating with life and energy, but either blurred out of all recognition or fixed in unnatural poses, like wax dolls glaring at nothing—"puppets without muscles, and silhouettes without substance." Such was the world as depicted by the slow exposures of the old photography—an inane reiteration of topographical notes, or a spiritless multitude of lay figures in Sunday clothes.

But, with the advent of the modern hand camera, all this has changed. The ripple on the water can be seen and almost heard; clouds, fleecy or heavy, float across the sky; the elegant movements of the swiftest animals are recorded; bustling crowds of men, women, and children are shown to us, picturesque in their ever-varying, unconscious attitudes in the course of their daily occupations, their toil, or their play. The traveller to distant countries will no longer bring uninteresting records of ruins and desert solitudes, but animated pictures of the life, the troubles, and pleasures of the whole human race, from the tropics to the polar regions. A hand camera, ever ready, easy to carry, and able to withstand all changes of climate and vicissitudes of travel, will help photography to outstrip the other arts in the representation of all the evanescent phenomena of nature, in making nations know and understand one another, in furthering the brotherhood and union of the human race. Useful to every one in indelibly recording what he sees, it will help the stay-at-home to portray his friends in familiar and natural attitudes, the traveller to bring back living records of his wanderings, the artist to show us nature as he sees it, deprived of its ugliness, and with its beauty enhanced.

This, then, is the true sphere of photography as a fine art. Creation is impossible to us, let us therefore leave this to other arts. But we still have the great power of *selection*, and of showing our good taste and artistic feeling. Let us cultivate this to the highest pitch we can attain, and employ it in the representation of life, and movement, and beauty of form in nature; a field large enough, and one which the other arts cannot touch. We shall then be doing good and useful work—work that will live.

The course which we should follow in our aim towards artistic perfection is, I think, clear enough, but to follow it means hard work. Let us be true to ourselves, always willing to learn from others, but doing what we honestly think right, whatever the uneducated multitude may say. Let us study nature, for it is the fountain-head of all beauty. Let us cultivate art, that we may improve our good taste.

There is no reason whatever why we should not photograph everything that interests us, whether it is a picture or not; but let us acquire sufficient practice and knowledge to be able to see and secure a beautiful pose or subject whenever nature unexpectedly presents it to us in the course of our rambles. In order to do this with certainty, we must not only use good tools, but must gain great skill in using them. But let us never forget that tools and skill are but means to an end.

I should like to see the day when a photographer only shows *as pictures* one or two of the very best photographs he has taken during the year—when he does his utmost to make these as perfect as possible, by carefully enlarging them, if necessary, by printing, mounting, &c.

Let us have exhibitions of such selected work, let it be judged by *trained* artists, and then we shall stand a chance of proving that photography can be made a fine art, for artistic expression is possible by means of the hand camera.

Mr. R. Keene, alluding to the remarks about the plate marks in the mounts, considered that they were frequently a great improvement to a photograph.

Mr. W. M. Ashman thought it might not possibly be known to Mr. Guardia that in former times streets could be photographed without being perfectly desolate. Skies also were not cloudless.

Mr. Traill Taylor asked Mr. Guardia how long it was since hand cameras were invented, in virtue of which such a revolution in artistic photography had been effected.

Mr. Guardia.—Five years.

Mr. Taylor appealed to Mr. Guardia, for his own sake and that of accuracy, to strike out from his paper all those mis-statements about deserted streets, clouds and atmosphere being unknown, soulless caricatures of human beings, with like statements equally devoid of truth, as well known to every one who was acquainted with the state of photography much longer than five years ago.

Mr. Mowll, too, could not agree with all Mr. Guardia had read. It required much greater intelligence and skill a few years ago than was imagined in these "press-the-button" days, and the work turned out now was not better than it was then.

Dr. Mitchell said that while artistic pictures can easily be made by the hand camera, much depended upon the man who was using it. Hand cameras were often very useful on account of their compressed bulk.

After remarks by Mr. Birt Acres and Mr. Fry,

The President had to differ from Mr. Guardia, and alluded to the high art merit of the works of Wilson of Aberdeen, Wortley, and numerous others, produced long years before hand cameras were known.

MULTIPLE FILMS.

By S. Herbert Fry.

The subject of compound or multiple-coated films is so new, and supplies so many fresh ideas for practical work, that I cannot pretend in this paper to do more than deal in a touch-and-go fashion with it. My remarks will only be valuable, if at all, for some practical suggestions as to the best methods of utilising the advantages which the principle of combining emulsions of differing characteristics and speeds into one film offers.

Novelty.

Although it would, perhaps, be safer to say that, for the prevention of halation, multiple films in gelatine emulsions are rather the result of a happy thought than an entirely new idea, yet, as far as a practical manufacture is concerned, there is, I think, little doubt of their absolute novelty. Experimentalists may have dreamed of some such thing; as, indeed, of what have they not? but it has not hitherto become a realisation.

Still, we have in the old collodio-albumen dry plate a compound film consisting of a collodion bath plate with an albumen sensitised film placed on top of it, and one of our veteran workers, Mr. Forrest, of Liverpool, only a few days since, spoke to me most eulogistically of that old method, and hopefully of the multiple gelatine film for sympathetic reasons.

That process is not only beyond my recollection, but probably there are few in this room who had any practical acquaintance with it.

Manufacture.

In making a multiple film dry plate, a coating machine may be said to be necessary to secure a regular flow of emulsion for the second and third coating. With this exception there are no technical difficulties but such as are common to the manufacture of dry plates generally. Each coating is dried before the next one is laid upon it, and the most important consideration for the emulsion-maker is to provide an emulsion with as small a proportion of gelatine to silver salt as possible.

Theory of the Film.

In determining the relative speeds and characteristics of the different films a large field for experience and experiment is open, and time alone can determine whether the present arrangement is that best suited to attain the end in view. This may roughly be stated to be the nearest approximation to a single film in which the top surface shall be of the highest possible speed, and the bottom of the film of a density-giving silver salt, an emulsion slow and dense in the highest degree. The film should gradually change from one characteristic to the other. In theory the lowest portion of the film should perfectly resist the passage of actinic light. Bolas has, I think, referred to this point in some of his recent writings, and I take it to be the ideal of a sensitive film suitable for all purposes.

Such a film, with our present knowledge, is not possible. We must be satisfied with the best substitute for it. I refer to this especially because it has been asserted that there are steps or jumps in the sensitiveness of a multiple-coated film which are ascribed to the difference in speed of the various separate coatings. I do not propose to do more than allude to this for a simple reason. An examination of the pictures

produced by the films does not, I think, reveal any obvious fault answering to this criticism. I can conceive that, were a multiple film wrongly used, as, for instance, were the top film stripped off with the idea of securing a negative upon the lower film only, then, in such a case, there might be a lack of detail due to the removal of the top layer, and this might appear to be a jump in the sensitiveness between the two films. Such a method of working is not to be recommended, and I do not purpose to seriously consider improper uses of the film. It not infrequently happens that dangers or difficulties anticipated in theory do not occur in practice. This is such a case.

As to the part played by the underlying films, I regard them as prepared to take up and usefully employ such actinic rays as fall beyond the scale of correct representation in the overlying films.

Distribution of the Image.

Let us assume a case in which the range of contrast is great, such as a dark interior with a light and bright window. Let us also assume that which, I think, is generally the case, that for such a subject an exposure upon a dry plate is more or less of a compromise between the time necessary to properly photograph the deep shadows, and that necessary for the bright lights. Indeed, if it be not so, where is the difficulty in making such pictures?

In the multiple film the image of the window will be formed upon the lowest film, and the middle tones upon the second film, whilst the details in the deep shadows will be upon the top film. In other words, the image will be distributed in a selective manner, and this can be easily demonstrated by stripping off portions of the film of such a negative, and ascertaining the action of light upon the lower films.

In the example given I have supposed that the exposure has been abnormal, that is to say, that the exposure has been made to act upon the sensitive material so as to sufficiently impress the details in the deepest shadow upon the top film, leaving the brighter portions to act selectively upon the lower and less sensitive emulsions.

It is with such an exposure that the best value can be obtained from the multiple film. It is possible that, because better effects of light and shade are produced upon a multiple film by abnormal exposures, some have considered it a matter of necessity that such films should be, in a photographic sense, slow. This is an inference not warranted by the premise, as there is no reason to believe that the top film in any way loses speed by being imposed upon a film of emulsion instead of a glass plate. Without hazarding any conjecture as to the why and the wherefore, I think that, in a pictorial sense, there will be found a greater range of gradation and more roundness, and, if I may coin a word, more stereoscopicity, of effect, with an increased (or abnormal) exposure than obtains in a homogeneous film with any exposure.

It must also be borne in mind that, with the ordinary dry plate, the effect of more exposure than will influence the region of correct representation makes for flatness of image and loss of true gradation. With the multiple film, however, it tends towards increased roundness of image. With an exposure calculated to reproduce the shadow details to their fullest extent, and which I describe as abnormal because it is more than can be usefully given to a homogeneous film, are the best results obtained with the new tool. I am disposed to suggest that this is only a natural result of the ability of the multiple film to successfully render a longer range of contrast. In other words, the sensitive film which will reproduce in natural ratio the widest range of light and shade may be expected to produce at the same time the best pictorial effect.

It is for this reason that I am entirely opposed to the idea of over-exposure and stripping the top film, a method which I regard as an indication of failure to properly understand the principle of the compound film. We are, by this method, only able to make a picture upon one of the lower films. Now, for this purpose, it is best to use such a one in its simple form, and not to risk failure by exposing through some other film, which has to be wasted. Wilful waste makes woeful want, as the old alliteration has it.

In point of fact, the useful detail of the negative will be found upon the top film, and this detail we cannot afford to lose in our negatives.

Halation.

The question of the freedom of the compound film from halation or light reflected from the posterior surface of the supporting glass plate, depends upon two points—first, that the difference in sensitiveness between the top and bottom films shall be at least as great as the difference in the value of the light reflected from the brightest and the least bright portions of the object to be photographed; and, secondly, upon the method of development employed. There can be little doubt as to the efficiency of the principle employed, viz., that the light shall be intercepted and usefully (in the photographic sense) employed by the lower film. When "backing" is resorted to to prevent reflections, it is but a makeshift method of obviating the disagreeable effects of light in the wrong place. The principle of the multiple film is to prevent the light passing into the glass or support. In actual work a triple film gives practical freedom from this defect in most trying circumstances, and that without backing.

This is not the place to discuss whether a commercial article is effective or not; but I am compelled to add, that if the difference in sensitiveness between the top and bottom films in the commercial article be not now sufficiently wide to secure without halation the most violent contrasts which may present themselves for representation, the principle still applies, and it is but necessary to lower the photographic sensitiveness of the bottom layer to perfectly effect the object. Or, as an alternative for extreme ranges of contrast, a fourth film might be added. So much depends, however, upon the method of development, that I believe three films to be ample for all practical purposes.

Exposure.

I now pass to the question of development and practical treatment of the films. There are two exposures for multiple films.

First, *the normal*, is the correct exposure for the top film, supposing it to be coated upon a glass plate by itself in the ordinary way. For such an exposure development will be normal, and precisely the same as it would be supposing the sensitive film to be of a homogeneous rapid character. That I need not discuss further.

The second exposure is one which I prefer to call *abnormal* rather than over-exposure. It will be apparent that, with underlying films of less rapidity, and each underlying film protected by a light-absorbing filter of emulsion above it, without recourse to any device in development for restraining or retarding the effects of the light action, the lowest films are capable of absorbing and using a largely extended exposure. I am informed that the relative rapidities of the three emulsions in the triple films are as 1, 4, and 30, and, when to this margin of speed which exists between the top and bottom film is added the resistance to light passage of the first and second films themselves, it will be obvious that there is a considerable available margin of latitude in exposure. The point, therefore, when over-exposure in the usual sense of the word begins, is so far away from the normal as to render it unnecessary to take it into immediate consideration.

Development.

With an abnormal exposure, development must be "tentative." There are two methods:—

First, by working with solutions of suitable energy to develop the image until sufficient detail be obtained, and then, by the liberal use of a soluble citrate, to develop up density and contrast from the lower films, in which there is a store of density-giving emulsion to which the ordinary worker is quite unaccustomed; or, secondly, to begin with a very dilute and restrained (with bromide) solution, so as to secure in the lower film sufficient density first; afterwards, if necessary, acting upon the top film with a more energetic developer, to bring out such detail as may be desired.

I am not quite certain as to which of these methods I prefer, but I am largely influenced by the fact that it is the second method which the inventor of the plates relies upon to make his pictures. I have had the pleasure, on more than one occasion, of seeing him develop 15 × 12 interiors by this method with such ease, and so much regular success, as to make me doubtful of the propriety even of mentioning the first method.

I cannot do better, therefore, than give his method, premising that the same principle applies whatever developing agent be employed. The developer Mr. Sandell prefers is a mixture of hydroquinone, eikonogen, and rodinal, as follows:—

Concentrated Solution.

Hydroquinone	30 grains.
Eikonogen	100 ,,
Rodinal	9 drachms.
Sulphite of soda	2½ ounces.
Carbonate of potassium	2½ ,,
Water to make	20 ,,

Supposing we have to develop a plate which has received, say, three times a normal exposure, generally the best results can be obtained

with from three to six times a nominal exposure. Commence development with a weak solution, thus:—

Dilute Tentative Developer.

Stock solution	1 part.
Water	15 parts.
Bromide of potassium (10 per cent. solution)	

About two grains of the latter to the ounce of solution.

This will probably begin to produce an image in from two to four minutes. The highest lights should appear first (although they are in the lower films), and density and detail should grow steadily. The important point to keep in mind is that the high light should be developed by the first solution, rather than the detail. If detail comes freely, the developer may be considered too energetic, and the remedy obvious. If detail comes but little, it is of no importance, for being within the topmost film it can be readily acted upon and drawn out by a more energetic solution, and that without there being time enough for the stronger solution to affect the density-giving sub-film. Should detail grow faster than density, then, as we can only attack the density-giving sections of the plate *through the top film*, we are forced to resort to the first method of development, viz., the use of restraining citrates and bromides to enable the solution to get down into the lower films without overdoing the top layer. But by this procedure we risk making a thicker negative than by cautious development by the second method. In developing abnormal exposures in multiple films, if there be any error, let it be on the side of a too dilute developer to commence with.

The manifest simplicity of Mr. Sandell's method should, I think, commend it, and I suggest it as the easiest one and the most reliable. In case, of need, however, density can be obtained by the first method with certainty, but it may become a little difficult to watch the action of development. By the second method, the progress of development can be easily followed, and it is not only not necessary for the image to be lost sight of, but it indicates the use of a too strong and energetic solution, or an insufficiently restrained one. The notion that with a multiple film development must be a closed book I ask you to remove from your mind. There is no such necessity, and, should the image be lost to sight, it is the clearest indication of injudicious procedure. I never expect to see any indication upon the back of a triple film of the image, and when I lose sight of the progress of development I know that it is because I have been impatient or unfortunate in my judgment. In such a case, however, with the reserve force of the multiple film a negative will be the result, where with a simple emulsion extreme flatness would be expected.

I have not mentioned pyrogallic acid development, nor do I propose to advocate any particular developing re-agent. Whichever be the reducing agent with which you are best acquainted, will be for you the right one to use. It is not the developer (the reducer), but the developer (the individual), which makes the negative. For pyro development, however, I think there is nothing better than the following:—

A.

Neutral sulphite soda	55 ounces.
Boiling water to make	10 ,,

B.

Pyrogallol	1 ounce.
Nitric acid	20 minims.
Water to make	10 ounces.

C.

Bromide potassium	1 ounce.
Water to make	10 ounces.

D.

Carbonate soda (anhydrous)	1 ounce.
Water to make	10 ounces.

E.

Citrate soda	1 ounce.
Water to make	10 ounces.

B, C, D, and E are not exact ten per cent. solution. I prefer the sulphite in a separate solution, and concentrated.

Normal Developer.

Pyro solution	20 minims.
Bromide solution	10 ,,
Sulphite solution	60 ,,
Carbonate solution	40 to 80 ,,
Water to make	1 ounce.

Tentative Developer.

Pyro solution	5 minims.
Bromide solution	5 ,,
Sulphite solution	60 ,,
Carbonate solution	10 ,,
Water to make	1 ounce

In place of this latter, the normal developer may be diluted from one quarter to one-tenth strength, although I prefer to have a larger proportion of bromide than is in the normal, and an equal strength of sulphite. The latter because, whilst doing no harm by its presence, it enables one to add stock pyro and carbonate to form a more energetic solution, without discolouring the film.

Fixation.

There is only one other point to which I need call attention, and that is, that the fixing bath should be new and strong—eight ounces of hypo to a pint of water, and fixing should not be performed on white light. An acid fixing bath works well with multiple films, both hardening the gelatine and brightening the negative at the same time. The best form is:—

Hypo	8 ounces.
Acid bisulphite soda	2 ,,
Water	1 pint.

With such a fixing bath, complete elimination of the soluble silver salts is quickly performed unless the solution is unduly cold. In this case the remedy is obvious. Warm the fixer to 55° to 60° Fahr.

SOME POINTS IN CONNEXION WITH DEVELOPMENT.

By C. H. Bothamley, F.I.C., F.C.S.

At a meeting at which so many papers on the all-important subject of development are to be read, it is difficult to deal with the matter without in some way encroaching upon the ground covered by the other writers. Apart from the introduction of new developers, few photographic questions of late have attracted more attention or excited more discussion than the relation of the gradations of a negative to the time of exposure on the one hand and the mode of development on the other. At present it cannot be said that any final decision has been arrived at as between the theory that the gradations depend only on the intensity of the light and the time of exposure, and the theory that the gradations may be modified by the mode of development.

One of my scientific friends rarely troubles himself about any energetic scientific controversy whilst it is still going on. He generally says that he will go into the question "when the dust has settled a little." He is a busy man, and his attitude in this respect is quite intelligible. It is clear, however, that if every one were of the same mind the dust never would settle, for the dust of a scientific controversy, heavy though it may be, does not as a rule subside by its own gravitation. The views that I have the honour of submitting to this Convention you will, perhaps, with your usual indulgence, be good enough to regard as a small attempt to act the part of Aquarius, and to help a little towards the settling of the dust of the controversy that is now being waged over the relation between exposure, mode of development, and the gradations of negatives. I cannot, I regret to say, lay before you any new facts; but I will venture to ask you to look at some of the old facts in a way which, if not new, has, at any rate, not received the attention that it seems to merit.

The controversy, in its present aspects, has been excited by the remarkable papers of Messrs. Hurter & Driffield, and the no less able papers of Captain Abney.

Now, in the first place, it has not been sufficiently recognised that Abney, and Hurter & Driffield are quite agreed on the main point, that the amounts of silver reduced at different parts of a negative are determined by the amount of light action, and not by the mode of development. The question between them is really limited to the precise form of the equation that connects the two quantities, Hurter & Driffield holding that the deposit of silver may be regarded as homogeneous, whilst Abney holds that it must be regarded as heterogeneous, and consisting of solid particles distributed in accordance with the "law of error."

Many photographers, however, on the basis of their accumulated experience, contend that they have the power, by altering the mode of development, to alter the gradations of their negatives, &c.

It will not be very difficult to show that both of the parties may be right. To a great extent the confusion and misunderstanding arises from the use

of the same words in different senses; it is the old story of a difference in language and not in facts.

Not a little of the difficulty arises in the first place from the fact that Hurter & Driffield use the word density in a sense that is quite accurate and justifiable from a scientific point of view, but which unfortunately is not the sense in which the word is commonly used by the photographer. By "density" Hurter & Driffield mean the absolute quantity or mass of silver in the film at a given point; the photographer means the *opacity* of the film at that point. The two are intimately connected, but they are by no means identical, and one cannot but regret that photographers should have adopted the word density when the correct word, opacity, was already coined. It is an important example of the folly—I ask no pardon for using so strong a word—the folly of which the practisers of any art whatever are guilty, when they use in a loose and inaccurate sense words which already have a definite and recognised meaning in any of the sciences on which the art in question may happen to be based.

Hurter & Driffield's fundamental result is that the ratio of the densities corresponding to different amounts of light action cannot be altered by changes in the mode of development. So far as any quantitative evidence goes, that statement must at present be accepted as correct. Photographers say that they *can* alter *the gradations* of their negatives. There is really no *necessary* antagonism between the two statements.

At the outset you will probably admit that the way in which photographers, as a rule, estimate the gradations of their negatives is, at the best, somewhat rough-and-ready, and cannot claim any special degree of accuracy. What a photographer has in his mind when he talks about gradations is, in ninety-nine cases out of a hundred, *printing qualities*. Of course, this is the all-important point in actual practice, seeing that the negative is but a means to an end. Now, the printing qualities depend on the ratio of *the opacities* of the different parts of the negative, and it is quite possible for the ratios of the densities to remain constant, as Hurter & Driffield say they do, whilst the ratios of the opacities vary widely. It is not necessary to enter into a detailed explanation of the law that governs the relation between the quantity of an opaque substance, such as the silver in a negative, and the quantity of light that it absorbs; the law is a simple one. May I ask your attention to the following table:—

First Case.				Second Case.			
Thickness of the Silver Layer.	*Ratios of the Densities.*	*Quantity of Light Transmitted.*	*Ratios of the Light Transmitted.*	*Thickness of the Silver Layer.*	*Ratios of the Densities.*	*Quantity of Light Transmitted.*	*Ratios of the Light Transmitted.*
1	1	$\frac{1}{2}$	4	2	1	$\frac{1}{4}$	64
2	2	$\frac{1}{4}$	3	4	2	$\frac{1}{16}$	16
3	3	$\frac{1}{8}$	2	6	3	$\frac{1}{64}$	4
4	4	$\frac{1}{16}$	1	8	4	$\frac{1}{256}$	1

It appears that in the two cases the ratios of the densities are the same, but the ratios of the opacities, or, in other words, the printing qualities, differ widely, because the *absolute values* of the densities are different. The two cases represent the same negative, development in the second case being carried on longer, so that the quantity of silver deposited at any part of the negative is, in the second case, just twice as great as in the first.

What it seems to come to, then, is this, that according to Hurter & Driffield we cannot in development alter the *ratios* of the densities, but, by stopping the processes at different stages, we do alter the *absolute values* of the densities, and thus very considerably alter the ratios of the opacities, that is to say, the printing quality.

It may be asked, however, how this explains the apparent effect of the usual modifications in the composition of the developer. The reply in the first place is, of course, that some of these modifications simply have the effect of making development slower, and thus making it easier to stop the process at any desired point.

It is, however, for a full discussion of the problem, essential to take into consideration a point that is often neglected: Is any one prepared to contend that sufficient attention has hitherto been paid to the influence of general fog—a uniform deposit of silver all over the negative—in modifying the "gradations" and altering the printing qualities of a negative? We frequently meet with or hear the statement, "beautifully clear in the shadows;" but how often is this an accurate statement of fact—how often does it represent inaccurate observation? It is very easy to be deceived by contrast, but, if the plate is put in contract with white paper, it will in the great majority of cases be found that there is really an appreciable deposit where there seemed to be no silver at all upon the negative when it was examined by transmitted light. The term "general fog" is here used in the ordinary sense to denote a uniform deposit all over the negative, produced by the action of the developer independently of any action of light.

Then comes the question, What is the effect of general fog on the ratios of the opacities, or, to use the common phrase, the "gradations?"

Since to add a constant quantity to the terms of a ratio diminishes the ratio, it is clear that the fog will lessen the ratios of the opacities, and thus tend to make the negative flatter or softer. The greater the amount of fog, the smaller and smaller will the ratios become, or, in other words, the flatter or softer will the negatives be.

In all Hurter & Driffield's experiments the influence of fog was eliminated by subtracting the value of the fog from all the measurements before calculating the ratios. It is noteworthy that in almost all cases the fog value was altogether too distinct to be negligible. In actual practice, however, whatever fog there may be is not eliminated or removed, but exerts its influence all through the various uses to which the negative is put.

As a matter of fact, very few of the developers commonly used can be allowed to act upon ordinary plates for four or five minutes without producing an appreciable amount of general fog. The amount of fog is increased by—

(1.) Increasing the proportion of alkali.
(2.) Increasing the concentration of the developer.
(3.) Reducing the proportion of bromide.
(4.) Prolonging the time of development.

Whilst, on the other hand, the amount of fog is reduced by—

(1.) Reducing the proportion of alkali.
(2.) Increasing the proportion of bromide.
(3.) Shortening the time of development.

The proportion of pyro does not seem to exert any marked influence in this respect. Diluting the developer acts in two ways; the dilution of itself tends to reduce the amount of fog, but the prolongation of development, necessitated by dilution, tends towards the production of fog.

When the photographer endeavours to compensate for over-exposure, he reduces the amount of alkali, and increases the amount of bromide; but, as we have just seen, these are modifications which tend to prevent the production of general fog, and consequently increase the contrasts of the negative. When, on the other hand, the negative is under-exposed, the proportion of alkali is increased, the proportion of bromide is reduced, and sometimes the developer is diluted; but all these modifications tend towards the production of fog and a consequent reduction of the contrasts of the negative. It is scarcely necessary to point out that so long as fog remains slight there is a tendency to continue development, and thus, as pointed out at the beginning, to increase the ratios of the opacities, that is, to increase the contrasts by increasing the absolute values of the densities. When, however, fog makes its appearance, there is a tendency to stop development at a stage when the absolute values of the densities are comparatively low, the ratios of the opacities are low, and the negative is "soft" in its gradations.

To sum up, it would seem that, so far as present experimental evidence goes, the photographer cannot by modifications in development alter the ratios of the densities of the silver deposit at different points; these are determined by the amount of light action. He can, however, and does, alter the ratios of the opacities, or, in other words, the printing qualities: (1) by stopping development at a particular stage, (2) by making such modifications in the mode of development as tend either to reduce the general fog and thus increase the contrasts, or to increase the amount of fog and thus lessen the contrasts. The two kinds of modifications are designed respectively to meet over-exposure and under-exposure.

A discussion followed.

News and Notes.

Manchester Photographic Society.—July 15, Rowsley (ramble).

Northern Photographic and Scientific Association.—July 15, Battersea Park.

Hackney Photographic Society.—July 18, *Metol-Hauff.*

Photographic Club.—July 19, *The Permanency of Gelatine Prints.* 26, *Collodio-chloride Printing.*

Change of Address.—Mr. Redmond Barrett has changed his address to 129, The Grove, Hammersmith, W.

Gosport Photographic Society.—July 15, Chichester, leaves Portsmouth Harbour at fifty minutes past one, p.m.

Birmingham Photographic Society.—July 15, Last day for sending in photographs for the Meriden Excursion Competition. 18, Social evening.

ERRATUM.—In Mr. Hugh Blackwood's letter last week, "F. Darlot & Co.' should read "F. Darton & Co.," the firm's address being 142, St. John-street, Clerkenwell, E.C.

"THE PHOTOGRAPHIC TIMES."—We understand that Mr. W. E. Woodbury is now Editor of the *Photographic Times* (New York). That journal is to be increased in size, and prize competitions are to be instituted.

THE JAPAN PHOTOGRAPHIC EXHIBITION.—It was arranged that Her Imperial Majesty the Empress was to visit on June 23 the Exhibition being held in Tokyo, by the Photographic Society of Japan. To the Exhibition a separate exhibit of Japanese photographs has been added.

NEW PREMISES FOR THE PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—We understand that the Photographic Society of Great Britain will shortly remove from their present premises at 50, Great Russell-street, to more convenient and less loftily situated rooms at the house of the Institute of Chemistry in Bloomsbury-square.

"FAIR HOLIDAYS."—We understand that, by an arrangement among the principal photographers in Greenock, most of the studios in that town were closed for one week, from Monday last, July 10, thus enabling both *employés* and assistants to have a week's holiday. Some such arrangement may commend itself to professional photographers in other large towns.

METOL-ANDRESEN.—The following new formula is recommended for the use of metol-Andresen:—Dissolve in 8 ounces of water, Andresen's metol, 10 grains; then add, carbonate of potash, 60 grains; sulphite of soda, 30 grains; bromide of potassium, 2 grains. For over-exposure add a few drops of a ten per cent. solution of acetic acid. For under-exposure add a few drops of a ten per cent. solution of carbonate of potash.

PHOTOGRAPHIC EXHIBITION AT HOVE.—In connexion with the sixteenth annual Exhibition of the Hove Industrial and Horticultural Society, to be held at the Town Hall, Hove, on September 20 and 21, 1893, there will be a photographic section under the auspices of the Hove Camera Club. Particulars and entry forms can be obtained of the Hon. Secretary of the Industrial Society, H. Emery, 142, Church-road, Hove, Brighton.

AN OUTING.—Messrs. Adams & Co., of Charing Cross-road and Aldersgate street, inform us that the whole of their factories as well as their retail establishments will be closed on Saturday next, July 15, the occasion being the outing of the staff numbering forty-eight persons. Messrs. Adams say: "In order to cope with a very heavy season the majority have been working from eight a.m. till nine p.m. since Christmas last, and deserve a little relaxation." We trust an enjoyable day will be spent.

SOUTH LONDON PHOTOGRAPHIC SOCIETY'S EXHIBITION.—The South London Photographic Society will hold their fifth annual exhibition at the Peckham Public Hall, Rye-lane, Peckham, S.E., on November 7, 8, 9, 10, and 11 next. In addition to the members' classes there will be open classes for the following: Medalled pictures; medalled lantern slides; pictures that have not received any award; lantern slides that have not received any award. It is understood that the number of pictures and slides which any exhibitor may send in will be limited.

ASHTON-UNDER-LYNE PHOTOGRAPHIC SOCIETY.—July 15, to Chew Brook. Leader, Mr. C. E. Redfern. Waggonettes will leave the Society's Rooms, Henry-square, at 1.30 prompt. Tickets, 1*s.* 6*d.* each, to be had at the rooms, or from the Secretary, up to Wednesday evening, July 12. Mr. Carrodus, from the Technical School, has promised to accompany the party and give the members any assistance he can in the choice of pictures, &c. 29, Ramble to Liverpool, &c. Leader, Charles Lord, Esq. Further particulars later. Robert T. Marsland, Hon. Secretary, 74, Blandford-street, Ashton-under-Lyne.

HOW TO AVOID BLISTERS.—Mr. Williams R. Kennan, of Dame-street, Dublin, writes: "The following I find the best way to avoid blisters in albumenised paper. After toning in the usual way, mix some liquor ammoniæ with hypo bath and fix prints as customary; but when fixed leave the prints in the hypo bath with some of the hypo, and dilute very gradually with water, keeping the prints moving. The secret is in not making a sudden change from the hypo to the plain washing water, giving plenty of time to eliminate the hypo. When this is done, blisters are a thing of the past. I send you this, as it may prove useful to some of my brother professionals who like myself believe still in albumenised paper.

PHOTOGRAPHING AT RAGLAN CASTLE.—"View Finder" writes: "Last week I went to Raglan, in Monmouthshire, for the purpose of photographing the fine old ruined castle. On arriving at the castle enclosure, I found that, in addition to an entrance fee of sixpence, half-a-crown extra for the privilege of photographing was demanded of me. I told the person in charge that it was an exorbitant amount to pay; but he denied this, stating that, having photographs himself for disposal, he had lost the sale of them (so he said) through so many amateurs coming to the place, and remarked, 'people, instead of buying my photographs, now take them for themselves.' This seemed so absurd that I pointed out to him that, on an average, not one person in a hundred was a photographer, taking the population of the country; but all argument was useless, as he only referred me to a notice board, on which was painted: 'Amateur photographers wishing to take photographs of the Castle can do so upon payment of 2*s.* 6*d.*; professional photographers, 21*s.*' Although I had undergone a hot and tedious journey—the light was perfect—and I had come specially to photograph, I determined not to do so, and I hope my example will be followed by others."

*** *With the* JOURNAL *of Friday next, July* 21, *will be presented a group of members of the Photographic Convention of the United Kingdom, taken at Plymouth on July* 5 *last. The picture is reproduced in collotype by Messrs. Morgan & Kidd, of Richmond, Surrey, S.W., the negative being by Mr. R. L. Kidd, and including portraits of* 107 *members.*

Our Editorial Table.

TRAITÉ PRATIQUE DE PHOTO-LITHOGRAPHIE.

By LEON VIDAL. Paris: Gauthier-Villars & Son.

M. VIDAL'S book is an exhaustive treatise on the subject. It deals successively with the various methods of preparing negatives for photo-lithographic purposes, the nature and properties of bitumen, bichromated gelatine, &c., photo-lithographic transfers, collotype, photo-zincography, and cognate processes. Due justice is done to the writings of the principal experimentalists, and the work is freely illustrated.

No. 23,378.—"Photographic Lenses." GOERZ & VON HOEGH.

IMPROVEMENTS IN OR IN CONNEXION WITH PHOTOGRAPHIC CHANGING BOXES

No. 1385. ARTHUR SAMUEL NEWMAN and JULIO GUARDIA, trading as "Newman & Guardia," 71, Farringdon-road, London, E.C.—*June* 2, 1893.

THIS invention relates to photographic changing boxes—*i.e.*, to apparatus such as that for which the said Arthur Samuel Newman received the grant of British Letters Patent, No. 8329, of 1886, and similar changing boxes (whether same be formed as separate detachable boxes from the camera or whether same be formed integrally with the camera)—our present improvements being specially applicable to those changing boxes in which the sensitised surface (such as a glass plate or film) is held in a carrier or sheath, and such plates or sensitised surfaces passed round successively from front to back or back to front, as the case may be, without lessening the number of plates or sensitised surfaces in such pack.

Hitherto, in "changing boxes" of such character, a spring or springs has usually been arranged on the inside of the back of the changing box or chamber containing the plates, &c., so as to constantly push forward the whole series or pack of plates, &c., towards the front of the chamber, and thus bring the front plate up to the register, or, as it is termed, "up to focus."

This arrangement has many drawbacks which need not be here detailed; but, according to our present invention, we obtain all the spring pressure that is necessary by arranging and mounting a spring or springs on a partition or dummy carrier, or sheath, or it may be an ordinary sheath sufficiently strengthened, and its partition, &c., carrying the springs thereon is placed either on the back or front, or in any desired position, in the pack or series of plates to be exposed, and passes round just the same as each of the sensitised plates, &c.

The springs on this partition or dummy sheath press forward those plates in front of it, so as to cause the front plate to come up to the focus while the plates behind this dummy sheath are pressed backwards against the back of the chamber, and this condition obtains whatever may be the position of this dummy sheath, save when this sheath is at the front position, it will then press backwards on the plates only when it is placed in the rearmost position, it will then press forward the whole series of sensitised plates, &c.

The springs on this dummy sheath or partition may be arranged and mounted in any suitable manner, subject to the following conditions:—

(1.) The spring or springs must be so arranged as to permit the dummy sheath being raised at the back and placed into the "pack" again at the front or *vice versâ*.

(2.) The spring or springs must be of such a form and so arranged and mounted as not to injure or cause any injury to the sensitised surfaces.

* * * * * * *

The form of the sheath alone forms no part of our present invention, and may be of any suitable shape and construction to suit our purpose; but, for the purpose of carrying our present invention into practice, we may mention that we find it advantageous to use all the sheaths (both those for holding the sensitised surfaces and the dummy) constructed according to Newman's Patent, No. 20,299, of 1890; but we do not, of course, wish to limit ourselves to this particular construction.

It will thus readily be seen that by placing one of these dummy sheaths amongst a pack or series of plates arranged in a chamber, and capable of being changed in the manner described in Newman's said Patent, No. 8329, of 1886, all shake in the chamber will be taken up; and, while the front plate will be always brought up to register (*i.e.*, come up to focus), this arrangement will also ensure the rearmost plate always coming exactly over the lifting device by which each plate is raised into the light-tight bag to be changed from back to front or *vice versâ*, as the case may be.

Having now particularly described and ascertained the nature of our said invention and in what manner the same is to be performed, we declare that what we claim is:—A partition, or dummy sheath, or carrier, having springs of any suitable description mounted thereon and arranged to act in and in

combination with a photographic changing box of the character such as hereinbefore described, in which a pack or series of plates or sensitised sheets are successively passed round from front to back or back to front, substantially in the manner and for the purposes hereinbefore described, and illustrated by way of example in the drawings hereunto annexed.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
July 17	Dundee Amateur	Asso. Studio, Nethergate, Dundee.
,, 17	Fillebrook Athenæum	Fillebrook Lecture Hall.
,, 17	Hastings and St. Leonards	
,, 17	Leeds Photo. Society	Mechanics' Institute, Leeds.
,, 17	Richmond	Greyhound Hotel.
,, 17	South London	Hanover Hall, Hanover-park, S.E.
,, 18	Birmingham Photo. Society	Club Room, Colonnade Hotel.
,, 18	Brixton and Clapham	376, Coldharbour-lane, Brixton.
,, 18	Hackney	206, Mare-street, Hackney.
,, 18	North London	Canonbury Tower, Islington, N.
,, 18	Paisley	9, Gauze-street, Paisley.
,, 18	Rochester	Mathematical School, Rochester.
,, 19	Bury	Club Rooms, 13, Agar-street, Bury.
,, 19	Leytonstone	The Assembly Rooms, High-road.
,, 19	Photographic Club	Anderton's Hotel, Fleet-street, E.C.
,, 19	Southport	The Studio, 15, Cambridge-arcade.
,, 19	Southsea	3, King's-road, Southsea.
,, 20	Birmingham Photo. Society	Club Room, Colonnade Hotel.

,, 21	Maidstone	"The Palace," Maidstone.
,, 22	Hull	71 Prospect-street, Hull.

North London Photographic Society.—July 4, Technical Meeting, Mr. J. R. Williams in the chair.—Consequent on the demonstration given at the last meeting, a discussion took place on amidol and metol as developers. Mr. A. E. Smith showed prints from duplicate negatives, one developed with amidol by Mr. Morgan in the course of his demonstration, and the other developed with pyro by Mr. Smith. The prints from the latter were far superior. Mr. Spiller obtained better results with amidol than pyro in developing instantaneous exposures, especially when the light had not been very strong. Mr. Brewer showed some excellent cloud negatives developed with amidol. When required, he had no difficulty in obtaining density, using plenty of bromide. The negatives were on isochromatic plates, one or two yellow screens being used as occasion required. He had had a special lens flange made, with a slot in it to take the screen, a band passing over the slot to keep out light. Mr. Groundwater had used metol for negative work, and, diluting the normal formula with an equal amount of water, obtained satisfactory results. There was a good show of hand cameras, mostly of well-known brands, but Mr. A. E. Smith showed one of his own make with a very ingeniously contrived shutter. Two wooden drop pieces, actuated by springs, work in a rebate; they are released by a lever attachment in succession, and more or less quickly according to the length of a toothed catch adjusted to the lever. Mr. Douglas had one made by Turnbull, of Edinburgh, which had focussing screen, and would rack out far enough to allow the use of one combination only of the rapid symmetrical lens with which it was fitted. It was considered a matter of great regret that the word "detective" should ever have been applied to the hand camera. It had given the dog a bad name, and the public now looked upon any one carrying a hand camera with suspicion, which, moreover, recent advertisements in the photographic press had tended to accentuate.

North Middlesex Photographic Society.—July 10.—The subject of *Cresco-Fylma Enlarging* was dealt with by the Secretary. He fully explained the negatives, which were most suitable for treatment by this process, and how to go about the actual work of enlarging, and showed numerous examples of successful work, both negatives and positives, opals, transparencies, &c. A discussion followed, which was sustained by most of the members present. The result of the outing to Sewardstone was that Mr. A. J. Golding was first, the President (Mr. J. W. Marchant) second.

Hackney Photographic Society.—July 4, Mr. Puttock in the chair.—Messrs. Rita, Low, Fort, and Dr. Harris were duly elected members. The popularity of the Society was truly demonstrated, as application for membership was made from Burmah. Messrs. T. H. Smith, Dear, Gosling, Hudson, Roofe, showed work. The Hon. Secretary then showed Spratt Brothers' new camera stand. It was easily set up, the principal advantage being that in place of screws at the first joint it automatically locked and fixed itself. Mr. Gosling showed a view finder which he had fixed in a small black box. The image could be seen in any light clearly. Mr. ROOFE asked, Could halation be reduced in any way? Mr. BECKETT thought methylated spirit rubbed on the negative with wash-leather would do it tolerably. Mr. Cross showed a negative which he had intensified, but which was much stained. The general opinion was that it was not thoroughly fixed. Mr. NUNN asked if halation was not sometimes caused by stopping down. Mr. Beckett suggested that halation was not shown so much with a large stop because "camera fog" was more evenly diffused. From the question-box: "How to obtain brown tones on lantern plates?" Various replies were given, such as using printing-out lantern plates, Alphas, using carbonate of ammonia. A good reducer was asked for, and that given by Howard Farmer was recommended. Mr. Roofe asked what to do to avoid metallic deposit on plates? The HON. SECRETARY said methylated spirits would reduce it and advocated for old plates full exposure and less alkali than usual.

South London Photographic Society.—July 3, the President, Mr. F. W. Edwards, in the chair.—Mr. W. J. BELTON gave a demonstration of the manipulation of the Paget print-out lantern plates and opals. He explained the various stages in a very lucid and able manner. For printing the opals in ordinary printing frames he showed a simple cardboard mask and frame which the Paget Company were placing in the market for sale for a few pence. He also showed a frame specially constructed for printing the opals, and gave the formulæ of the toning and fixing bath (both combined and separate) which he used. At the conclusion of the demonstration the results were passed round, and the lantern slides shown in the Society's lantern. During the course of the evening the President, on behalf of the Royal Humane Society, presented Mr. Charles Farrant, one of the members, with a testimonial for saving life. It appeared that on May 25 last Mr. Farrant, in company with another member, were photographing along the banks of the Thames at Greenwich, and noticed some children playing on one of the landing-stages. Thinking they would with but little arrangement make a good picture, Mr. Farrant and his friend proceeded to get his camera ready, when all of a sudden a cry for help was raised, and it was seen that a lad was fast being carried out into mid-stream. Without stopping to divest himself of any of his apparel, Mr. Farrant swam to the rescue, and succeeded in bringing the boy safe to land. Attendance, forty-eight.

Brixton and Clapham Camera Club.—Tuesday, July 4 (Dr. J. Reynolds, F.R.G.S., in the chair).—It was decided to afford members systematic assistance in the more elementary principles of photography. With this object in view the Club elected a Committee of Instruction, consisting of six members, each member of which will give the first half-hour of each general meeting for the purpose of answering any questions on elementary photography that may be submitted to him. A Committee was also formed for the criticism of negatives and prints produced by the less experienced members. Any one will now have an opportunity of submitting his work to the Committee, who will report as to the composition, development, and exposure of the negatives, also on the development, printing, toning, and mounting of the prints. In the event of lantern slides being submitted for criticism, it will be necessary in every case for the member to furnish a description of the scene, the nature of the process by which the slide was produced, *i.e.*, collodion, gelatine, &c., exposure, development, and mode of toning; also to submit the negative from which the slide was produced. As soon as the usual business of the Club had been transacted the President gave a short but interesting description of some of the extinct monsters that inhabited the earth in the pre-historic period. The description was illustrated by some beautiful lantern slides which were very kindly lent for the occasion by the Rev. H. N. Hutchinson, B.A., F.G.S., some of whose Palæontological and geological researches are embodied in his works on *Extinct Monsters*, *The Autobiography of the Earth*, &c.

Birmingham Photographic Society.—July 4, Mr. J. H. Pickard in the chair.—A number of negatives taken on the recent whole-day excursion of the Society to Dovedale were staged on racks on the table. These negatives were inspected with great interest, not only by those gentlemen present, who had gone the excursion, but also by the general body of members, and the display afforded convenient means of comparison of results and notes as to the obtaining of those results. A full and useful discussion was evoked by this means, about fifty negatives and prints being shown.

Bournemouth Scientific and Antiquarian Society.—July 6, Excursion to Beaulieu Abbey.—The party, consisting of about thirty of the members and their friends, including the President and one of the Vice-Presidents of the section, also several ladies, took train to Brockenhurst, and, after a delightful drive by way of Lady Cross Lodge, and Hatchet Gate, reached the picturesque village of Beaulieu. The old Abbey (founded in 1204 by King John), the village and the scenery by the river proved of great interest to the photographers, the weather being most suitable for securing excellent pictures.

Photographic Society of Japan.—A regular Monthly Meeting of the above-mentioned Society was held at the Rooms of the Geographical Society of Japan, Nishikonyacho, Kiobashi, Tokyo, on Friday, June 2, Mr. Edmund R. Holmes in the chair.—Messrs. Bradfish and Pierce had sent in some ready-sensitised paper of two different kinds. One had a polished surface, and appeared to be a gelatino-chloride paper, the other had a matt surface. Mr. K. Arito was able to state that the paper was in no way discoloured, so that there was evidence of its good keeping qualities, and that it printed brightly and clearly. He had not, however, had time yet to tone any proofs. Mr. I. Tanaka was instructed to experiment with the paper, and to report his results to the next meeting. Work done by the anastigmatic lens of Carl Zeiss, of Jena, was shown. The examples showed a most remarkable uniformity of definition from the centre to the extreme corners of the prints. Mr. W. K. Burton explained that these lenses were of large angular aperture, of flat field, and, at the same time, without astigmatism. There were various lenses that combined any two of these qualities; but, so far as he knew, this was the first that combined the three. The form of the Zeiss anastigmatics, even of large angular aperture, was such—being mounted in a short tube—that they could be used as wide-angle lenses if stopped down. He would, however, be in a position to report more fully to the Society on these lenses in a month or two. There was a discussion as to the manner of disposal of the donation made to the Society by H.I.M. the Empress on the event of her visit to the Exhibition, there being a general feeling that this money should not go into the ordinary funds of the Society, but should be used to provide some permanent memorial of the visit. It was eventually decided that the money should be used to pay for the striking of a small silver medal to commemorate the event, and to be presented to each member of the Society. After the regular meeting there was an extraordinary meeting to consider the matter of the Secretaryship. It was proposed, seconded, and carried that Mr. W. K. Burton be elected "Corresponding

Secretary" in addition to Mr. I. Ishikawa and Dr. Augustus Wood, ordinary Secretaries.

MAY 20.—Annual Meeting. Professor D. Kikuchi, M.A., in the chair.—Mr. W. K. Burton was elected Vice-Chairman, and Dr. Augustus Wood, Foreign Secretary. Prince A. Tokugawa, Dr. Professor J. Scriba, Professor John Milne, F.R.S., Mr. O. Keil, and Marquis T. Konoye were elected Vice-Presidents.

FORTHCOMING EXHIBITIONS.

1893.		
August	Welsh National Eisteddfod.	The General Secretary, Pontypridd.
Sept. 25–Nov. 15 ...	Photographic Society of Great Britain, 5A, Pall Mall East, S.W.	Assistant Secretary, R. Child-Bayley, 50, Great Russell-street, W.C.
October 1–31	Hamburg. Das Ausstellungs Committé des Amateur Photographen Verein, Schwanenwik, 33, Hamburg.	
,, 9–Nov. ...	Photographic Salon, Dudley Gallery, Piccadilly, W.	Hon. Secretary of Organizing Committee, A. Maskell, 215, Shaftesbury-avenue, W.C.
December	Madras.	The Hon. Secretary Amateur Photographic Society, Madras.

Exchange Column.

Exchange cabinet portrait lens by Laverne, cost 6*l.* 6*s.*, for hand camera, or pair of stereoscopic lenses.—Address, W. H. GEDDES & SON, Applegate, Arbroath.

Wanted a 15×12 camera slide and lens, if out of repair would do; will exchange Harrison's head and body rest, Fallowfield cold rolling press, and Dallmeyer's aluminium No. 3 portrait lens.—Address, J. MULLENS, Geneva-road, Winsford.

Answers to Correspondents.

*** *All matters intended for the text portion of this* JOURNAL, *including queries and Exchanges, must be addressed to* "THE EDITOR, THE BRITISH JOURNAL OF PHOTOGRAPHY," 2, *York-street, Covent Garden, London. Inattention to this ensures delay.*

*** *Correspondents are informed that we cannot undertake to answer communications through the post.*

*** *Communications relating to Advertisements and general business affairs should be addressed to Messrs.* HENRY GREENWOOD & Co., 2 *York-street, Covent Garden, London.*

*** *It would be convenient if friends desiring advice respecting apparatus, failures in practice, or other information, would call at the Editorial Office either on Wednesdays from* 4 *to* 6, *or Thursdays from* 9 *to* 12 *noon, when some one of the Editorial staff will be present.*

E. J. CAR.—The book has not yet been published.

W. T. M. DAVIDSON.—Wilkinson's book, or Burton's *Printing Processes* Marion & Co.

E. R. C.—The term is quite misleading. The prints are simply collotypes printed in colours after the manner of chromo-lithography, separate plates being used for the various colours.

T. BIGGS.—If upon testing the gelatine with litmus paper it strikes a red colour at once, it should not be used for mounting silver prints in optical contact with glass, as, sooner or later, it will have a deleterious action on the picture.

G. EDWARDS.—The fault is what you were told, the pictures are much out of focus. As the camera is a "fixed focus" one it is clear that the lens is not at the right distance from the plates. The one who supplied the instrument will see that the fault is remedied.

A. J.—We have found no such tendency. If the prints are properly manipulated they should not change colour in the way mentioned. As no details of the method of working or the toning baths employed are given, we are unable to say what is the cause of the trouble.

NOVICE.—We do not make a practice of recommending any particular maker's goods. Consult the advertisement pages of the "Lantern Record," or procure the catalogues there advertised. By indicating your requirements to any one of those firms, you will easily get what you desire.

D. LLOYD.—1. Use a small stop, and give a full exposure—say, six seconds, with *f*-32. 2. Possibly forced development of ammonia-prepared plates, but it is difficult to say with certainty. 3. About 18°, we believe. 4. It would be useless to attempt to obviate "movement" of the head by the aid of retouching.

C. HEARLEY asks how long black varnish ought to take to dry on a negative, as he has some, obtained from a first-class oilman, that does not dry in less than three days.—A photographic black varnish dries in, comparatively, a few minutes. Procure a bottle of Bates' black. It may be had at any photographic warehouse.

T. H. WHARTON complains that the surface of opal glass is very different from what it was some years ago, and is not nearly so nice to work upon with colour. He asks the reason.—Most of the opal glass at the present time is grained by the sand-blast method, formerly it used to be hand ground. It is that which makes the difference in the surface.

C. GRANVILLE WOOD.—Precisely in the same way as prints on albumen paper are washed. The size makes no more difference in one case than in the other.

S. BLAKE.—To make a thin solution of indiarubber, take masticated rubber which may be obtained at such houses as Hancock's or Macintosh's, and dissolve it in benzole. Perhaps the simplest way is to buy a small tin of solution and thin it down, to the consistance desired, with benzole. This is less trouble than dissolving the rubber itself.

T. W.—In publishing photographs like two or three of those forwarded, it would be sailing very close to Lord Campbell's Act. Such works could never be classed as "Artists' studies." They are too coarse and vulgar for that. "Artists' studies," if indecent, will render the producer and venders liable to prosecution. Prints returned as desired.

R. T. F.—We know nothing of the people referred to. Carry out your threat to communicate with the local Superintendent of Police. If you habitually read this JOURNAL, you would have seen that we have, time after time, cautioned assistants against sending original testimonials, and have strongly advised them to write their names and addresses across their specimens.

S. A. G.—The cause of the prints on P.O.P. paper sticking to the glass is that it was not sufficiently chalked, or that the French chalk was not rightly applied. It is not stated whether the prints were alumed or not. But during the very hot weather it is advisable to do so as this treatment, acts as a great preventative of sticking. If the prints are alumed, and the glass rightly treated with the chalk, there will be no further trouble.

X. Y. Z.—If the Postal authorities repudiate liability for the injured photographs, on the ground that they were insecurely packed, we fear you have no remedy. Two thicknesses of stout brown paper is not sufficient protection for 10×8 prints on plate paper. Such pictures should always be protected with thin packing boards or stout millboards. Possibly the photographs can be soaked off and then remounted. This would, to an extent, mitigate the loss.

A. SAYERS.—It is impossible to say if gelatino-chloride prints are more permanent than those on albumen paper, as time has not been long enough to test them. There are many prints on albumen that were produced thirty years and upwards ago, that are as good now as when they were first made. Of course gelatine has only been on its trial for a tenth of that time. Some albumen prints show a yellowness in a year or two, and so have some on gelatine. Time is the only reliable test.

H. SPODE.—Several formulæ for carbon tissue have from time to time been published, all of which will yield good results, but they require a certain amount of judgment in applying them. As a beginner, we should recommend you to abandon the idea of making your own tissue, or at least until you have gained some experience in working the process. It will save you a lot of trouble and facilitate your mastering the process. The advice proffered will apply equally well to the idea of making transfer paper.

DRUID says: "A friend of mine has a lens bearing the name of a London firm, bearing also the word 'Caloscopic,' but no one can tell us what it is for. The front lens is about two and a half inches in diameter, and like a single landscape lens, or the front glass of a portrait lens, while the back is much smaller—less than an inch. This is composed of two lenses, but seems to have no focus, yet the thing seems complete as it is. Can you enlighten us on the subject?"—The lens is simply the old orthoscopic lens under another name—that adopted by its maker.

KNOWLEDGE IS POWER writes: "I should be very much obliged if you would inform me the best thing to put the card backs on opalines with. It must be free from anything that would act on the prints as the glue I used did, but it wants to set as hard and quickly, so as to hold the back in position without being weighted separately. Gelatine is not tenacious quickly enough."—Gelatine is quite as tenacious as glue, and sets quite as quickly—some kinds much quicker. Evidently our correspondent has tried an unsuitable sample. Nothing will answer so well as good gelatine.

A. Z., who encloses a cutting from an advertisement they are issuing, offering to make "splendid likenesses" from inferior pictures, writes as follows: "As you will see by enclosed, we are making rather a speciality of copying and enlarging. Of course we should not knowingly meddle with anything copyright, but, as we often receive commissions by post from strangers to us, we might without knowing it happen to get hold of something in this way that was copyright. Should such occur, could you inform us whether we should be liable for the infringement, or the party that employed us? Everything we send out not from our own photographs bears our name and address, and is stamped 'Copy.' If you will kindly give us your opinion on this point, you will greatly oblige."—If our correspondents reproduce a copyright picture, they must take the consequences of their act; the mere stamping of a piracy "Copy" does not relieve them in any way. The only way to protect themselves is to have a proper agreement for indemnity from those for whom they execute the commissions.

FALLACIES CONCERNING PHOTOGRAPHY IN THE PAST.

The ideas so freely expressed in the paper read at the meeting of the Photographic Convention by Mr. J. Guardia, with regard to the alleged shortcomings of photography anterior to the introduction of dry plates and hand cameras, are but a reflex of those entertained by many others who have only enlisted in the ranks of photography during the last few years The new recruits are too often given to referring to what they glibly term the dark ages of the art, without knowing anything at all of what used to be done in them, and what is still possible with what are now classed primitive means.

On former occasions we have found it requisite to direct attention to the fact that long prior—say, twenty or five-and-twenty years, or even longer ago—to the bulb-squeezing and button-pressing era, results, both as regards artistic merits and instantaneous effects, were obtained that have not yet been surpassed. But the recent paper by Mr. Guardia, reiterating that all the present excellence of photography is due to modern appliances, coupled with the prominence given it through its being read at the Convention, where, of course, the discussion upon it was brief, and even that not reported in full, renders it once more requisite to point out what was actually the case, and what was done, daily, long before their introduction. In doing so the prevalent idea with many will, to an extent at least, be dispelled, that all the good work now produced is only possible with modern resources.

The author of the paper, referring to the aspects of nature as recorded by photography before hand cameras were invented, says it was a "dead maze of trees, and fields, and buildings. The rivers and lakes showed no ripple, they were merely a mass of glaring white. The streets were deserted, and tenantless houses were but a mockery without reason. The beauty of clouds and atmosphere was unknown—was represented by acres of white paper. Here and there a group of soulless caricatures of human beings were, indeed, to be seen, all stuck up in constrained attitudes; not breathing, and moving, and palpitating with life and energy; but either blurred out of all recognition, or fixed in unnatural poses, like wax dolls glaring at nothing, puppets without muscles, and silhouettes without substance." This is how photography is described as depicting the world before the introduction of the hand camera. Now, it is perfectly true that hundreds of bad photographs were taken before the advent of the hand camera, and it is equally as true that thousands, nay, tens of thousands, of bad ones have been taken since; also that some of the early workers, like many later ones, were ill advised enough to show their inferior work, and even, like many at the present time, to send it to public exhibitions.

Most of our older readers will remember the excellent sea and cloud studies of Le Gray, taken something like forty years ago, and those by Colonel Stuart Wortley at a later date. The waves in these were not a mass of glaring white, neither were they devoid of cloud and atmosphere. These pictures were not of hand-camera sizes, but fifteen by twelve, or larger, and what is more, if we remember rightly, the former were from paper negatives. Sky and atmosphere, even at that remote period, were not necessarily represented by "acres of white paper." Clouds were frequently printed in, and usually with discretion. It was seldom then that a landscape was seen lighted from one direction, while the clouds were illumined from another. Clouds were then, as now, obtainable in the negative with the subject.

Apropos of this point, and the neighbourhood in which the paper was read, we have now before us a couple of stereoscopic negatives of Saltash Bridge, each of which contains excellent natural clouds. The bridge is not here depicted, as it is familiar to the members of the Convention, but is shown with one tube *in situ*, and the other about midway between the ground and its final resting-place, while the piers of the viaduct portion of the structure are seen in course of erection. Therefore the negatives must have been taken in the late fifties. But examples like these were common enough even at that period.

Old apparatus is condemned wholesale, and is charged with being designed by incompetent persons such as carpenters and cabinet-makers, and credited with many of the shortcomings (?) of photography before the hand camera. However, many will remember the instantaneous stereoscopic pictures of breaking waves by the late Mr. G. W. Wilson, which have not yet been excelled. The "instantaneous" shutter Mr. Wilson employed was nothing more than his Scotch bonnet deftly used. We have in our mind, while on this topic, a fully exposed 12 × 10 instantaneous view of Regent-street, taken about 1858, which showed the wheels of vehicles, and the feet of pedestrians crossing the road sharply defined. The exposure, we were told, was made by one person uncapping the lens while another immediately thrust a black cloth over it.

Those who have seen Mr. Frank Haes' photographs of the animals at the "Zoo," taken something like thirty years ago, and those of Mr. York, of a somewhat later date, are fully

aware that they will hold their own against any of the modern work. With regard to street scenes, and the like, we have the instantaneous views of Paris by Mr. William England, and those of London by Mr. Blanchard, and others, produced a quarter of a century ago, that still have to be excelled. These workers, it is true, had not the advantage of more or less complicated arrangements for making their exposures, and they worked the "messy" wet-collodion process. The earlier photographs of Muybridge, and which obtained for him his reputation were also by this, by modern workers, much-decried process. In whatever direction one may look, it is difficult to see, in modern work, anything that has not its equal in what was done years ago. It must, however, be admitted that, to accomplish that, much greater skill was necessary than is the case now; consequently the greater credit should be accorded to those who were successful.

There is no gainsaying the fact that modern dry plates, with their extreme sensitiveness, have conferred a great boon upon photography by enabling it to be worked with greater ease and comfort than was possible with any previous process. They have also permitted the use of more convenient appliances. But for this it must be conceded that the majority of those who now produce excellent work would not have taken up photography at all.

This article is not intended in any way, even for an instant, to disparage the ability of modern workers, but simply to dispel some of the fallacies that are constantly being promulgated by many, that the quality of the present work is entirely due to the introduction of modern processes and appliances, and that, prior to their introduction, good pictures were an impossibility.

EXPOSURE, DEVELOPMENT, AND FOG.

There can be little reason, after the most recent contributions to the discussion of the question of ratio of gradation, to doubt the correctness of the views held on either side when considered from their respective standpoints, the apparent discrepancies being rather those of expression than of fact. In other words, while Messrs. Hurter & Driffield are, there can be little doubt, correct in their contention that the gradation in a negative is produced by the action of light alone, regardless of the composition of the developer—so far at least as normal conditions prevail—still the practical man is equally accurate in his claim that he can modify the character of his negatives in development by departing from those normal conditions.

The extreme care with which the researches of those gentlemen have been carried out is not more strongly evidenced than by the fact of their recognising the necessity for making due allowance for the effect of the fog, or abnormal reduction invariably present under even the most favourable circumstances. Such fog, unless varying in the same ratio as the image itself —in which case it can scarcely be abnormal reduction—must necessarily alter the gradation, and Messrs. Hurter & Driffield in all their experiments have made allowance for the fog inherent in the film as measured from an unexposed portion of the plate.

In making this allowance, they have necessarily looked upon the fog as equally pervading every portion of the film, irrespective of the additional effect of light; but, as was pointed out by Mr. G. Watmough Webster in the discussion following Mr. Bothamley's paper at the Convention, it is questionable whether that view is the correct one. Mr. Webster's contention, as a practical man, is that fog is more likely to show itself in an unexposed plate or in the unexposed portions of a plate than where light has partially acted, while Mr. A. Cowan, an equally practical man, dissents from this view. Possibly even here, as we shall endeavour to show, both gentlemen are in a measure accurate from the particular standpoint each takes.

It is now some twelve or fourteen years since we first saw an example of this in connexion with a gelatine plate. In the dark room of a well-known professional photographer—afterwards a plate-maker—we witnessed the development of a whole-plate upon which two cabinet exposures were supposed to have been made; but by some accident one half of the plate had received no exposure at all. For a considerable time no sign of any reduction whatever was visible upon the unexposed portion of the plate, but towards the close of the development when the solution was finally strengthened for the production of detail and density, the blank half of the plate began to veil, and, by the time the negative on the other portion was complete, dense fog had obscured the otherwise clear glass. At the same time, the shadows of the negative and the rebate of the dark slide on that portion of the plate were perfectly clear, or as near it as the best negatives usually are.

It was at first assumed that the one half of the plate had been fogged by the admission of light into the camera by some means but that was negatived by the fact of its remaining clear for so long a time, and also by the portion protected by the rebate of the slide being equally veiled, no less than by the impossibility of such an occurrence on one half only of the plate. Upon due consideration there seemed no possibility of escaping the conviction that the unexposed portion of the plate had succumbed under a greater strain than the other half was subjected to.

Collodion workers will, no doubt, remember similar effects, more especially with dry plates and silver development. The latter form of development, in fact, was particularly liable to abnormal action under the least suspicion of under-exposure, since the soluble silver salt it contained would only remain in that condition for a limited period dependent on the restrainer present; and when it was deposited, if the exposed portions of the plate did not exert a sufficiently powerful attractive force to draw the metal to themselves, it had to deposit itself uniformly over the surface of the negative, whether exposed or not This was notably the case with negatives exposed in a bad light, or with subjects possessing but little contrast, for if the reverse conditions prevailed, although the plate might have been insufficiently exposed to make a good negative, the brilliantly illuminated portions of the image attracted to themselves more than their due portion of silver, and thus kept the shadows free from fog, at the same time producing the effect of harshness.

It has occasionally been our misfortune in these days, when working with a binocular camera, to find on development that one half of the stereogram had not been exposed, and in such cases the unexposed portion was invariably more or less fogged, as in the case quoted above, although the shadows of the other half might be perfectly clear.

It seems clear, then, that there is a tendency for fog to appear in inverse ratio to the action of light that has touched the plate—that is to say, if there be any inherent tendency in the film to produce fog, for it is here where we think Messrs. Webster and Cowan differ. If the plate be a good one, and quite free from latent fog, and the development be carried on in a "safe" light, there appears to be no reason why it should

not stand the application of a developing solution of reasonable strength for an unlimited time. But the case is different where a tendency to fog exists, for the application of a developing solution of any strength is bound to bring it out if allowed sufficient time. That the fog may not make its appearance in the case of a fully exposed negative may depend on different circumstances, it may be that the negative image is complete before the fog has had time to develop, or it may be held in check by the bromine given off by the reduction of the adjacent portion of the image. At any rate, a foggy plate will undoubtedly often give a clear negative, when it will not remain clear when entirely unexposed.

To test the matter, a plate of a brand known to work in a remarkably clean fashion was exposed in the camera, one half being covered with a sheet of opaque paper. The exposure was such that a developer of full strength had to be applied for a rather prolonged period; in fact, it may be said to have been under-exposed. After fixing, however, there was no more sign of veil on the covered portion of the plate than in the shadows of the exposed parts, and the same result was obtained on repeating the experiment with variations.

Another plate, of a different make, which usually requires very careful treatment, was submitted to the same test, but in this case the unexposed half of the film was unmistakably and badly fogged. With this make of plate the experiment was varied by exposing one half of a cut plate fully—that is to say, sufficiently to ensure that it was not under-exposed—and the other for half the time. The two were then developed in the same dish, and for the same period, being removed when the longer exposed half was sufficiently developed. After fixing, while the latter was perfectly clear in the shadows, the other half, although not showing any great lack of exposure, was distinctly veiled, although submitted to exactly similar treatment.

In another experiment one of the cleaner, working plates was intentionally fogged by a brief exposure to artificial light with a view of testing whether light fog pure and simple was amenable to the same law. Upon exposing a part of the plate in the camera, and developing in the same manner as before, the exposed portion came out with slightly less veil than the other, though we were unable to so accurately time the preliminary exposure as to produce a really clear negative.

From these experiments, and for other reasons that might be adduced did space permit, we think it is quite possible, as Mr. Webster suggests, that it is a mistake to reckon fog reduction as a constant, though, perhaps, in actual practice, the difference it makes is not of very high importance.

The Photographic Society's Exhibition.—In view of the near approach of the Exhibition season, it may be opportune to remind our readers that the Exhibition of the Photographic Society of Great Britain opens in the Gallery of the Royal Society of Painters in Water Colours, 5A, Pall Mall East, on Monday, September 25 next, and will remain open until November 25. The Exhibition will be inaugurated by the usual *conversazione* and reception by the President (Captain W. de W. Abney, C.B., F.R.S.) at the Gallery on Saturday, September 23. Forms of entry and all necessary particulars are obtainable from Mr. R. Child-Bayley, Assistant Secretary, 50, Great Russell-street, W.C.

Volatility of Silver.—We recently referred to the experience of one of our correspondents who believed he lost a large quantity of silver by volatilisation when reducing residues, and in connexion with this subject, in a recent number of *Comptes Rendus*, M. Moissan gives an account of some remarkable experiments in the melting of metals by the aid of electricity. Whether our correspondent was right or not in his belief in the manner of his loss, it has long been known that silver is volatile, and some of these experiments we refer to consisted in bringing the silver to a state of ebullition, which was done in a few moments, distilling the vapour, if we may use the expression, and then condensing it in the form of small globules, varying in size from small shot to microscopically small spherules. Gold also was distilled, the condensed product being in the form of powder exhibiting a beautiful purple sheen.

Refractory Metals for Photographic Use.—M. Moissan's paper contained also accounts of experiments with other metals which were pregnant with interest. Taking, for example, molybdenum, by the electric furnace he obtained an easily detachable regulus of the metal combined with carbon which was of extreme hardness. This molybdenum carbide is so hard that it scratched glass and steel, and it was not attacked by moist air. If it were possible to face the steel plate of a rolling press and burnisher by some such material as this, the plate would be invaluable, for there can be no doubt that many an imperfectly glazed or surfaced print can be traced to the use of a steel plate, which, through long use or accident, has lost its original burnished surface. Possibly, also, zirconia cylinders for the optical lantern might be obtained by means of the electrical furnace; for M. Moissan was able to reduce this earth to vapour, and condense it into a fine white powder, the individual particles of which were hard enough to scratch glass.

Action of Light on Cobalt.—Messrs. Auguste & Louis Lumière are continuing their experiments in this direction, and, in the journal above quoted, describe a process founded on their previous discovery that cobaltic oxide is rapidly reduced to a cobaltous salt when exposed, in presence of organic matter, to the action of light. They impregnate paper with a cobaltic compound, expose to light under a negative, and by means of certain reagents—preferably potassium ferrocyanide—bring out an image.

Assistants and Their Specimens.—Numerous complaints of the detention, by photographers advertising for assistants, of the specimens and testimonials submitted to them by applicants are again reaching us. We should scarcely have been surprised at this had we not previously dealt with the matter on several occasions, denouncing the dishonesty shown on the one hand, and the stupidity and carelessness on the other. We again strongly advise operators or assistants when submitting specimens to write their names and addresses on some prominent part of the photographs. This will prevent improper use of them by unscrupulous persons. Again, copies of testimonials only, and not the originals, should be sent. In neglecting these precautions assistants are largely to blame in not securing the return of their specimens and testimonials. As for those photographers who make a practice of wilfully not returning specimens, &c., submitted to them, we may remind them that we have a black list in which their names are entered, and which we use in the interests of defenceless assistants.

Photographic Study of Sources of Light.—M. Janssen first made a special study of this subject by photographing the solar surface with exposures of gradually diminishing length. M. Crova has applied the same method to the standard Carcel light and the electric arc. The true proportion of the constituent parts of the flame to one another is only seen when reduced exposures are given, four such photographs having lately been shown at a meeting of the French Academy. The flame was shown thus to be divided into several zones, separated by distinct lines of demarcation, and similar photographs of flames of a candle, an amyl-acetate burner, and a batswing jet exhibited similar phenomena. Most interesting phenomena were observed when the image of the electric arc was examined on the ground glass of the camera. The positive carbon showed a

surface riddled with dark spots, and granulated like the surface of the sun in M. Janssen's photographs, the granulations being distinctly observed in a state of violent motion on the ground glass. The important deduction is drawn that, in estimating the potency of these light surfaces, it is not admissible to screen off all but a very small portion of the luminous source in order to reduce the amount of light in the same proportion as the area of the luminous surface. With very small surface elements, both the amount of light and the temperature, and hence, also, the tint of the light, may be constantly changing.

New Focussing Arrangement.—The advances made in the construction of the camera proper and the mechanical motions in connexion with its working have apparently entirely displaced the rack and pinion in lenses of very long focus. Few photographers of the present day have ever seen, for example, the once-used Hook's Universal handle for turning the pinion of the lens when the latter was placed at a considerable distance from the ground glass. It was a very useful addition, the pinion projecting through the milled head to form a square head on which the handle fitted, and the joint itself was a most ingenious piece of mechanism, which might with advantage be utilised for modern work. There has, however, been recently invented a focussing device which is capable of advantageous practical application to the huge portrait cameras so much to the fore of late years. The first practical application of the device has been to the eyepiece of a five-inch telescope belonging to Mr. Beach, one of the proprietors of the *Scientific American*, and it has been found to answer its purpose most admirably. Briefly, it consists of an attachment to be applied to the sleeve of the rack and pinion of the lens, to be moved to and fro for focussing, and when not in use does not interfere with focussing in the ordinary way. An ingenious and not too complicated mechanical arrangement works two levers, which are actuated by a pneumatic pear, and the motion is so communicated as to work the pinion in a forward or backward direction as required. We have not yet heard of the device being applied to photographic lenses: but, as it appears to possess such advantages over ordinary means for large instruments, there seems every probability of the adaptation taking place.

CONVENTION NOTES.—I.

It was feared by some that, owing to the geographical situation of Plymouth, the Convention would be but sparsely attended this year; but, although its distance certainly prevented some hitherto regular frequenters of its meetings from being present, yet, all things considered, it was well attended, several having come from Belfast, Dublin, Glasgow, Liverpool, Manchester, Chester, Derby, and localities not less distant, not to speak of London.

The kindness of Plymouth, in which we include Stonehouse and Devonport, could not possibly be surpassed, and the attention bestowed upon the visitors by the brethren there will not readily be forgotten.

Plymouth and its environs team with delightful subjects for the camera, but those who go there for pictures alone have not the same chance of obtaining them during a busy Convention week that they would have were a quieter time selected, when they could go wherever they pleased and stay as long as they preferred.

There is much of historical interest that centres in Plymouth. None now need to be told that it was in this port—at that time the chief naval arsenal of the kingdom—the English fleet lay in waiting for the appearance of the Spanish Armada; that it was from Plymouth the great colonising expeditions set out, one of which annexed Newfoundland; that from here, over 270 years since, sailed the *Mayflower* with the Pilgrim Fathers who founded the American Republic; much less do they require to be told that in the Hamoaze, an important estuary in the immediate vicinity, lie peacefully slumbering at anchor a mighty navy, replete in every respect with everything that can conduce to destruction—formidable ramming warships of the latest construction, numerous torpedo vessels—all reposing side by side with specimens of the "wooden walls of England"—the once formidable *Téméraire* among them—spending the evening of their existence as training ships.

The town of Plymouth is neat and clean and its streets are busy. In several druggists' shop windows are seen the inevitable camera, mainly of the "hand" genus, with announcements as to photographers, requirements being procurable within. The windows and interiors of two photographic establishments in George-street, those of Mr. Heath and Mr. Hawke, are worthy of examination on account of the real excellence of the numerous portraits—largely of members of the Royal Family—there exhibited. Mr. Yeo, too, who lately obtained a medal at the Pall Mall Exhibition, has a fine exhibit at his gallery. Indeed, all through the town the works exhibited by photographers are equal to any we have elsewhere seen and are superior to those in many large towns.

The group which we issue with the present number was taken by Mr. R. L. Kidd. Mr. Kidd deserves special commendation for the enterprise displayed by him on that occasion, for after developing and drying the negative it was despatched by him to his works at Richmond, where it could not possibly have arrived till the forenoon of the day following (Thursday), and yet on the morning of the succeeding day (Friday) numerous copies, printed on bromide paper and mounted with a sunk plate mark, were on exhibition in Plymouth ere the members of the Convention had breakfasted. The print we give, however, is not a bromide one, but is printed by the firms' collotype process.

Apropos, the members of the Convention portrayed in the group do not by any means represent all who were present at the meetings, nor, for that matter, all who were present when the group was taken, for the temptation to have a "shot" at their fellow-members proved too great for resistance by several who had their cameras, and who "blazed away" regardless of the fact that they themselves would inevitably be left out in the cold. At the Convention dinner on Friday, a large, and what may be designated the official, group, taken by Mr. W. Heath, was placed on exhibition. We had only a hurried look at it, but it seemed to us as being absolutely faultless.

Is it not a mistake in the Council to receive such a large number of papers to be read? It is altogether impossible that every one of these can be brought before the notice of the meeting. Imagine three or four, or even half that number, of long papers on topics more or less important being brought before a *séance* which can last at most but an hour or an hour and a half; and this, too, after a day pretty actively spent in other Convention duties! A President would be something more than human if he could curtail discussion on any one of these to, say, half an hour, and then what is to become of the other papers yet in store, and down on the programme for that evening's proceedings? The system usually adopted is, doubtless, the best, viz., when the usual hour of separation has come, to take those papers *as read* the authors of which are not themselves present. In our last issue we gave all those that were really read: in the present and succeeding numbers we shall give all those which, not having been actually read, were taken as such.

GELATINO-CHLORIDE NOTES.

Much doubt and difficulty appears to exist in connexion with the mounting of gelatino-chloride prints, though why it should be so, if the instructions were carefully followed, is not clear. The new paper,

of course, requires some little different treatment from that given to albumenised, but those who have become accustomed to the latter refuse to change their habits.

The most important point is, of course, the use of the alum bath, which should never be omitted, however little tendency to softening the film may show, but it should always be used last thing after fixing and well washing. When so applied it forms, in addition to hardening the gelatine, a safeguard to the permanency of the print, and the trouble involved is not worth counting. It should never be used before toning, as recommended in some of the instructions, for it not only leads to irregularity of tone, as mentioned in a recent leading article, but, to my idea, spoils the tone, or, at least, renders it difficult to get the rich tones otherwise obtainable.

But I would go further than merely insist on the use of alum, and would make a point of invariably drying the prints before proceeding to mount them. This completes the hardening process, and removes any last traces of "stickiness" their surfaces may have, and even when rewetted they are no more difficult to handle than albumen. Instead of mounting the prints direct from the last washing water, blot them off and lay them out to dry in a warm room, which will not take very long at this time of year, and they may be finished off at the fire. If they are properly alumed, there is not the least danger of their sticking to the blotting-paper or of "fluff" adhering to them. Then, before mounting, soak them in water again to soften and swell them, and proceed.

The drying before mounting is, of course, a necessity if the prints are not trimmed to size before toning, and even in the case of cut sheets the operation of trimming has to be performed at some stage It puzzles me to know why the manufacturers send out cut sheets the exact size of the negative instead of a quarter of an inch smaller each way. The margin has to be trimmed off in any case, unless the finished prints are to be improved by being mounted with a black margin, representing the rebut of the dark slide. There is, however, one advantage, namely, that the edges of the print are cleaner after trimming before mounting than would be the case if cut sheets the exact size of the final prints were used, for then the handling in the course of manipulation is liable to loosen the gelatine and cause ragged edges.

As to the style of mounting, let those who like the "bon-bon-box glaze continue to use plate glass, and allow the mounted prints to dry before stripping. But, for ordinary purposes, ebonite or ferrotype plates will be found better. The latter, indeed, if of the best quality, have a surface little inferior to glass. Some of the papers on the market now, however, require no squeegeeing on to glass or anything else, but dry with a surface equal to superior albumen prints when mounted in the same manner, though they are improved by burnishing, which is an operation beyond the reach of most amateurs.

Celluloid, however, is my favourite where a squeegee support is used, and either sort of surface—matt or polished—can be got, according to the side of the celluloid used, the prints stripping as easily from the smoothed or grained side as from the polished. The transparency of the celluloid is also an advantage, especially when the plan of mounting to be described is adopted, and it is one I have found very convenient.

I have sheets of celluloid cut to the exact size of the prints when ready for mounting, and the damped prints are squeegeed on to these. The celluloid sheets may, in fact, be utilised as trimming shapes, the untrimmed print being squeegeed in contact, and then cut to the exact size with a pair of *sharp* scissors; in fact, this is the more convenient plan. This having been done, the back of the print is starched or gelatined, and together with the celluloid placed on the mount and left to dry. There is no danger of the prints sticking together if placed in a film under pressure; indeed, they are all the better for such treatment. When quite dry, the celluloid comes away easily, and is ready for another batch of prints after polishing with talc or wax.

If I might make a suggestion to the dealers in photographic goods, it is that they should send out cut sheets of celluloid prepared for this purpose with rounded corners. If put up in packets of a dozen, I should think they would be appreciated.

W. B. Bolton.

MY FIRST DAGUERREOTYPE.*

In process of time my lessons came to an end and I was supposed to be ready for operations on my own account. I had done a great amount of buffing and had seen the rest of the operations very frequently, but had actually never completed a picture without assistance. I had not money enough to build a studio, but my friend assured me that the Americans preferred a large window to the top light of a glass roof, and he had been fortunate enough to secure a large room with a few windows, and in this ready-made studio he produced portraits the lighting of which could not be surpassed even now.

I searched far and wide for a suitable locality, but found not one with the much-desired bow windows, and finally had to be content with a large upper room over a shop. There were two windows, but by darkening one I thought I might be able to manage with the other. I had a north light, and that was at any rate something in the right direction.

For many days I was busily employed in fitting up my dark room, and in other ways getting ready for the serious operation of admitting the public, who would without doubt rush in with the money in their hand eager to pay in order to be practised upon, and this eager anticipation and active work made time go like lightning. At length I deemed the place ready for work, and proceeded to try my apparatus. I had no trouble with the buffing, and the faultless plate, with its black polish, was first put over the iodine vapour, and then slid on —when the right change of colour had been obtained—to the bromine compartment. Apparently all went well, and the plate had successfully passed through the various changes of colour then deemed necessary for the highest state of sensitiveness, and I exposed my first plate on a plaster copy of the "Greek Slave," for in her I had a model I could trust not to move. I gave what I judged to be the right exposure, and with great eagerness watched the dawn of my first picture. Alas, there was no dawn for all remained night, and the fair slave was still captive, hopelessly imprisoned within the fair film of the sensitive plate. Surely, thought I, a white subject must make some impression if every operation had been correctly carried out, and I proceeded to prepare another plate. I felt certain I had removed the cap of the lens, but doubtless I was in error on that point and must therefore be more particular next time.

Needless to say that, at the next experiment, every possible precaution was taken to ensure success; but, alas! it did not come. The plate was lifted from the mercury bath more times than I can count, but still no trace of an image whatever. In my lessons I had been taught that something dreadful would happen if I exceeded the regulation time in the bath. I became desperate, and dared everything. The time was doubled, and again doubled, but still no picture. I had been told that something equally dreadful would result if I increased the temperature beyond the fixed limit. As desperation increased, I recklessly pulled up the wick of the spirit lamp, and ended by bursting the thermometer. It was not made for very exalted temperature, so what could it do when the mercury filled the tube to extreme limit but crack its sides? Clearly there was nothing more to be done that day but rush off to my tutor and cry out for help. He could offer no explanation, but promised to come over at the close of the day and examine matters for himself. I rushed off to buy a new thermometer, but found I could get none of the pattern needed that would record very high degrees of heat. When I explained my difficulty, the assistant assured me that the instrument was more than sufficient for my requirements. When I reached home—for my studio was "kitchen, and parlour, and all"—I made the patient slave submit to three more exposures, varying in duration, and this she did with stony indifference.

In due time my friend appeared, and, after a careful examination of all my arrangements, he proceeded to develop the exposed plate. Failure attended his first and second efforts, and then he declared that it was absolutely impossible that I could have exposed the plates. I might have taken off the cap of the lens, but I had failed to pull up the slide. I assured him that I had pulled the slide entirely out, and shut down the lid of the camera, and had held the metal slide in my hand as well as the cup of the lens, in order to be perfectly sure of my proceedings. He scratched his head at this, and then an idea struck him. The mercury was oxidised, and wanted filtering. Had I a piece of chamois leather? I rushed out, and in a few minutes had procured a piece, and then the mercury was duly filtered and replaced in the bath. The last plate was tried with the mercury, as recorded by the thermometer, far above the extreme regulation limit, but with the same negative result, so my instructor in turn was hopelessly beaten, and was compelled to admit he could offer no explanation of the mystery.

* Concluded from page 424

He departed, and I was left alone with my own gloomy thoughts Was this, then, to be the end of all my efforts—ignoble failure? Were all the bright anticipations that had buoyed me during all my exertions to be submerged in this "Slough of Despond?" Surely this was a fitting reward for my overweening conceit; for, like many other beginners, I never for a moment doubted myself, and though I had not been furnished with as much practical work as fairly belonged to me during my period of tuition, I felt that, once started and left entirely to my own resources, I should find no difficulty whatever. The veil was removed from my eyes—indeed, torn from them by this utter collapse. The next morning I was at work before breakfast, hoping against hope that my luck would change. The Greek Slave once more endured the audacious gaze of the lens, but the plate remained proof against her charms. I left it in the mercury bath, and tried to drown my trouble in a cup of tea. I could not eat, but tried to forget my troubles for a moment by reading. The subject of the book caught hold of my mind, and held it for how long I cannot say; but all at once the remembrance of the plate in the bath came back, and I rushed eagerly into the dark closet. The lamp had flared up unusually high, and the thermometer was again broken. With fear I lifted up the plate, but, oh, joy! there was my first Daguerreotype. There was the fair Greek delineated with a purity and beauty I had never seen before. Surely such a Daguerreotype had never before been offered to the gaze of man, for to my gladdened eyes it was indeed beautiful.

The key to the enigma was at length furnished. The mercury baths of American manufacture were wonderful examples of fine iron casting. Mine was a clumsy imitation, and almost a furnace was needed to get up the necessary heat to properly vapourise the mercury; the bottom of the bath was cut down to the necessary thinness, and my first great photographic trouble was at an end.

VALENTINE BLANCHARD.

JOTTINGS.

I SEE that the next meeting of the Convention will be held in Dublin. Writing on the subject twelve months ago, I suggested that, in the event of the Home Rule Bill being carried, the title, "Photographic Convention of the *United* Kingdom" would stand in need of alteration. The Bill seems to be in a fair way of becoming law before long, and I therefore hope the Convention Committee are prepared with a new title.

Reading through several accounts of the Royal Wedding and its incidents, as published in the daily papers, I came across the now stereotyped references to the "inevitable" photographer, the "ubiquitous" Kodaker, and other sneers of a similar nature. Why the photographer should be singled out for reference in this manner on all festive occasions passes my comprehension. To my thinking, photographers taking views of great historical gatherings, &c., are placing posterity under an obligation to them, and be the results never so poor, it is to be hoped that, in the interests of historical accuracy, as many of them as possible will go down intact to future centuries. Ridiculous writers in daily papers, however, do not think of this; in trying to be funny or smart in their references to photography, they too often only succeed in being foolish, as witness their sempiternal denunciation of process reproductions of artists' drawings, process illustrations in magazines, &c. On that point I am glad to notice that Mr. Henry Blackburn emphasises the fact that the faults so loudly complained of by the daily press critics are not those of photography, but of the artists themselves in not preparing their work according to the requirements of photo-mechanical workers.

It is singular that topics such as those headed "Depression in Photography," and "Amateurs and Professionals," which are just now in course of discussion in your pages, should crop up at a period of the year when one would imagine professional photographers wanted all the time they could get for looking after their businesses. Apparently, however, a great many of them have no business to speak of to attend to, so that they take advantage of your kindly columns to proclaim that fact to the world, to assign causes therefor, and to discuss more or less plausible remedies for bettering their condition. Chief among the causes generally assumed for the undoubted depression in professional circles is the growth and influence of amateur photography. There is, I fear, no denying the fact that there are thousands of amateurs who do landscapes, groups, architecture, copying, printing, toning and fixing, mounting, &c., quite as well as the average professional, and whose work, being gratuitously distributed, is bound to act as a deterrent on the general public patronising professionals. Do we not all prefer something for nothing instead of paying for it?

Then as to portraiture, the professionals' chief buttress and support. It is all very well to sneer at the portrait productions of amateurs as being crude and poor, but this does not apply in nearly all cases, for in this branch of work there are undoubtedly large numbers of men who, in posing and lighting, provoke and justify comparison with an average professional, and whose productions, be they good or bad, please and satisfy their friends, and so prevent the latter from going to a professional. All this, and more, tells against the professional, who, I am bound to say, in a great many cases is either too ignorant, too careless, or too poor to keep himself abreast of the times in taste, novelties, new processes, and all reasonable means for attracting and retaining public patronage. What wonder, then, as one of your correspondents neatly puts it, that he should "suffer through the laws of political economy?" The struggle for the survival of the fittest is going on in photography as in everything else, and at present it looks as if the lower grade professional, the man of limited capital and limited knowledge, will have to go under. The "tin-type" man and the "large direct man" seem to flourish well enough; the middle-class man is apparently being squeezed out of existence.

All the talk about licensing and boycotting amateurs, making them pay more for material, &c., is simple waste and nonsense, and to think that any considerable number of them will refrain from photographing their friends, their oxen, their maidservants, and their other belongings because it might injure some professional unknown is nearly as bad. I take too pessimistic a view of the matter to suggest any remedies. Professionals might combine—but they won't; they might abstain from cutting each other's throats in the matter of prices—but they don't; they might, as a rule, turn out better work—but they won't. They will not help themselves, so how can anybody else help them? The only hope that I can give them is a poor one, and that is time! Time rights all things—or some of them. In course of time the great amateur craze may die down, and then the poor professional will come to his own again. But pigs might fly if they had wings. In the meantime I should like to say that I and many of my friends and thousands of others have for years grown our own potatoes, our peas, our lettuces, and other succulent vegetables, and still the greengrocer's remains a flourishing trade. The greengrocer usually is a good man of business, and—must I say it?—your photographer usually is not.

It is a pleasure to note from time to time, among the lengthy commonplace records of the commonplace doings of the photographic societies, little items of news indicating the existence of a desire to impart to their members objective photographic knowledge. The Birmingham Society, for instance, set an example at its last reported meeting which merits imitation on account of its undoubted practical value to photographers, especially amateurs of limited experience. A series of negatives taken by the members on an excursion were staged for examination, and appear to have had instructive effects on those present. If particulars of plate, exposure, stop, developer, &c., are given, no better method of imparting a lesson in development could be given, and it is in the hope that the Birmingham Society's lead will be followed that I venture to applaud it. Different methods of intensification, reduction, and other processes might also be demonstrated in the same way.

COSMOS.

STEREOSCOPIC PHOTOGRAPHY.

A REPLY TO "TECHNIQUE."

[Read at the Stereoscopic Club, July 5, 1893.]

SINCE the last meeting of this Club there have been many things done and published on photographic matters that might well occupy our attention as fit subjects for discussion. At the present time I

wish to call your attention to an article on "Stereoscopic Photography" published in the April number of *Photographic Scraps* over the name of "Technique." As most photographers are aware, *Photographic Scraps* is a private journal, published monthly, under the control of the Britannia Works Company, and "Technique" is their editorial contributor. No doubt many of our members have read the article in question, but by this time may have forgotten much of the particular statements it contained.

First of all, "Technique" is of opinion that the heading of his article—"Stereoscopic Photography"—would have given "greater gratification" to readers of photographic literature thirty years ago than to readers of the present day. If he infers, as I presume he does, that there were more amateur photographers interested in the stereoscope, or more stereoscopic cameras in the field, at that time, then I must beg to differ, since I believe there are more stereoscopic photographers (amateurs) to-day than there ever were, and I shall be prepared to submit some particulars and to argue my own case before a committee of three gentlemen, and to back my opinion to the extent of a very good dinner for the committee, "Technique," and myself.

Next we are told that the stereoscope did give a great impetus to photography at the period alluded to (thirty years ago), and that "there were abundant reasons for this; not the least was the apparently wonderful character of the pictures, which it was imagined were only possible as photographs, whereas in reality very good stereoscopic pictures can be made by pen or pencil by any one understanding the principle of the stereoscope and of perspective drawing."

Now, if a tyro in photography had made such a statement, it would have been excusable, from the fact that he had not studied the subject: but when a professional scribe, one who writes on scientific matters for the guidance of others, and who sets himself up as an authority, displays such total ignorance of the subject, then I say there is not much room for excuse.

As a matter of fact, there has never been an artist clever enough to make "a good stereoscopic picture by pen or pencil," and nobody who understands the principles of the stereoscope would be so foolish as to try. It is quite true there are outline designs—geometrical figures in white lines on a black ground—made for the stereoscope, but to call these "good stereoscopic pictures, drawn by the pen or pencil," would be a deliberate intention to mislead. If we leave out of the question the absolute impossibility of making two pictures stereoscopically dissimilar, and therefore ignore the whole principles of binocular vision, I say again there has never been a man born who could make two pictures so near alike as not to have their differences detected by the stereoscope.

The stereoscope is used as a test for suspected forgeries in bank-notes, a photograph of a genuine note being placed in the instrument along with another photograph of the suspected note, and a difference in the engraving so slight as not to be detected in any other way is at once made manifest by the stereoscope.

Next we are treated to some historical matter which is equally incorrect; and, as "Technique" would have been a very little boy at the time alluded to, I must remind him that dry plates were not introduced commercially at 2*s.* 2*d.* per dozen for half-plates, I remember paying 12*s.* per dozen; so that the price of commercial dry plates had nothing whatever to do with either the popularity or the decline of the stereoscope.

Next we are told that "one great complaint that always clung to stereoscopic pictures was the smallness of the view and the extreme minuteness of the object, not all subjects being alike suitable subjects for the stereoscope."

With respect to size, it has been demonstrated in this Club that when these small pictures are viewed by properly constructed instruments we get the apparent natural size of the object, and there were properly constructed instruments even so far back as twenty-five years ago.

I admit that thousands of improperly mounted pictures have been placed upon the market, and long-focus stereoscopes were introduced with a view of meeting the defects in the slides; but because this was done for commercial gain, or by those who do not understand the principles, is no sound argument against the stereoscope. To say that "all subjects are not alike suitable for the stereoscope" just amounts to saying that all subjects are not suitable for binocular vision, or that, to look at certain subjects in nature, we should close one eye, which everybody will admit to be ridiculous.

A comparison is then drawn in favour of the "pleasure of turning over the leaves of an album and the efforts and the trouble of twisting about to peer into a stereoscope."

This is rather funny, for, as a rule, amongst my photographic friends I don't often find many albums worth looking at; but I have taken some trouble to produce a decent one, and I have tried the experiment scores of times by giving my friends first the album, which they usually finish with in about ten minutes. After this I give them the very same pictures by the stereoscope, and these excite their admiration for an hour.

But, continuing, we have another comparison between the "selfish stereoscope" and the "popular lantern slide." Well, as regards selfishness, the same argument might be used against the microscope, but it would not detract from the merits of the instrument. I remember reading somewhere that a stereoscopic slide was always in season, daytime or night, winter and summer, in company or alone, and we cannot say so much for a lantern slide; besides, I wonder if it ever occurred to "Technique" that from stereoscopic negatives lantern slides were just as easily made as from quarter-plate negatives, and very much easier than from half-plate or larger-size negatives, or did it ever occur to him that a stereoscope could be passed round amongst a few friends, or that two or three stereoscopes were possible to be in use at one time when friends were present?

Next we are told that "the majority of stereo slides are printed on paper and mounted on cards," and another comparison unfavourable to such stereoscopic slides is given by showing the rapidity and conveniences of printing lantern slides. Now, here again, "Technique" has overshot the mark, for, so far as amateurs are concerned, only a very few make paper slides, because stereo transparencies on glass are so much easier to produce. Quite recently I had the honour to adjudicate upon a stereoscopic slide competition organized by the editor of the *Amateur Photographer*, and out of twenty-three competitors only four sent paper slides. The other nineteen sent glass transparencies; but, apart from that competition, I happen to be in perhaps the very best position to know what amateur photographers are doing in stereoscopic photography, and I do not think that more than five or six per cent. of them make paper slides.

But now we come to some *personal experience* of "Technique," who tells us that he has made stereo pictures by a quarter-plate camera at two operations, "the camera being placed upon a simple arrangement known as Latimer Clark's parallel bars, which permitted a side-to-side motion of the camera in order to obtain the requisite angle for stereoscopic effect." In reply to this, it must be said that Latimer Clark's "parallel bars" do not permit any *angle* at all, they keep the axis *parallel;* some modifications of this arrangement were made in years gone by, and these did permit *an angle*, but they were wrong in principle and in practice too, and the difficulty complained of, by the two halves of the negative being unequal, is just what might have been expected by anybody who had studied the subject. But "Technique" concludes his "personal experience" by his observance of these and some other defects in a number of slides published in the *Stereoscopic Magazine* of 1862.

The next paragraph treats of "the number of people who cannot see pictures stereoscopically because there is something wrong with their eyes."

This is a tale I have heard hundreds of times, and in at least ninety per cent. or more I have had the pleasure of proving that it was not their eyes that were wrong, but the badly mounted slides or the defective stereoscopes that caused all the trouble. Here is a case in point. Just a little time before this article from the pen of "Technique" was published, Mr. John Howson, the managing director of the Britannia Works Company, called upon me, and, in the course of a very pleasant chat on general photographic matters, he told me that he had never in his life been able to see a stereoscopic slide stereoscopically by a stereoscope because there was something wrong with his eyes. "They are not of equal foci," he said. "Oh, is that all?" I replied, and I examined his eye-glasses. Seeing they were about like my own, I picked up a stereoscope from the table, and the first stereoscopic slide I could put my hands upon. After adjusting the instrument to my own sight, I handed it to Mr. Howson, saying, "You ought to see that;" and "I do," he replied, "I never saw anything more beautiful; show me another," &c. In conclusion, Mr. Howson paid me a very pretty compliment.

But "Technique" has a most wonderful control over his optic axis that leaves both Mr. Howson and myself in the shade, for he states that he can not only see slides stereoscopically without a stereoscope, but that he can "look at them from top to bottom of a window in Cheapside or Regent-street, and see every one stereoscopically at six inches to ten feet distant."

I admit there are a few people who can see slides stereoscopically without a stereoscope, but, out of a good many people who state that they can do this, at least ninety per cent. are mistaken. Instead of seeing the right-hand picture with the right eye, and the left-hand

picture with the left eye—which, with slides mounted at three inches centre would entail a considerable divergence of the optic axis—they really see the right-hand picture by the left eye, and the left picture by the right eye; this is done by converging the optic axis (squinting). Thus they see the very opposite to stereoscopic, viz., *pseudoscopic*.

But, in either case, stereoscopic or pseudoscopic, pictures viewed in this way—without a stereoscope—look very much smaller than they really are, and by the stereoscope they look larger than they really are. But to be able to see slides stereoscopically at six inches or ten feet distance, as "Technique" says he can, is a most extraordinary performance; and, if the proposed committee and the dinner be arranged, I should like to have *something extra* on that.

Finally, "Technique" sums up the "essence of his remarks" by advising his readers to put their money in monocular cameras, and get as much solidity and relief as they can.

Now, allow me to sum up the essence of his remarks. I could do it best in two words, but will manage it in one word—PREJUDICE

W. I. CHADWICK.

SOME POINTS IN CONNEXION WITH DEVELOPMENT.

THE tables given by Mr. Bothamley (page 445, July 14) are well calculated to show the power of control in development, but are misleading when the effect of fog is considered.

From the following paragraph it seems to be assumed that, because in the second case an alteration in column 1 has produced an alteration in column 4, that therefore any other alteration will produce a similar result. "Since to add a constant quantity to the terms of a ratio diminishes the ratio, it is clear that the fog will lessen the ratios of the opacities."

Now, it is quite possible to alter column 1 without making any difference whatever in 4, but this can only be done by adding equal amounts to column 1, exactly what is done by adding fog, and the ratios of light transmitted remain unaltered.

Tables 1 and 2 are as given by Mr. Bothamley (correcting the misprints in column 4), and 3 and 4 are the same with fog added.

1.				2.			
Thickness of the silver layer.	Ratios of the densities.	Light transmitted.	Ratios of the light transmitted.	Thickness of the silver layer.	Ratios of the densities.	Light transmitted.	Ratios of the light transmitted.
1	1	$\frac{1}{2}$	8	2	1·0	$\frac{1}{4}$	8
2	2	$\frac{1}{4}$	4	3	1·5	$\frac{1}{8}$	4
3	3	$\frac{1}{8}$	2	4	2·0	$\frac{1}{16}$	2
4	4	$\frac{1}{16}$	1	5	2·5	$\frac{1}{32}$	1
3.				**4.**			
2	1	$\frac{1}{2}$	64	3	1·0	$\frac{1}{8}$	64
4	2	$\frac{1}{16}$	16	5	1·66	$\frac{1}{32}$	16
6	3	$\frac{1}{64}$	4	7	2·33	$\frac{1}{128}$	4
8	4	$\frac{1}{256}$	1	9	3·00	$\frac{1}{512}$	1

From the above we see that the only effect of fog is to reduce the amount of light transmitted in a given time, the gradation remaining unaltered.

J. STERRY.

PHOTOGRAPHIC CONVENTION OF THE UNITED KINGDOM.*

The following papers were taken as read:—

LATITUDE IN EXPOSURE AND SPEED OF PLATES.

BY F. HURTER, PH.D., AND V. C. DRIFFIELD.

IT is generally assumed, because our researches have led us to pronounce exposure and not development to be the determining factor in photography, that therefore the production of similar prints from a series of negatives which have received widely varying exposures, and have been submitted to widely different treatment in development, totally upsets the whole of our conclusions.

Our attention has been called from time to time to such series of negatives, and, in all the instances which have come to our notice, there has been no difficulty whatever in arranging the negatives in the order of their exposures, nor has it been much more difficult, by mere inspection, to so arrange the prints. If, however, such negatives be measured, and their density ratios ascertained, the order of the negatives, with respect to duration of exposure, is readily decided beyond all possibility of error.

As an instance of such a series of negatives we give our measurements of four plates, sent to us two years ago by a gentleman in Ireland, as an illustration of the latitude in exposure obtained by appropriate treatment during the operation of development. The subject was the same in all four plates, and consisted of a field bordered by trees. In the middle distance was a grey house, one side of which was illuminated by the diffuse light of the sky, and the other side by the sun. We measured the densities of the sky, the two sides of the house, the most transparent shadows in the trees, and a spot in the grass. In order to ensure the measurement of precisely the same spots in all four plates, masks with circular openings were fixed on each negative, so that the circles coincided when the subjects coincided. The four plates respectively received exposures of 1, 10, 30, and 60 seconds, and the resulting negatives yielded prints differing so little in quality that they were deemed to have completely demolished our contentions. The following table gives the results of the measurements:—

DENSITIES.

Exposures.	1″	10″	30″	60″
Darkest shadow in trees ...	·378	·553	·973	1·028
House (shadow side)	·833	·750	1·371	1·315
Grass	·930	1·005	1·706	1·581
House (sunlit side)	1·721	1·571	2·121	1·921
Sky	2·598	2·236	2·578	2·308

A glance at the densities of these negatives, particularly those indicating the extreme range (darkest shadow and sky), shows how widely they differ from each other; whilst a glance at the negatives themselves surprises one by revealing the inability of the eye to readily appreciate these differences. The eye is still less capable of appreciating the great alteration in the density ratios given in the next table.

DENSITY RATIOS.

Exposures.	1″	10″	30″	60″
Darkest shadow in trees ...	1	1	1	1
House (shadow side)	2·2	1·35	1·40	1·28
Grass	2·46	1·81	1·75	1·53
House (sunlit side)	4·55	2·84	2·17	1·86
Sky	6·87	4·04	2·65	·24

These ratios decrease with increased exposure in perfect accordance with all our experiments. The negatives are very different indeed in this respect, and fully bear out our contention that the density ratios are a function of the exposure, and not of modifications in development. We have no hesitation in asserting that such negatives may always be arranged in the order of their exposures by any one acquainted with the subject. In printing quality, as regards time, these negatives also differ considerably.

It is clear, therefore, that these negatives do not illustrate in a very striking manner what they were intended to illustrate, namely, the great latitude in exposure. They do, however, illustrate another point, namely, the great latitude there is in the quality of prints acceptable to the eye, and the curious inability of the eye to judge numerical values of density differences. In this faulty perceptive power of the generality of eyes lies a great deal of the latitude of exposure.

Various authorities give wholly different limits for this latitude in exposures. Professor Burton has given it as 1 : 30, but states that he has succeeded with some plates with exposures ranging from 1 : 80. We ourselves stated in our original paper that the plates which we used in our experiments (Nos. 21 and 22) would have given good pictures of subjects with contrasts varying from 1 : 80, though the exposures had varied from 1 : 2; that is, the plates were capable of recording *truly* contrasts ranging from 1 : 60.

Latitude in exposure depends—

(1) Upon the quality of the plate.

(2) Upon the range of contrasts in the subject.

(3) Upon the degree of truth with which the contrasts are to be presented in the positive print.

* Continued from last number.

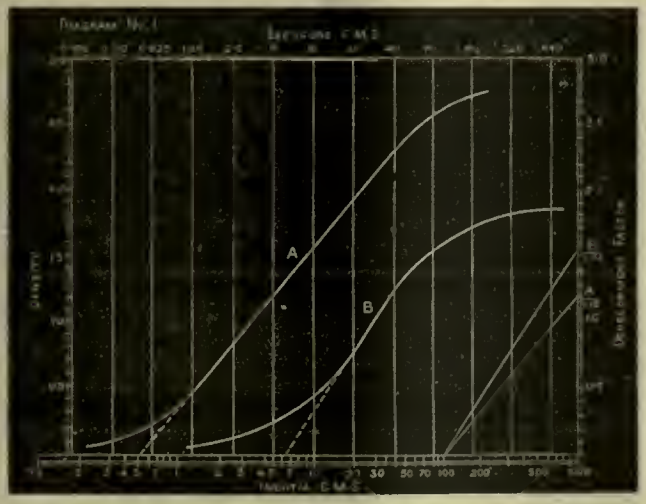
The quality of the plate is the most important question. There are some plates which have no latitude of exposure at all, or which are, at any rate, incapable of rendering any range of contrasts in this subject with any degree of truth, whatever exposure may be given. There are other plates capable of recording *truthfully* a comparatively wide range of contrasts, though exposures may vary from 1 : 5 or 1 : 6, and, if truthfulness of the intermediate tones be not absolutely demanded, such plates are capable of yielding useful negatives within such ranges as 1 : 20 or 1 : 30.

These different qualities of photographic plates are best represented graphically by the curve which we have termed the "characteristic curve" of the plate. The method of obtaining this curve will be presently described. Diagram No. 1 presents two characteristic curves of two well-known brands of plates which we will call A and B. We at once perceive a characteristic difference between these two plates. While the curve belonging to plate A is nearly straight from exposure 0·625 cm. to exposure 80 cm., plate B yields a curve which has hardly any straight part in it. Now, we have shown that, if a plate must truly represent the contrasts of the subject, it can only do so if it possesses a perfectly straight portion within its characteristic curve. The longer this straight part is, the greater is the latitude of exposure for that plate.

Plate A would represent a subject with contrasts varying from 1 : 20 with a high degree of truth, though the exposures varied from 0·625 : 4, from 1 : 6. If several exposures were made upon several plates, the exposures ranging from 1 : 6, they would yield negatives of very different appearance, giving, however, identical prints, though the negatives were all simultaneously developed in the same dish for the same length of time. But, though all these negatives yielded identical prints, the professional photographer would discard them all but one, which to him, at all events, would be the only really good negative. *There is one exposure, and only one, which yields a true representation with minimum density.*

Plate B, on the other hand, would never give a correct representation of any subject. Such plates could not be sold or used if the eye were capable of readily detecting photographic untruth in prints. It is owing to this defect that such a plate can be used at all. But the unsatisfactory nature of the plate, as revealed by the characteristic curve, makes itself evident in practice by the very limited range of exposures which will yield satisfactory negatives. With such plates Professor Burton would have tried his art of altering density ratios in vain.

Next in importance to the quality of the plate is the question of range of light intensities, which have to be recorded truly. Plate A is capable of representing light intensities lying between 1 and 70. If intensities had to be photographed embracing a greater limit than 1 : 70, it could



only be done by sacrificing truth or proportionality to truth altogether. In the case of plate B, the limit would lie between 1 and 2. The question arises, What are the usual variations in light intensities which have to be considered in photographic practice? Many photographers appear to have highly exaggerated ideas upon this subject. We do not exactly know what Professor Burton's opinion is; but it would appear, from his remarks, that the power of altering density ratios by variations in the developers can only be exercised in the case of plates which have received light intensities varying from one to at least several hundreds. From this we are led to assume that he supposed that the two prints he has recently published represent light intensities varying from one to at least several hundreds.

Now, it is an easy matter to ascertain the limits of light intensities which have to be dealt with in any given subject, and the following is the outline of the method we adopt in such an investigation. We cut a plate into two parts. Upon one part we make a series of exposures to the standard candles so as to determine the characteristic curve, the other part of the plate is exposed in the camera to the object of which it is desired to ascertain the range of light intensities. We give such an exposure as will produce a correct negative, but it is not necessary to hit this very accurately. The two parts of the plate are then developed together for the same length of time, and with the same developer, and the highest and lowest densities of the negative, and such others as are of interest are measured, as are also the densities resulting from the candle exposures. It will be evident that this graded plate, produced by exposure to the candle, serves as the scale wherewith to measure the light intensities actually at work in the camera, and which produced the densities of the negative. For such experiments it is, of course, desirable to select subjects which present sufficient areas of uniform density in the negative. A useful subject, because it comprises the entire range of tone which a paper print admits of rendering truly, is an ordinary folding screen, upon each of two folds of which are fixed a sheet of white cardboard and a sheet of matt black paper. The screen is so placed that one fold is illuminated by direct sun light, and the other by the diffused light of the sky, and so that the sky itself is included in the picture. This subject gives us five densities on the resulting negative, namely :—

Sky.
White, illuminated by the sun.
White, ,, ,, diffused light.
Black, ,, ,, the sun.
Black, ,, ,, diffused light.

The following are the details of such an experiment, and diagram No. 2 illustrates graphically the method of ascertaining the equivalent of the light intensities in candle-meter seconds. A plate was cut into four parts; three of them were exposed in the camera to a subject as just described, and the fourth was exposed to the standard candle, the exposures ranging from 0·312 cm. to 160 cm. The three exposures given in the camera were 0·8, 4, and 24 seconds respectively, and all four plates were developed together in one dish for the same length of time. The densities of the negatives and of the graded plate were found to be—

Densities of Negatives.

Exposure.	0·8″	4″	24″
Sky	0·940	1·695	2·260
White in sunlight	0·940	1·735	2·280
White in shade	0·620	1·360	2·080
Black in sunlight	0·120	0·530	1·290
Black in shade	0·060	0·320	1·025

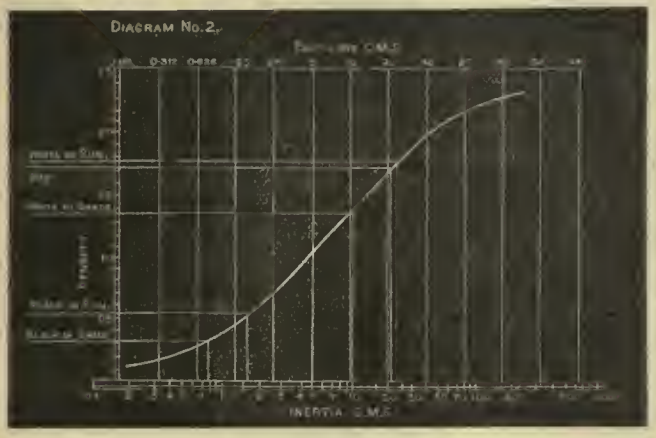
Densities of Graded Plate.

Exposure. cm.	Density.	Exposure. cm.	Density.
0·312	0·150	10	1·360
0·625	0·275	20	1·665
1·25	0·440	40	1·935
2·5	0·700	80	2·160
5·0	1·040	160	2·295

The densities of the gradations obtained by these ten exposures were plotted as a curve, the logarithms of the exposures as abscissæ, and the densities as ordinates. Parallels corresponding to the densities of the three negatives were then drawn, and where they intersect the characteristic curve perpendiculars were drawn through the points of intersection. These perpendiculars indicate at one the equivalent exposures in centimetres which produced the corresponding densities. In diagram No. 2 the densities of the negative which received an exposure of four seconds are thus plotted, and it will be seen that the respective equivalent exposures are—

Negative, 4 sec. exposure.
Sky ..... 20·80 cm.
White in sun ..... 22·50 ,,
,, shade ..... 10·20 ,,
Black in sun ..... 1·62 ,,
Black in shade ..... 0·77 ,,

It will thus be seen that the whole range of light intensities, from matt black in the shade to the sky or white cardboard illuminated by the sun, is as 0·77 : 22·5, or as 1 : 29. Similar results were obtained with the



other two negatives, and the following table gives their equivalents, the highest light being put = 30.

Relative intensities of light emitted by	As shown by negatives exposed.			Mean.
	0·8″.	4″.	24″.	
Sky	30	27·7	29	28·9
White in sun	30	30	30	30
,, shade	15	13·6	13·0	13·8
Black in sun	1·83	2·1	1·78	1·90
,, shade	1·16	1·02	1·01	1·06

We learn from this experiment that an object illuminated by direct sunlight is about twice as bright as the same object in the shade; and that the whole range between a matt black object in the shade and a brilliantly illuminated sky is about as 1 : 30. It will also be seen that the exposures given in the camera vary as 1 : 30, and yet the same relation as to light intensities is revealed by the shortest, as by the longest, exposure.

If we now examine Professor Burton's statements in the light of this, to him, evidently new knowledge, we have to point out that, according to his own confession, he cannot alter density ratios between limits of exposures 1 : 10; and he would not, we presume, undertake to seriously alter density ratios between such narrow limits as 1 : 30, since he says that "it is necessary to have ranges of exposures of at least several hundreds to one to be able readily to vary the density ratios."

Now, assuming certain conditions, *actually never present in photographic practice*, it seems, according to Professor Burton, true that it is possible to vary density ratios when the exposures vary between at least several hundred to one. Such variations do not occur in ordinary subjects; the light intensities vary between limits of 30 : 1 at most. Professor Burton's faculty of producing negatives which yield similar prints is not due to his mode of development; it lies wholly in the latitude of the plate and in the narrowness of the range of light intensities in his subject. He could have obtained identically the same result, and possibly a better, by means of *one* developer, and by simply varying the time of development for the shortest exposures.

Two negatives are alike in their printing quality when the density differences are alike throughout, whatever the density ratios may be. Two negatives may have totally different density ratios, and yet be equally true to nature and yield identical prints, whatever printing process may be employed, so long as it is the same in both cases. Thus, so long as the light intensities of a given subject lie within a certain limited range, and the time of exposure is such that the densities produced fall within the straight part of the characteristic curve, so long will the density differences for the same subject be independent of exposure, and alike.

Suppose the length of the straight part of the curve cover a range of exposures 1 : E; and the light intensities to be photographed lie between the limits 1 : I, the latitude of the exposure would then be $1 : \frac{E}{I}$; and within these two limits any exposure would produce negatives which, developed in the same developer for the same length of time, would yield negatives giving identical prints. Take the case of plate A. The straight part of its characteristic curve may be taken as extending from exposure 1 cm. to exposure 80 cm., *i.e.*, 1 : 80. If a subject had to be photographed which was illuminated by diffused light only, and in which the light intensities varied from matt black to white or even more, say a range of 1 : 20, the plate would yield negatives, with exposures varying from 1 : 4, almost identical in printing quality, though they were all developed together. If a little deviation from truth is permissible, and the portion of the characteristic curve lying between exposures 0·312 cm. and 160 cm. (a range of 1 : 512) be considered as sufficiently accurate, the same subject would permit a latitude of exposure of $\frac{5}{2}1^2 = 25$, and there would still be very little differences in the negatives, particularly if development be prolonged in this case of the shorter exposures. For a sunlit landscape the latitude would be $\frac{5}{3}1^2 = 17$.

The experiment we have described was made on a plate, the straight part of which only extended from an exposure of about 1·5 cm. to one of 50 cm. For an ordinary sunlit landscape its latitude of exposure is, therefore, small, namely, $\frac{50}{15 \times 30} = 1{\cdot}1$; and consequently, if a correct negative be required on such a plate, the latitude of exposure would have to lie within ten per cent. of its own value. The negative which was exposed for four seconds is the truest of the three; the one which received one-fifth of this exposure renders the high lights correctly, but not the shadows; and the one which received six times the exposure of the first-named negative renders the gradations as far as white in diffuse light correctly, but not the highest lights. The following table shows the density differences for the various parts of the negatives, which would have to be all alike if the negatives must yield identical prints :—

Exposure ...	0·8″	4″	24″
Density of clearest spot ...	·060	·320	1·025
Density difference—Black in shade and black in sun	·060	·210	·265
,, ,, Black in sun and white in shade	·500	·830	·790
,, ,, White in shade and white in sun	·320	·375	·200
Total range of negative—Black in shade and white in sun	·880	1·415	1·255

It will be seen that the negative which received four seconds, the correct exposure, gives for all parts of the subject, with the exception of the highest lights, practically the same density differences as the one which received twenty-four seconds' exposure. In prints from these two negatives all gradations lying between black in shade and white in shade would be exactly alike, though the exposure was, in the case of one negative, six times as much as in the other. The negative which received one-fifth the correct exposure only renders the high lights with equal truth. If, however, this negative had been developed for a longer time than the other two, its range could have been considerably improved; the ratios remaining the same, the density differences would have altered, and it could easily have been brought to the following :—

Exposure	0·8″	4″	24″
Density of clearest spots	·100	·320	1·025
Density difference—Black in shade and black in sun ...	·100	·210	·265
,, ,, Black in sun and white in shade ...	·830	·830	·790
,, ,, White in shade and white in sun ...	·530	·375	·200
Total range of negative—Black in shade and white in sun	1·460	1·415	1·255

In this case the resulting prints would have differed little from each other, since all the main gradations lying between black in shade and white in shade would have been represented by the differences :—

0·8″	4″	24″
0·930	1·040	1·055

which are so nearly alike that the eye could not detect the difference.

Only in the highest lights, beyond white in shade, would the difference be at all apparent. The three negatives differ, however, very materially in the time they require to yield prints of equal depth in the shadows. The last of the series (twenty-four seconds exposure) requires six times, and the second (correct exposure) nearly twice (⅓ the time which is needed for the first to print to the same depth.)

From these experiments it is clear that latitude in exposure is not inherent in modifications of the developer, but in the plate itself, and in the comparatively narrow range of intensities which are ordinarily met with, combined with the inability of the eye to judge of the more or less truthful rendering of the various gradations.

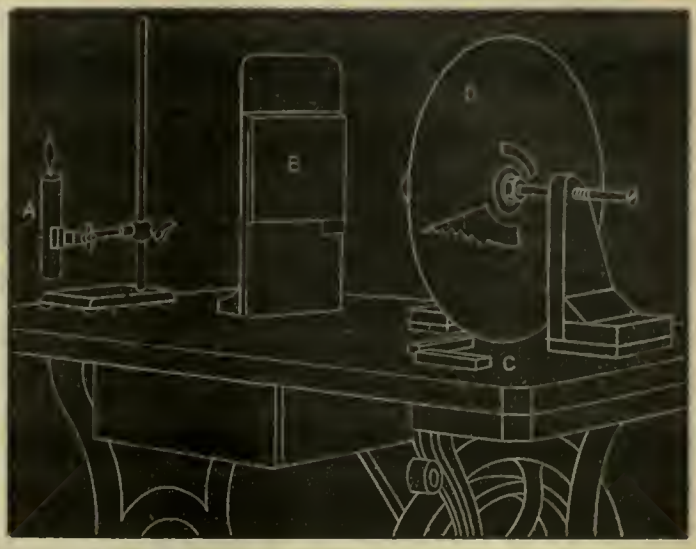
As already pointed out, among the many negatives which may be produced by mere variations in exposure, there is only one which combines truthful rendering of tone with minimum density; and it is this one which the practical photographer aims to secure. For the more accurate and certain production of this particular negative, it is necessary to ascertain the speed of the plate with tolerable accuracy; and we now propose to give a short practical description of the method we have adopted for this purpose. We believe that many amateur photographers would be glad to be in a position to determine speeds for themselves, and to obtain that knowledge of the properties of their plates which can only be derived from a study of the characteristic curve.

The course we pursued in our original investigations was to expose portions of the same plate consecutively to the light of a standard candle, doubling each successive exposure as we proceeded, and we naturally adopted this course when we came to make our first determinations of speed. The errors to which we found the candle liable, however, when we had not the experience in its use which we have since gained, showed that much was to be desired in order to secure a constant ratio of illumination between the different exposures, and, in order to secure this, we adopted the plan of making our exposures which we are about to describe, and which we believe to be the most satisfactory. By this method the whole of the exposures are made simultaneously, so that any fluctuations taking place in the light of the candle proportionally affect all the exposures, and the determination is consequently more decisive and less liable to error than if fluctuations in the light were to take place during one or more of the individual exposures. Moreover, the possibility of error arising from the difficulty of accurately timing very short exposures is wholly eliminated.

We will, in the first place, make a few remarks upon the standard candle as a unit of light. While we candidly admit that the candle is by no means an ideal standard, we must say that we are not at present aware of any satisfactory substitute. We adopted it, in the first instance, because it was ready to our hand, well known and recognised as a standard, and easily obtained. And we may perhaps be forgiven for entertaining a somewhat higher opinion of it than some of our friends, inasmuch as it was, at any rate, reliable enough to lead to the discoveries we have made. It is asserted that the amyl-acetate lamp is a better standard than the candle, but the practical difficulties in its use are such that we can only say it has not proved itself so in our hands. Altogether, we know of nothing, as yet, better as a standard than the candle, and, if the suggestions for its use which we are about to make be adopted, we do not think it will lead to serious errors. Two determinations of the inertia of this same plate which we have just had occasion to make, on two different evenings, differed only by 0·04 cm., a discrepancy of absolutely no practical moment. We have unquestionably found that the standard candles of different makers do vary, and for this reason we think it well to say that the candles we have used throughout our investigations were supplied by Messrs. Sugg & Co., Vincent Works, Westminster. The normal height of the flame of these candles, measured from the lowest point at which the wick blackens, is about forty-five millimetres.

Our method of using the candle for the purpose of speed determination is as follows. We will assume that the candle we are about to use has been used before. We light it, and then, with scissors, snip off the hardened tip of the wick; the flame of the candle will now be found to grow steadily in height, and as soon as the distance from the tip of the flame to the lowest point at which the wick blackens has reached forty-five millimetres the exposure may commence. The candle flame may now be relied upon to remain sufficiently constant for about ten minutes, and this is amply long for our purpose. If after this time, for any other purpose, the light is required, it will be well to again trim the wick, and start *de novo*. The height of the flame may be measured by a strip of cardboard, upon which two marks are made at a distance of forty-five millimetres apart. It is, of course, obvious that these experiments should be made in a room free from draught, and it is often a wise precaution to place the candle in a tall box, open on one side and well blackened inside. We are strongly in favour of keeping the candle well in view during the entire exposure, so that, should any fluctuation in light take place, we may be aware of it. If the candle be used in the open room, all white or bright surfaces capable of reflecting light should be removed.

If a plate be examined by placing it between the eye and the red lamp,



it will be found that the opacity of the film falls off at the edges. The edges should, therefore, be scrupulously avoided, and the strip should be cut from the centre of the plate, or, at any rate, well away from the margin. The operation of cutting the plate should be conducted as quickly as possible, and as far away as possible from the red light, so as to avoid all fogging action of the light upon the plate. The width of the strip may conveniently be made about one inch. When the plate is securely placed in the dark slide, the latter is placed in its position behind the disc. The distance from the candle to the place occupied by the plate is carefully adjusted, and the candle is lighted and trimmed. When the flame has reached the requisite height, the exposure may commence.

The disc is caused to revolve, and, at a given moment, the slide protecting the plate is drawn, and the exposure continued for the requisite length of time.

Now, as to the best range of exposures to decide upon in the case of a plate of the speed of which we know nothing, we should advise a series commencing with 80 cm. down to 0·312 cm. This range will be found to include as much of the characteristic curve of the majority of commercial plates as is required for a speed determination. A little consideration of the revolving disc, however, will show that, in order to give

an actual maximum exposure of 80 cm., it will be necessary to continue the exposure for twice 80, or 160 seconds, the candle being placed at a distance of one metre from the plate. The reason of this is that the actual maximum exposure only proceeds during half the revolution of the disc, the light only reaching the plate during the passage across it of 180° out of the 360°. Though we prefer to work with the candle at a distance of one metre from the plate, it may be brought nearer to it if it be desired to curtail the exposure. At a distance of 0·707 metre, the light of the candle is equal to 2 cm., and at a distance of half a metre it is equal to 4 cm.

Having exposed the strip, we next proceed to develop it; and here we must say a word or two upon the subject of the developer. We do this knowing perfectly well that we shall meet with considerable opposition; but we, nevertheless, again assert that, for all ordinary photographic work, there is no developer superior to ferrous oxalate. We prefer it because of the uniformity of the colour of the silver deposited by it, a point of very great importance when we come to the operations of printing and enlarging by developing processes, in which the exposure is arrived at by calculation: we prefer it because we never yet found a plate with which it disagreed, and this is more than can be said of other developers. It will also develop an old plate which may have been carelessly laid by for years; while, with another developer, it would be hopeless to obtain a passable result. We prefer ferrous oxalate because, of all developers, it is least liable to attack silver salts, which have not been acted upon by the light, and because it will not lend itself to the production of foggy messes. We do not wish for a moment to imply that other developers may not have their special uses; on the contrary, for example, we have found rodinal of the greatest value in the case of certain plates, when dealing with extremely short-shutter exposures, and also in flash light work.

However, to proceed with the operation of development. It is advisable that this operation be conducted at a fixed temperature, and we find 65° Fahr. the best to adopt, as it is easily obtainable both in summer and winter. The developer itself should be brought to this temperature, and maintained at it by placing the developing dish in a water bath of the same temperature. The constituents of the developer are intimately mixed by stirring, and, at the moment of pouring on to the plate, the time is noted. The dish should only be rocked for a few moments, in order to expel any air bubbles from the surface of the plate, and should then be covered up, so as to expose the plate no more to the red light than is absolutely necessary. Examination of the plate during development should be avoided as far as possible, as no red light whatever is safe in the case of even a fairly sensitive plate; and we believe that too frequent examination, prompted by curiosity or impatience, is to some extent responsible for alleged alterations in density ratios. About five or six minutes will, as a rule, be found the best length of time to continue development, in order to obtain that range of gradation most suitable for subsequent measurement. But, however long development may be continued, the time occupied should be carefully noted. The object of the fixed temperature, and the exact time a given plate takes to reach a certain development factor, is of the utmost importance, if we afterwards desire, upon a similar plate, to produce another negative having a different range of density gradations.

After development, the strip is fixed and washed in the ordinary way, and, after washing, it is well to wipe the surface of the film gently with a plug of wetted cotton-wool. The plate may be treated with alum if desirable, and both the alum and fixing baths should be fresh and perfectly clean. As the films of some plates are liable to loosen from the glass when submitted to the heat of the lamp in the photometer, it is sometimes well to soak the plates for a few moments in a weak solution of glycerine after washing and before drying. When the plate is dry—and this may be hastened by means of alcohol if desired—the back of it should be thoroughly cleansed, and the film wiped with a silk handkerchief. It will now be found advantageous to define the dividing lines of the smaller densities with a pen and ink on the film. This will materially assist when we come to measure the plate, which operation may now be carried out. We do not here propose to enter into any description of our photometer and the method of using it; this will be found in our original paper in the *Journal of the Society of Chemical Industry*.

The nine different densities and the "fog strip" having been measured, and having deducted from each exposure density the density of the incipient fog of the plate and that due to the glass and film as given by the "fog strip," we proceed to plot the characteristic curve on one of the skeleton diagrams supplied for the purpose by Messrs. Marion & Co. Assuming that our actual maximum exposure was 80 cm., we mark on the ordinate corresponding with this exposure this density, minus fog, due to the 80 cm. exposures; and so on till we reach the ordinate corresponding with exposure 0·312 cm. Having thus plotted all the nine densities, we take a piece of black thread and stretch it along that part of the curve which practically forms a straight line, and which indicates the position and extent of the correct period. This enables us to decide upon the position of the straight line before we actually draw it on the diagram. We now draw the line, and continue it till it intersects the inertia scale at the bottom of the diagram. The point at which the intersection takes place gives the inertia of the plate, which is then converted into the speed by dividing it into the constant 34. For example, inertia 1 = speed 34. We may now join up to either end of the correct-period curves passing through the remaining points of the determination. The curve at the upper end will represent a portion of the period of over-exposure, and that at the lower end of the period of under-exposure, the whole representing the most important features of the characteristic curve. The details just described will be better understood by a reference to diagram No. 1.

We should here like to express the importance we attach to obtaining, in every speed determination, distinct evidence of all three periods. It is only by so doing that we can be quite certain as to the position of the correct period. It would be quite possible for the higher densities in a series of under-exposure gradations to be mistaken for a portion of the correct period in the case of a high development factor—in fact, we have known this mistake to be made when, had there been evidence of the three periods, mistake would have been rendered impossible.

We generally have some idea whether the plate we are about to examine is a rapid or a slow one, and after a little experience it is easy to decide upon that range of exposures which will most probably yield evidence of the three periods; but should we, in the case of a plate, of the speed of which we have no idea whatever, find that the exposures we have chosen yield a series of densities which leave room for doubt as to the position of the correct period, it will be necessary to make another determination, a more suitable range of exposures being chosen. The first determination will indicate whether a longer or a shorter exposure be desirable.

We must here call attention to a difficulty which may possibly arise; but its occurrence is fortunately so rare as to speak well for the perfection of the machinery used for coating the plates. If, on plotting the densities, they are found to lie irregularly, so as to preclude the possibility of drawing through them a regular curve, there is serious reason to suspect an unevenly coated plate. In such a case as this, the best thing to do is to cut another strip from the plate from which the first was taken, and running in the same direction of the plate as the first strip. The second strip should now be uniformly exposed to the candle and developed the exposure and development being so timed as to produce an easily measurable density of, say, 1·0. If the plate have been unevenly coated, the density of the second strip, when measured in different places, will be found to vary. As an example, we have been able to lay our hands upon the record of a case which occurred in our own experience. The irregular series of densities obtained in the first instance led us to make a second exposure as described, when we found that the density measured in different parts of the strip varied from 1·335 to 0·820. When we remember that this means that one part of the strip transmitted more than three times as much light as another, the serious nature of such a fault as inequality in the thickness of the film will be apparent.

Reference has been made several times to the development factor. It is beyond the scope of this paper, however, to enter fully into this subject; but, as the numerical value of this factor is one of the data to be derived from every speed determination, we will state how it is graphically ascertained. From the point 100 on the inertia scale of the skeleton diagram, a line, parallel to the straight portion of the characteristic curve, is projected till it intersects the development factor scale. The point of intersection gives the factor which expresses the extent to which the development of this particular plate was carried. It is best for the purpose of speed determination to aim at reaching a development factor of 1·0, or a little more. It will be seen, on referring to diagram No. 1, that the development factors of the two plates A and B are 1·18 and 1·52 respectively.

We believe we have now explained the method of making a speed determination in sufficient detail to enable an amateur to carry out the operation. We trust, however, that any amateurs who take the matter up will not content themselves with plotting the characteristic curve of a plate for the sole purpose of ascertaining its speed, but will take an interest in tracing, in the conformation of the curve, the results which they obtain in their photographic practice. It is a knowledge of this curve alone which can give the photographer complete control of the materials

he employs. On some other occasion we hope to show more fully than heretofore the part which the characteristic curve plays in the calculation of the exposure for transparencies and printing processes generally, as also in the production of negatives and positives having a special range of gradation.

ON THE POWER OF COMPENSATING IN DEVELOPMENT FOR VARIATION IN EXPOSURE.

By W. K. Burton.

The experiments I am about to describe were certainly suggested by opinions expressed by, or at any rate commonly attributed to, Dr. F. Hurter and Mr. V. C. Driffield some three years or so ago, but I wish to make it amply plain that I do not intend this paper to be taken as a refutation of any opinion that they hold—at the present time at any rate. In the first place, I admire so much the method of investigation that these gentlemen have pursued, that I should be very sorry to write anything that might tend to lower the estimation in which these investigations are held, even if, as may be the case, the conclusions arrived at are not exactly in accordance with fact; and in the second place, because, if there is any refutation to be done, there are plenty of people on the spot much more able to undertake it than I am.

As far as I have followed them, Messrs. Hurter & Driffield at first stated that it was impossible, by development, to alter either the density or the opacity ratios in a negative. In other words, that were the thing represented graphically, with light as abscissæ, and one of them having density and the other having opacity as ordinates, then, the abscissæ remaining constant, the ordinates might be altered by variation in the developer, but that their ratio to each other could not be altered. It is, however, as a matter of fact, very easy to so alter the ratio by variation in development that two curves, representing either density or opacity, would intersect each other, in which case the ordinates would, of course, not be proportionate. I understand, however, that Messrs. Hurter & Driffield have considerably modified their views since their first statement was made, and it may be that I do not here represent fairly even the first position that they took up.

Be all this as it may, it is undoubtedly the fact that, some year or two ago, it was the general impression that it had gone out on high authority—with a sound of trumpets almost—that it was impossible to compensate for variation in exposure at the time of development, and that with the same exposure it was impossible to control in any way the result, except in so far as density was concerned.

Now, I hope to be able to demonstrate that we have power, by variation in development, to compensate for enormous differences in exposure, and that with the same exposure we have *enormous* control over the results.

The experiments that are to be described were begun some two years or so before the time that this paper is likely to be read, but were interrupted by work of one kind and another that seemed more important, the truth being that I felt no great enthusiasm to prove a thing that was a matter of every-day experience.

It was like proving, by the aid of a shokojimeter, that if you got no dinner you were likely to be hungry, if you had enough to eat your appetite would be appeased.

When I got thoroughly into the experiments, however, I found them of the greatest interest, because I began to find that our power of compensation is even greater than I had ever supposed, and I found it possible to work out at least an approximate rule for the variation in development that had to be made for a given variation in exposure.

I wish to state my very strong opinion that experiments on gradations of density (or of opacity) are not of any real value, as throwing light on the probable result of exposure in the camera, unless they include such a range of gradation as is commonly met with in actual camera work. I find this range to be generally, at least in ordinary cases, as several hundreds to one, often as a thousand to one, and sometimes as several thousands to one. What I mean is, that the plate has received at the time of exposure several hundred, or a thousand, or several thousand, times as much light at one point as it has at another.

In this connexion it is to be noted that the range of light reflected by the object photographed is always greater than the range of light that reaches the plate; that it is often much greater. Thus it is practically possible to have the nearest possible approach to absolute black in the object photographed, otherwise an approach to zero of light, in which case the range approaches infinity. In the case of the light actually reaching the plate this cannot be the case, on account of the unavoidable diffused light in the camera.

For the preliminary experiments a sensitometer on the principle of that of Messrs. Mucklow & Spurge was made. The areas of the apertures varied in the ratio of 1, 2, 4, 8, 16, 32, 64, 128, 256, 512, 1024, and 2048. The holes were bored by a watchmaker, the largest being one inch in diameter, and, as far as I can make out, the diameters are very nearly what they ought to be. The instrument is a convenient one, using quarter-plates, and many experiments were made with it. It was, however, considered that these could not be taken as conclusive, because plates could be exposed only in succession, and no standard light was available. Moreover, it was found that a gradation varying from 1 to 2048 was not sufficient for a thorough investigation of the subject.

It was, therefore, decided to construct a sensitometer in which plates could be directly exposed to light, each half having the same exposure. The plates were then to be cut in two, and the two halves were to be developed in any two developers, the effects of which it was desirable to compare.

This sensitometer is shown in the two photographs, I. and II. It is of very simple construction. Photograph II. shows a back view of the sensitometer. It has a door A, which is shown open. Through this door a plate $12 \times 2\frac{1}{2}$ (one quarter of a 12×10 plate), B can be introduced. The plate is held in a brass frame or carrier, D, that can be raised or lowered by the bar E, having a toothed or serrated edge. This bar is pressed by a spring in the direction of these teeth so that it will remain at any of fourteen different heights, holding, of course, the plate with it. The spring, F, presses the film side of the plate very nearly into contact with the front of the sensitometer. In fig. 1 will be seen a slit, G, two inches in length and a quarter inch wide. This slit is covered by the flap, H, unless the same is held open by hand, as seen in the photograph. The apparatus is designed to give exposures to different transverse strips of the plate of the size of the slit, G, in the ratios of 1, 2, 4, 8, 16, 32, 64, 128, 256, 512, 1024, 2048, 4096, and 8192. Many of the results of experiments will show that this range is not at all too long for investigating the effects of different developers on the two halves of the same plate, though the range is far greater than can be registered correctly. With any plate so exposed and developed, the strip having the shortest exposure is visible.

It was found by experiment that the shortest exposure that could be given with the flap varied very little, and was nearly exactly one-quarter second. A half-second could be guessed with some approach to correctness, one second with more, and two seconds could be measured roughly with a stop watch, four seconds with but a small percentage of error—all this after some practice, of course. It was, therefore, decided to make the exposures begin with a quarter-second, and work up doubling. It needs, however, only a very little arithmetic to discover that, even beginning at this short length of time, the last exposure must be considerably over half an hour, and to make hundreds of exposures of plates, in which the last item alone came to more than half an hour, was not to be thought of. For this reason the first exposures were all made a quarter-second each, but the distance of the plate at the time of the first exposure, 10 feet, was made 7 feet for the second, 5 feet for the third, 3 feet 6 inches for the fourth, 2 feet 6 inches for the fifth, and 1 foot 9 inches for the sixth and all others. These distances vary very nearly as 1, $\sqrt{\frac{1}{2}}$, $\sqrt{\frac{1}{4}}$, $\sqrt{\frac{1}{8}}$, $\sqrt{\frac{1}{16}}$, and $\sqrt{\frac{1}{32}}$. That is to say, the quantity of light was doubled at each approach of the sensitometer to the source of illumination, all the exposures at 1 foot 9 inches from the light needed only $\frac{1}{32}$ of the time they would have needed at 10 feet, and the longest exposure was reduced to 64 seconds.

It is not pretended that the successions were really actually those mentioned above, and it is of no consequence that they should be. Whatever irregularity there might be was bound to effect one half of the plate exactly as the other; and, as the after-process consisted in cutting the plate in half longitudinally, and developing the two halves in different developers, the only thing essential is that the two halves of the plate should have exactly the same exposures.

Nevertheless, I venture to state that the exposures of all those strips that were exposed at different distances gave very nearly the ratios mentioned, as the rapidest possible opening of the flap was found to remain very uniform, and a dead black screen was placed behind the light to prevent reflection, which would considerably modify the law of the quantity of light varying inversely as the square of the distance, at any rate considering our light as the centre of illumination. The exposures $\frac{1}{4}$ and 1 second are, of course, the most uncertain. From two seconds on, it may be considered that the acceleration is that stated within very narrow limits of error. In no case did the light vary more than about ten per cent. during the making of one set of exposures. The result of one set of exposures might thus be roughly compared with each

other, even comparing different slips, but the necessity for this has been avoided by always developing together, in a developer that will be stated, one half of each slip, so that any difference in exposure can be detected.

I have signed my name across each slip, before it was cut in two, that there should be no mixing up, and lest any should doubt the genuineness of the results. These plates would form a confirmation, were any needed, of the recent statement by an expert in handwriting, that no one can sign his name exactly the same twice, and that, if two supposititious signatures that exactly superpose each other are discovered, it may be concluded that one is a forgery.

To return to the plates, however, as the vendors of various sauces and other goods remark, "Without this signature none is genuine."

As a light an oil lamp was used. I have found a common oil lamp, with burner in good condition, well trimmed, with a fairly large reservoir, and with a good quality of mineral oil, to be much more constant for several hours than any candle that I have been able to find, if it is first allowed to burn till all parts that heat have become hot. Of course it is not so good for making comparisons on different days, because the light of a lamp is very liable to vary from day to day. I wish, however, here to remind you again that the results of my experiments are in no way dependent on either the intensity or the uniformity of the light.

It was found that, using a well-known brand of commercial plate, sold as "ordinary," a small lamp of five to six candle power was just capable of giving a developable image with an exposure of one quarter of a second at a distance of ten feet.

I have certainly at times worked exceptionally rapid plates that needed only one-fifth to a sixth of the exposures of these. We may, therefore, deduce the fact—by no means bearing on these experiments, but of some interest—that the most sensitive plates made will be visibly affected by an exposure of a mere fraction of a second at ten feet from a candle.

The greater number of the exposures were made with such a lamp as this; but, in some cases, where it was considered advisable that the first figure in the sensitometer, in the sense of the first exposed, should develop out quite markedly, the exposure was made to a lamp with a burner giving a nearly spherical flame (called, I think, a "rose burner") having a power of some twenty to twenty-five candles.

Where numbers of strips exposed are stated, it is to be understood that No. 1 is the strip that was first exposed, and that had the shortest exposure. The "first four strips," or Nos. 1, 2, 3, and 4 means, for example, these strips that received each quarter-second exposure at distances of ten feet, seven feet, five feet, and three feet six inches from the lamp.

I wish to state here that nearly all development was done by my assistant, Mr. K. Arito, from written instructions given to him by me, without comment. I had distinct reasons for this. In the first place Mr. Arito is a very careful operator, much more careful than I am—though that may not be saying much. In the second place, although, of course, he knew the general drift of the experiments, he knew nothing of what had given rise to them, or of the exact lines that I was working on. He was, therefore, much less liable to be carried into the inaccuracies that I distinctly state most of us are liable to be carried into unconsciously, or nearly so, when we wish experimentally to prove a particular fact. Still farther, it enabled me to make sure that the experiments could be repeated by any intelligent operator from briefly written descriptions.

Wherever "normal pyro and soda" developer is referred to, it is to be taken as referring to the developer that the writer has most commonly used for several years past, that is to say, one compounded as follows:—

To each ounce of developer—

Pyro (either dry or freshly mixed, without preservative)	2 grains.
Sodium carbonate (crystalline)	12 ,,
Sulphite of soda	12 ,,

This generally works without fogging, but sometimes, not always. When a new batch of plates is bought, a sample is tried, and the quantity of bromide needed to prevent any hurtful amount of fog is determined This never exceeds half a grain to the ounce of bromide of potassium with any plate that would generally be pronounced workable. In all these experiments a quarter of a grain of bromide of potassium was used to each ounce of "standard pyro and soda developer."

I do not wish to reopen the old discussion as to ammonia against other alkalies for development with pyro, but shall merely say that I have, for some time, considered that it was possible to get more out of a short exposure with soda, considering not detail only, but the whole of the negative, than with ammonia, and that the present experiments confirm this; that, moreover, I thought till recently that there was greater latitude of exposure with soda than with ammonia, but that these experiments have made me change my mind in this respect, as I have been able to get greater latitude with ammonia than with any other alkali that I have tried.

Here it may be mentioned that a set of experiments incidental to the main experiments was made to discover the relative quantities of bromide of potassium and of bromide of ammonium that were necessary to have the same retarding effect. It was found that, for unit quantity of bromide of ammonium, it was necessary to use that quantity multiplied by between 1¾ and 2 of bromide of potassium. Probably, the exact multiplier lies very nearly half way between these two—perhaps 1·875. It is near enough for all practical purposes to state that it takes nearly twice as much bromide of potassium to do the same restraining work as any given quantity of bromide of ammonium. It will be seen that the difference is much greater than the different weights of actual bromide contained in the same weights of bromide of ammonium and bromide of potassium.

After a somewhat random set of experiments, conducted to decide on the best lines to work on, more systematic experiments were undertaken. I here give the results of the most interesting of these, not by any means necessarily in the order in which they were carried out.

In all cases the temperature of the developer was kept at as nearly 65° Fahr.

A.

The instructions were:—

"All plates to be developed with a developer containing two grains pyro, twelve grains carbonate of soda, and twelve grains sulphite of soda."

"One-half of each plate, to be marked 'A,' to be developed without bromide, till the last figure is distinctly visible, till there is fair density, but development to be stopped before there is distinct fog."

"No. 1. Develop the B half with a developer containing one-half grain of bromide of ammonium per ounce, but stop when strip 2 only is of the same density as strip 1 in the A half."

"No. 3. One grain of bromide of ammonium to the ounce, stop development when No. 4 only is of the same density as No. 1 in the B half."

"No. 6. Eight grains of bromide of ammonium to the ounce, stop development when No. 7 only is of the same density as No. 1 in the A half."

There were intermediate numbers, and also numbers up to and including No. 8. I select, however, and send you the results of these three only, as being typical.

These were exposed to the large lamp, and the results must be taken as illustrating those of over-exposure. In the case of all other results sent, exposures were to the small lamp.

It will be seen that, in the case of No. 1, the density of the first few strips is, to all intents and purposes, the same in A and B, but that the density rises, after a little, more rapidly in B than in A. Farther than this, the opacity reaches a maximum at about the ninth or tenth strip in the case of the half A, whereas it keeps increasing till nearly the end of strip B. At the end the opacity of B is much greater than that of A at any part.

It will be seen that the compensation for over-exposure here has been considerable, and that the curves, both of density and of opacity, cross each other, so that the density ratios are changed.

In No. 3 the same thing is to be remarked, and, besides that, the first strip or two of B are less opaque than the corresponding strips of A. Here there is greater compensation for over-exposure, and the curves of both density and of opacity cross each other, so that the density ratios are changed.

In No. 6 the same thing is to be noticed, with the complete suppression of the first four, and nearly the complete suppression of the next two strips of the B side. It must, however, be explained here that intensification was resorted to. The reason for this was that, with the large quantity of bromide here mentioned, corresponding, say, to fifteen grains of bromide of potassium to the ounce, the image was white by transmitted light. I mean the deposit. It had no printing value at all, and I had not time to discover even if it was of silver. At any rate, it blackened, or rather browned, under intensification. It will be seen here that, at any rate, the curves of opacity cross, and that the opacity ratios are very much changed. This is, however, by the use of an intensifier. The next plate, with double the quantity of bromide in the developer, showed the same peculiarities even more strongly than the last, and it was found impossible even to "brown" the image.

A great number of experiments here intervened, having for their object the investigation of the effects of varying the quantity of pyro as well as that of the restraining bromide, and also to discover to what extent compensation for variation in development can be carried by combined variation in the developer with the after-application in the intensifiers. The results of all these experiments being summed up in those got with ammonia as an alkali (the experiments just referred to were all carried on with carbonate of soda), I therefore prefer to leave them out, as the recounting of them would be tedious, the more especially as I found the results, in the matter of compensation for variation in exposure, much better in the case of ammonia than with soda, in great measure on account of the whiteness of the deposit with soda, when much bromide was used, that has been already mentioned.

A set of experiments was now made to compare what I have called the "normal pyro and soda developer," in its results, with those of pyro and various proportions of bromide and ammonia. As I have said, I came to the conclusion that, vary the ammonia developer as I would, I could not get out as much with it as with soda without fog, and it is to be observed that the advent of fog is the limiting line of the action of any developer. The developer that is the most powerful reducer is not by any means of necessity the most efficient developer. It is that developer that can differentiate the most between bromide of silver that has, and that has not, been affected by light that is the most efficient.

B.

This series of experiments is intended to show the power of varying the effects of a uniform exposure, in a manner that would correspond to compensating for variations in exposure, with the ammonia developer, varying the quantities of each of the three constituents, and intensifying in certain cases. I think these experiments are conclusive as to the enormous control that we have over our results by variation in development.

The instructions were:—

"Develop all halves A with a developer containing half a grain of pyro, half a grain of bromide of ammonium, and two and a half minims of ammonia to each ounce. Develop either till slight fog shows itself or till all action has, for some time, ceased."

"Develop all halves B with a developer containing four grains of pyro, four grains of bromide of ammonium, and four minims of ammonia to each ounce."

(It is to be observed that these quantities had been determined on from the results of previous experiments.)

"No. 168B, restrain one figure (*i.e.*, stop development when the density of No. 2B is the same as that of No. 1A)."

"No. 169B, restrain two figures (*i.e.*, stop development when the density of *No. 3B* is the same as No. 1A)."

"Nos. 170, 171, and 172B, restrain three figures."

"Nos. 173, 174, and 175B, restrain four figures."

"Nos. 176, 177, and 178B, restrain five figures."

"Nos. 179, 180, and 181B, restrain six figures."

"Nos. 182, 183, and 184B, restrain seven figures."

"Intensify Nos. 171, 174, 177, 180, and 183 with bichloride of mercury followed with ammonia."

"Intensify Nos. 172, 175, 178, 181, and 184 with bichloride of mercury, followed by sulphite of soda."

Prints from the whole of this series are sent. It should be remarked that, in making all prints from these long sensitometer-exposed plates, the effect of fog is, so far as possible, eliminated where it is present, by shading the unfogged half of the plate during development, so that the most transparent part of each half is, as nearly as possible, represented by the same tint.

It will be seen that, except in the case of No. 182, the curves of opacity more or less distinctly cross. The meaning of this, in the particular case referred to, is that, whereas the first strips of the A halves show greater opacity (and consequently print lighter) than the corresponding strips of the B halves, the last strips of the A halves show less opacity (and consequently print darker) than the corresponding strips of the B halves. In many cases the first strips of the B halves are not visible at all, whilst they are even printable in the A halves; nevertheless, the opacity of the last strips of the A halves is greater than that of the B halves.

It will be evident that, even in the case of No. 182, the curves of opacity would cross were the gradation of light longer. On account, however, of the fact that seven strips have been restrained in the case of B, the gradation of light capable of giving a developable result is only 1 to 128 in B, as compared with 1 to 8192 in the case of A.

Certain irregularities will be readily noticeable in these results. They arise from the difficulty in following exactly such instructions as "restrain 4, 5, or 6 strips." On this account the whole system of compensation in development, for variation of exposure, and of varying the results with constant exposure, may be condemned by some. I shall only remind those who incline to do so that it is always a difficult matter in photography for even the most skilled to get the exact result they wish.

I considered that the last set of experiments described indicated powers to compensate, in development, for exposures varying as one to considerably more than 100 without resort to intensification, as one to several hundreds having resort to intensification, hence experiments to be described presently.

C.

These experiments were undertaken as introductory to a set of experiments with the ferrous-oxalate developer. The instructions were as follows:—

"Prepare a saturated solution of oxalate of potash, and another of ferrous sulphate (each at a temperature of 65° Fahr.), and make each acid enough, with sulphuric acid, to turn litmus paper quickly red."

"Develop all A halves with normal pyro and soda developer."

"Plate No. 17B, develop with one part iron solution to three parts oxalate solution."

"Plate No. 18, one part iron solution to four of oxalate."

"Plate No. 19, one part iron solution to six parts oxalate."

"Plate No. 20, one part iron solution to ten parts oxalate."

"All plates, both A and B, to be developed either till slight fog appears, or till all action seems to have ceased for some time."

One result of these experiments is to show the very slight difference in the action of this developer, by variation in the ingredients, except in so far as time of development is concerned. As the developer becomes more diluted, the opacity throughout is slightly increased; but this is really because the fog point came comparatively earlier with the concentrated than with the dilute developers, and in each case development with oxalate had to be stopped because the fog point was reached.

Another thing it shows most strikingly is the inferiority of ferrous oxalate, at any rate without the addition of bromide, in the rendering of gradation. A print from plate No. 18 is sent to illustrate this. It will be seen that, in the half B, the greatest opacity is reached at about the eighth strip, after which reversal takes place, whereas in the case of the half A (pyro-developed) opacity increases nearly to the end of the line. Here both the opacity and the density curves cross, and the density ratios are not the same.

D.

"Develop all halves A with 'normal pyro and soda developer.'"

"All oxalate developers to be made up of one part of the iron solution already mentioned to four parts of oxalate of potash solution."

"No. 87B to be developed with the above normal ferrous oxalate solution, without bromide, till slight fog appears, or till all action appears to have ceased for some time."

"No. 88B to be developed with ferrous-oxalate developer having one grain of bromide of potassium per ounce."

"No. 89B to be developed with ferrous-oxalate developer having two grains of bromide of potassium per ounce."

"No. 90B to be developed with ferrous-oxalate developer having four grains of bromide of potassium per ounce."

"No. 91B to be developed with ferrous-oxalate developer having eight grains of bromide of potassium per ounce."

"No. 88B to have one strip restrained."

"No. 89B to have two strips restrained."

"No. 90B to have three strips restrained."

"No. 91B to have four strips restrained."

Prints are sent of the results of all these exposures. It will be seen that, by stopping development before it is complete, in cases where bromide has been added, we have the power of compensation for variation in developing, or of varying the results of constant development, as in the case of the pyrogallol developer, though I am not prepared to say that the curves of either opacity or density actually cross in the cases under consideration.

E.

So far all experiments described have had for their object the alteration of the results with fixed exposure. The next experiments were intended to investigate to what extent it was possible to get identical results with varying exposures. It was decided to rely on exposures in the camera for this, although some preliminary experiments were made with the sensitometer, using the long plates of glass.

It was soon found possible to produce, with exposures varying as much as ten to one, or even twenty to one, negatives so nearly identical that they were both pronounced, by experienced photographers, good negatives, neither over nor under-exposed, and that, moreover, were of such a nature that these photographers would not undertake to state which of the two negatives had had the longer exposure.

This was not enough, however. The experiments already described indicated the possibility of compensating for a variation of at least one to 100, and an attempt was made to systematically investigate the variation in the developer that was necessary to compensate for a given variation in exposure.

In the first place exposures were made on a well-lighted landscape varying in the ratios of 1, 2, 4, 8, 16, 32, 64, and 128, and attempts were made to discover the variation in the constituents of the developer that would give similar results with all these exposures.

For various reasons it was decided to keep the quantity of alkali—for reasons already stated ammonia was preferred—constant, whilst the quantities of pyro and of bromide were varied.

The first thing to do was to find the best relative quantities of pyro ammonia, and bromide for the production of a normal negative by a normal exposure. A normal negative I can only define as the kind of negative that an experienced photographer wishes to get. This, I consider, must remain a matter of opinion or even of taste. A negative with opacities directly proportional to the light reflected by the different parts of the subject would be a perfect negative (apart from the rendering of colour values) if all printing processes were such that different parts of prints made by them reflected quantities of light proportionate to the opacity of the negative. This is not, so far as I know, the case for any printing process through any great range, and is far from being so in the case of many of them.

There is a still farther objection to the above definition of a perfect negative, namely, that no plate that is made has the power of producing such a negative with ranges of light nearly as great as are common in landscape work. We must of necessity make up our minds to sacrifice something either of the shadows or of the high lights, and it is purely a matter of taste which we prefer to sacrifice. A close examination of the photographic pictures recently sent from the Camera Club to Japan, for exhibition in the latter place, and representative of the most artistic work done in the Occident, seems to show me that workers of the most advanced school tend to turn out work that would have been spoken of as "under-exposed" some few years ago. That is to say, they see fit to abandon that so-called "golden rule"—in any way supremely idiotic—"take care of the shadows and let the high lights take care of themselves,' and often, at least, prefer to sacrifice something in the shadows for the sake of the high lights.

Normal exposure I shall define as the shortest exposure that will give the negative that the photographer wants to get. Normal developer might perhaps be defined as the best developer for producing this normal negative with normal exposure, but it looks rather like giving definitions in a circle.

Let me state here, parenthetically, that the prints you are to see just now are not by any means from negatives of the kind that I like to get. The negatives are altogether too hard. This was because I assumed that the developer that was "normal" for certain quarter-plates that I had been using would also be normal for 12 × 10 plates of the same brand, but a different number. This was not so, however. Of course I ought to have repeated the experiments, but I had already exposed over a gross of 12 × 10 plates, besides innumerable quarter-plates, and the time was getting short for putting my material in form, so I let the negatives slide as illustrating my point quite well enough.

To return, however, to the plates exposed in the ratios mentioned above, the ammonia was kept constant, and various multipliers of bromide and ammonia were tried for each doubling of the exposure.

My first impression was that the bromide ought to be increased in a rapider ratio than the pyro, but this seemed to be a mistake. It appeared that better results—that is to say more uniform—were to be got by increasing the pyro and the bromide in the same ratios.

At first I tried using half as much again more pyro and bromide for each doubling of the exposure, that is to say, multiplying the quantity of pyro and of bromide each by $\frac{3}{2}$ for each doubling of the exposure. It was found that with this increase of the quantities of chemicals mentioned the contrast increased greatly with the increased exposures, and the negatives from those that had had the longest exposures appeared actually under-exposed as compared with those that had had the shorter exposures.

Next was tried using one-third as much again more pyro and bromide for each doubling of the exposure, that is to say, multiplying by $\frac{4}{3}$. The result was the same as in the last case, but to a less marked degree. This entirely knocked on the head a theory I had formed that the proper multiplier was probably $\sqrt{2}$.

Next was tried using one-fourth again more pyro and bromide for each doubling of the exposure, that is to say, multiplying $\frac{5}{4}$. It was found that this multiplier was somewhat too small. That is to say, the negatives that had had the longest exposures were thinner than those that had had the shorter. The falling off in density was not, however, perceptible through the first five negatives.

It is evident that the proper multipliers, if a constant multiplier is what is correct, and it is evident that such is very nearly being the case, must lie somewhere between $\frac{4}{3}$ and $\frac{5}{4}$, or $1\frac{1}{3}$ and $1\frac{1}{4}$; between, that is, 1·2 and 1·25. Let us say it is 1·3, the thing might be put in the form of an equation, as follows:—

Let C = quantity of pyro (or of bromide) used for right exposure.

Then, if exposure = 1 ..... Pyro = C
" " = 2 ..... " = C × 1·23
" " = 4 ..... " = C × $(1{\cdot}23)^2$
" " = 8 ..... " = C × $(1{\cdot}23)^3$
" " = 16 ..... " = C × $(1{\cdot}23)^4$
" " = 32 ..... " = C × $(1{\cdot}23)^5$
" " = E ..... " = C × $(1{\cdot}23)^n$

∴ When 2^n = E

Therefore, $n = \frac{\log. E}{\log. 2}$

∴ Pyro = $C\,(1{\cdot}23)^{\frac{\log. E}{\log. 2}}$

Then, since $(1{\cdot}23)^{\frac{1}{\log. 2}} = 2$

Finally, pyro = C × $(2)^{\log. E}$

From which equation a curve, or a table, might be made for practical use.

This law is, at least, approximately true for several brands of plates, for sundry initial variations of developers, at least, within limits of the normal exposure, and this multiplied by 100 or so.

Your attention is now asked for a set of prints from negatives that have had exposures varying as 1, 2, 4, 8, 16, 32, 64, and 128, the same brand of plate being used, and the exposures being made about mid-day—as a matter of fact, from a little before till a little after, as quickly one after another as was possible, the weather brilliantly clear.

I should like to know if any one, seeing these prints, will undertake to place them in the order of their exposures. I cannot myself. I cannot, in their present form, even tell which is the first and which the last. They are, however, cut from 12 × 10 prints, and it was pointed out to me by a very "cute" friend—he is from the United States of America—that it was possible, in the original condition of the prints, to tell the two that had had the longest exposures, on account of the effect of the motion of the overhanging branches of a tree that gave a little beauty to the otherwise very uninteresting little bit of landscape—uninteresting, unless it may interest some old friend to know that the vehicle in the foreground (put there to get a bit of really dark shadow, to help the judgment in development) is that in which his humble servant is ignominiously trundled about the streets of Tokyo by a blue-coated, bare-legged coolie!

I cannot tell the first six negatives one from the other by inspection, but the last two I can tell from the others, and from each other, on account, not only of the yellowness of the image, but on account also of a yellow deposit (I do not know what else to call it) in the shadows, or rather, all over the plate, including those parts of the plate protected by the rebate of the printing frames. This discolouration is one of the only two reasons that I know of why compensation for variation in exposure should not be indefinite. It makes the time taken for printing very long. I have, in experiments with quarter-plates, got results without this stain and objectionable colour of image, with exposures varying more than those mentioned, and thought, at one time, that I had got to the bottom of the matter. I find, however, that I have not. Its appearance is uncertain. Perhaps it is due to impurity in some one or more of my chemicals acting for a long time. I somewhat suspect the sulphite I am using.

Another reason why compensation must be limited in practice is the outrageous length of time that development takes when the exposure is much above normal, and is compensated for by variation in the developer. The plate of the eight, from which the prints that are shown were made, that took the longest exposure, took two hours to develop.

It may be urged that the prints are not identical; it is quite true that they are not. I only point out that there is no uniform variation, and remind you how very difficult it is to make even two really identical

negatives (assuming that the conditions are such that it is possible), if only one factor varies, say, the rapidity of the plate. I should like to see any one make eight identical negatives on eight plates, varying in sensitiveness as 1 to 128 at the first attempt, and it must be borne in mind that this was the first experiment made after I had concluded that the formula given above represented approximately the variation in developer necessary, that the brand of plate used was somewhat different from any we had been using before, and that the only instructions Mr. Arito had were, "Use these developers for the different plates, and make eight negatives as like each other as you can." I am sure it would have been possible, by several trials, to get negatives practically identical.*

As to the actual developers used, I must confess that to avoid the trouble of multiplying the quantity of pyro and of bromide by a much awkward fraction, 1·23, which I had not then arrived at, for each increment in exposure, or of integrating from the initial quantities, by the use of a table of logarithms, I multiplied in the first three cases by four-thirds, in the last four by five-fourths, the result being not much different from what would be got working by the actual formula.

The nearest quarter grain and, towards the end, the nearest half grain was taken in every case.

The following were the actual developers used:—

Per ounce of developer.

1	Pyro, 3 grains, Bromide of ammonium, ¾ grain.
2	Pyro, 4 grains. Bromide ammonium, 1 grain.
4	Pyro, 5 grains. Bromide ammonium, 1¼ grains.
8	Pyro, 6 grains. Bromide ammonium, 1½ grains.
16	Pyro, 8 grains. Bromide ammonium, 2 grains.
32	Pyro, 11 grains. Bromide ammonium, 2½ grains.
64	Pyro, 14 grains. Bromide ammonium, 3½ grains.
128	Pyro, 19 grains. Bromide ammonium, 5 grains.

Ammonia, 2 minims.

The sulphite used was only five grains per ounce in the first six cases, ten in the last two. The reason the quantity was kept so low was that, with the long times of development necessary in the case of the longest exposures, the plates were found to partly fix out before development was over if the sulphite were kept at four or five times the quantity of the pyro. I do not yet know whether this was due to impurity of the sulphite or not.

The exposures actually given were as follows:—

Mins.	Secs.
	1½
	3
	6
	12
	24
	48
1	36
3	12

They were made by myself, by the aid of a stop watch, with such care as I am capable of. There may be an error of a fifth, or even perhaps a quarter of a second, in any one of them, but I think not of more. It is true that this amounts to a considerable percentage in the case of the shorter exposures; but the error is as likely to be in one direction as in the other, and, in any case, it leaves the range of exposures as one to fully a hundred.

In a sealed envelope, which I hope will not be opened till any who have had patience enough to listen to this paper as far as this point have tried to put the prints in their proper order, are given numbers corresponding to letters on the backs of the prints. It is to be understood that No. 1 corresponds with the shortest exposure, and so on.

Conclusion.

I hope I have proved by these experiments that we have power both to vary in development the results of uniform exposures, and to compensate for differences of exposure. I should not have thought it right to trouble you with so long a paper on the matter, but that the possible variations, and the possible compensations, have proved so much greater than I imagined them to be, and so much greater than they are, I think, commonly supposed to be.

It will be seen that throughout these results, in so far as they constitute change in ratio of gradation, are brought about only by stopping development at certain stages before it has gone as far as it would go. I doubt if it is possible to change gradation of density or of capacity at all, if development be carried as far as it will go. At any rate, the change that can be effected is but slight. This is leaving out of the question the reaching of, or approaching to, a maximum possible density.

When some twelve or thirteen years ago I stated that "bromides restrain both the increase of density, and the increase of detail, but the former to a less degree than the latter," I believe I stated, in somewhat crude language, the reason why it is that bromides in the developer give us the power both of varying our results with constant exposures, or of compensating for varying exposures.

Before that time, if I remember rightly, I had found, to my own surprise, that it was possible, if only time were given, to bring out the same figure on plates exposed under the Warnerke sensitometer, however great the quantity of the bromide added to the developer, within pretty wide limits. The results of these experiments were communicated to The British Journal of Photography in one, or I think more than one, article that I have not access to here, and were, I remember, discussed at the rooms of the Society of Arts, probably before the South London Photographic Society.

After that, a more elaborate set of experiments was made, investigating the results of varying each of the three ingredients of the alkaline developer, the results being communicated again to The British Journal of Photography, and the actual plates being handed to the Camera Club, after that institution had been founded.

The results of these experiments are referred to by Mr. H. J. Channon, in a very interesting paper in the *International Annual* for 1891, p. 255. I also received much information from this gentleman, and various papers, all of which courtesy has, I fear, passed unacknowledged, for which omission I crave forgiveness.

I have given the results of only a fraction of the experiments that intended to describe. These include the comparisons of the effects of hydroquinone, eikonogen, rodinal, amidol, and "cristalos," using various alkalies, or, in some cases, none, with what I have called the "standard pyro and soda developer;" but this paper has grown to such an unconscionable length, that I must leave the results of these experiments to some other communication, or to limbo.

I wished to say something about Messrs. Hurter & Driffield's method of determining the sensitiveness of plates, but shall merely now say that it seems to me by far the nearest approach that has yet been made to a perfect means of determining the sensitiveness of plates, taking into account, as it does, the useful densities, instead of the faintest detail, as heretofore—yet not perfect. The reason why I consider it not perfect will be understood from the objection that I have to any definition of a perfect negative that has yet been given, other than that negative that appears perfect to the man who makes it, the assumption being that he is a man of skill, and of something more, and knows what he wants eventually to produce, to wit, a picture.

I wish, finally, to express my gratitude to my colleague, Mr. C. D. West, M.A., Mr. K. Arito, and Mr. O. Kondo, for their invaluable assistance in all the experiments described.

P.S.—Just a word about the re-reversal that we read of as arising from very prolonged exposures. I have tried to get this often enough without success, and determined to make a supreme effort this time. The long sensitometer was used, and plates were exposed to the full blaze of sunshine for times from quarter-second to 34 mins. 8 secs. There was not a trace of reversal, developing either with pyro or with ferrous oxalate. This corresponds to an exposure in the camera, to a brilliantly lighted landscape for many days, with the conditions as they commonly are. I think that, if it is possible to prove a negative, these experiments prove the non-existence of reversal in the case of gelatine dry plates. I should like to know of any one who has had actual experience of re-reversal in the case of gelatine dry plates, or of any other plates, for the matter of that.

Remarks on Professor Burton's Paper by Mr. H. M. Elder.

A great many of Professor Burton's earlier remarks seem to be due to the unfortunate confusion caused by the special meaning given to the word "density" by Messrs. Hurter & Driffield. His opinion as to the range of gradation commonly met with in camera work differs very

* The print marked "9" on the back was from a negative that had an exposure the same as the longest of those mentioned, and that was developed with the first of the developers given. It was removed from the developing dish as soon as marked fog set in. Another plate was exposed for the same length of time, and was developed in the same developer, but was given the same time in the solution that had been necessary for the plate that had an exposure of one and a half seconds—namely, five minutes. The result is almost complete blackness, but with some reversal. If there were a week to spare, and certainty of sunshine all day long on every day, I should make a print from this negative too.

largely from that of Captain Abney, who, at a meeting lately held at the Camera Club, said that as a rule this range did not much exceed intensities of light in the ratio of about thirty-three to one. In the example quoted at the time, it was asked what was the ratio of the light reflected by the white and black in the case of a figure draped in black velvet with a white shawl.

Passing on, however, to the main object of his paper, Professor Burton has abundantly proved in a qualitative manner that the ratio of gradation in a negative is dependent on the time and method of development, and his numerical formulæ for the strength of pyro developer to compensate for increased exposure is a very interesting one. It seems, however, that a mere qualitative proof of this fact is not of very great importance, except in so far that it will tend to reassure those photographic weaklings who have been frightened by Messrs. Hurter & Driffield's much-misunderstood paper into disbelieving the evidence of their own experience. What would seem now to be wanted is a complete quantitative investigation of the whole problem. It is, of course, a long and laborious task, but it may be lightened by working systematically at it. I would point out, that from Professor Burton's paper it is almost impossible to really repeat his experiments, since certain important factors are left almost unnoticed. The prints themselves, as the author has pointed out, show many irregularities, and this was inevitable from the method of work. It is easy to see that in the feeble light of the developing room it is a sheer impossibility to carry out such instructions as were given to Professor Burton's assistant with any certainty, and I think that it speaks very highly for Mr. Arito's care and ability that the irregularities are not more marked than they are. Then, again, it is impossible to draw any very definite conclusions from mere inspections of negatives and prints. It is an absolute necessity, in carrying out such work as this, to make actual measurements of the transparencies of the resulting negatives. No doubt, if Professor Burton had done this, the irregularities would have been more marked than they are, for it has been pointed out again and again, by Captain Abney and others, that the eye is utterly untrustworthy as a measuring instrument by which to judge of the density of a deposit on a photographic plate. If there is any truth in a formula which I put forward at the Camera Club Conference of the present year, to represent the action of light and development upon a photographic plate, it ought to be capable of accounting for such results as those of Professor Burton's; and, if any one will take the trouble to examine the effect of varying the two constants that depend on development in this formula, I think it will be easily seen that it will account in a large measure, and, I believe myself, entirely, for these results, and that even the complete formula of Messrs. Hurter & Driffield fails to do so. Professor Burton's paper is an interesting and very valuable one, and would have been far more so if he had not trusted so much to human judgment, both in making his experiments and in interpreting the results. By this I mean, what is wanted is a series, and a long one, of definite experiments on plates definitely exposed, developed in developers of known constitution for known times (not until a certain appearance most difficult to seize is shown), and then measured carefully, so that the results can all be numerically expressed.

OUR PICTORIAL FAILURES.

By the Rev. F. C. Lambert.

Let me commence my remarks by a confession. In a moment of vanity I was induced by the irresistible suavity of the Hon. Secretary to promise a paper for this meeting on some art topic. Little did I then think how difficult it would be to find a suitable subject. Thus once more the old saw is illustrated, "Pride goeth before a fall.' At the moment of my rash promise I had failed to realise the numerous conditions of the case; and thus more time than I care to tell has been consumed in search of a subject—in a way, too, that has made me feel the force of one who describes his fruitless chase after a certain all-too-familiar, but unmentionable, insect. "No sooner you put your finger on him, but he isn't there at all, and the reason of that same is directly you catch him you miss him." Thus, again and again have I thought I had hit upon something new, only to find it not true; or again on something old and true, but so very *conventional* that it could no longer be held to interest a *conventional* gathering. Or again, if a subject presented *conventional and convivial* features—for the two are in our case somewhat closely akin, if not interchangeable terms—then I grasped it, only to find it was neither new nor true. Hence I reach the crux of my apology. In our "failures," we each may hope to find some conventional, *i.e.*, extenuating or mitigating, circumstances. Our failures are, alas! only too true; their truth is only too deeply driven home by their painful frequency. And yet the cloud has a silver lining. Our failures are ever *new;* their newness and freshness has all the doubtful charm of being very much "up to date."

I shall presume that most of us when visiting a photographic exhibition have at least two objects in view: Firstly, to see and as faras possible enjoy the work of others; secondly, to gather hints and information from the work which has most favourably impressed us. The second of these only concerns us for the present moment.

I venture to think that I am speaking for many others as well as myself, when I say the general impression, after visiting an ordinary photographic exhibition, is one of failure rather than success. To put the matter in other words, the number of pictures that one thinks about afterwards, or would care to possess for constant companionship on the walls of our living rooms, is exceedingly small. Would half a dozen out of every hundred exhibits under or over-state the mark? Leaving a liberal margin for personal taste, the nett result is that the majority—a saddening majority—are, if not failures, certainly not definite successes. There must be some grave reason for so significant a conclusion. Nor should the inquiry fail to interest, stimulate, and add to the value of the discussions of this gathering. On this point I would suggest the following points as being contributory in varying degrees to the general product of non-successes. The free discussion of the topic, whether leading to rejection or acceptance, cannot fail to draw some attention to the subject, and hence tend to diminish the number of failures. But I am not without hope that the results may be distinctly positive and fruitful in producing a greater number of distinct successes.

Some suggested reasons of our pictorial failure:—

1. *The Commonplace.*—I venture to put this first because it seems to include—in somewhat free-and-easy terms, I admit—the majority of the unremembered. This includes the characterless many, who neither please nor pain—everything about them, selection (save the mark!), exposure, printing, mount and frame, are simply "middling." Hence we are utterly indifferent as to their future fate. Why are they entirely lacking in interest, in the general absence of any positive conspicuous defect, you ask? I reply, the worker in his so-called selection has exactly failed to select. He has taken things as they are. Selection surely implies rejection as well as acceptance. In the cases before us it has been all acceptance and no rejection. Nay rather, may we not say that the general tendency, where it shows any thought at all, points to over-crowding rather than selection? Perhaps collection would be a better word. The "art of leaving out" in many cases, if known, is sternly ignored.

A large element in the commonplace is the presence of so much which is utterly unessential, immaterial, uninteresting, and hence discursive and generally weakening. It acts like a diluent. A teaspoonful of the best and purest and strongest whisky would have but a poor chance in a gallon of the purest *aqua-pumpibus*, negative and innocent as that diluent might be.

2. Next comes *Indefiniteness.*—By this I do not refer in any way to the method of producing the out-of-focus or so-called fuzzygraph method of working. The indefiniteness here indicated is that due to lack of definite aim or intention. This is the man who "aims at *nothing* and hits *it*."

We are assisted to recognise this class of work when it appears with such delightfully bewildering and vague titles as "a study," "a nocturne," "an effect." The only, if any, effect generally produced is that of bewildered inquiry, or perhaps a reminder of some recent puzzle picture subscribed, "Find the dog, the policeman, and the baby."

Impressionism may be all very well in its proper place, provided always that the artist has an impression and some reasonable power of expressing it. But if the would-be-impressioniat desires to snatch applause by feeble imitation, or shelter his incompetence under vague titles, then he is in no way a true friend to the progress of photographic art.

The third place may be assigned to the defects due to *imitation.* The old saw which says that "imitation is the sincerest form of flattery" requires its "teeth setting" more in a line with actual fact. Experience seems to show that it is only those seeking spurious greatness in the cloud of dust they raise who find any acceptable flattery in the mimicry of a tail of followers, who, in turn, having no ideas of their own, are ready and willing to accept such ideas of their leaders as require the least, if any, effort to assimilate or digest.

It may well be doubted if any one who has thoughts, methods, or ideas, of his own of any real value would accept on any terms the fulsome flattery of brainless imitation.

Would Shakespeare, Milton, or Tennyson, Reynolds, Constable, or Turner, have turned aside one hair's breadth to win a following of those who at best could only accentuate the defects of their leaders, and dilute beyond recognition their choicest merits. We may look, and look in vain, for any great artist in form, colour, song, or stone, who has wrought his way to lasting greatness by imitation, such as is not altogether unknown by those who are eager to be dubbed photographic artists. Earnest, conscientious, and laborious study and analysis of the greatest works of the greatest men is no doubt of inestimable service to those who aspire to be

their compeers, but true study points to principles rather than rules, results rather than methods. The student will be as anxious to avoid the semblance of imitation as he is desirous of reaching, if not outstripping, the triumphs of the masters who inspire him, at the same time there will be an equal anxiety to make his work his own beyond the chance of merit it may possess being suspected of having been filched, or even borrowed, from the work of another. Much has been said, sometimes with truth and sense, and sometimes otherwise, on the subject of schools in photography. The pages of the history of painting teach us that "schools" are not to be manufactured at the whim and fancy of individuals. The causes at work were deeper-seated and more fruitful than the passing popularity of an eccentricity or novelty. Furthermore, this difference between painters and photographers seems to lie on the surface, whereas among the schools of painters each and all profess (and practise with varying degrees of truth) to study in and appeal to nature—each school professing itself to be a more faithful exponent of nature than the others, and in that sense all are impressionists—while, on the other hand, photographers with an equally charming candour, one and all profess to study in and appeal to the same great school, nature; yet it would seem as though not a few were content to have their seeing and thinking second-hand, since by their productions, their efforts show an industrious and not always unsuccessful effort at imitating the productions of each other.

4. *An inversion of the means and the end* must be held in part responsible for some misspent energy. An all-consuming anxiety to display to its utmost limits the possibilities of some instrument, the capabilities of some process, is a terrible temptation to many. Microscopic definition, biting sharpness, topographical precision are phrases that have had their day and due regard. The transitional phase of differential focus is passing into further development of astigmatic distortion, or the suppression of definition by diffraction.

In those of an independent or experimental turn of mind, their means may, and do, at times, produce results which are not only extremely interesting, but also have a value as being expressions of a personality, but the counter-balancing disadvantages come *pari passu*. No sooner does one see a success snatched by some pioneer, but it is quickly imitated and diluted to such an extent that its virtues, even though few, are ignored, while its defects, no matter how many, are each and all repeated until the unfortunate founder, or leader, of the school is saddened by finding that the world only sees his excellencies or his multiplied defects.

The "fatal facility" of production tempts the great unthinking crowd to rush headlong down the course of destruction, leaving in their trail "wrecks and ruins" of wasted material. Now do they rush for the pictorial crown through *f*-64 of a highly corrected symmetrical doublet, now through a pinhole, now it is a spectacle lens, now an astigmatic lens. Having tried and found wanting any and every lens, and finally no lens at all, inspiration whispers, "Try a new printing process." Thus, from chocolate-box-lid polish and gloss to roughest sand-paper is but a step In each and every case an anxiety to display the means, rather than use the means according to the end desired, meets us again and again, and accounts for some proportion of the pictorial failures.

5. Lastly, some small place must be found for the failures due to *misdirected rivalry*. That a certain picture obtains a measure of notice is enough to set some at work to outstrip this picture by some slight advance either in subject, pose, lighting, or other method or means employed. The results of such rivalry must of necessity be unhealthy, as being the product of jealousy and imitation. All thinking art workers are agreed that the first quality of success is that the work attempted shall be felt worthy of the effort expended on it for its own sake. In other words, if a man's heart is not in his work, there will be very little art in it. Obviously, then, where one attempts to imitate and rival the productions of another, it is not a case of true affection, but the green-eyed monster that is secretly at work.

To sum up briefly, our inquiry seems to point to a handful of causes tending to produce work which, if not distinctly and definitely failures, are undoubtedly not successes. Let us go, in imagination, five times round the walls of a photographic exhibition. On each journey we shall weed out such pictures (or rather prints) as show the following shortcomings:—

1. The commonplace, due either to overcrowding of entirely extraneous, uninteresting, unessential elements. For the most part, if they are not positively offensive, they are absolutely uninteresting, dull, and characterless. They are "*the jelly-fish order*."

2. The indefinite or meaningless, that have nothing to say, and say it in silent eloquence. Their result, if any, is only to irritate. These are "*the penny puzzle-card order*."

3. The feeble imitation class, wherein what little excellence (often difficult to find) has been obtained by other than honest, straightforward, individual, and personal work. These we may dub the "*petty larceny class*."

4. Means *v.* end, where the worker is anxious to display his dexterity in the use of his tools, perhaps with the hope that, as "fine feathers make apparently fine birds," so, possibly, artfulness may pass current for art. Let us call these "*the conjuring-trick class*."

5. Rivalry, where one worker endeavours to build a fame upon the head of another worker; not because he cares about the subject, but because he is anxious to try and make himself the larger by ungenerously belittling another probably more modest worker. As it is not easy to find a name for these, perhaps we may best pass them over as the "*nameless unworthies*."

Having removed, gently but firmly, the foregoing five siftings, it may be reasonably hoped that whatever, if any, are now left will have suffered no loss, but gain rather, by having passed into "Standard Six."

PHOTOGRAPHY AND THE GREAT BARRIER REEF.*

Mr. Saville-Kent's work is the outcome of an eight years' residence in the Australian colonies in the capacity of Inspector and Commissioner of Fisheries, and he has been fortunate in securing much valuable assistance from scientific and official persons. The scope of the book "is to render an account, in clear and popular language, of the most highly attractive subjects, from a commercial and biological standpoint, that are associated with the Barrier region, and in the former connexion more especially to indicate the lines on which, through the application of scientific methods, more remunerative returns than heretofore are to be realised." It may be explained that the Great Barrier Reef of Australia is an enormous coral region between Torres Straits and Queensland, "built up by the direct and indirect agency of soft-fleshed polyps of multitudinous form and colour, and teeming with animal organisms of myriad form and hue representative of every marine zoological group."

Necessarily the book is largely, although not exclusively, of scientific interest, the general reader being here and there kept in mind in some of the descriptive sections of the volume, while, when Mr. Saville-Kent comes to discuss the potentialities of the fascinating region he has so ably laid bare for us, the commercial spirit of the age will find plenty of food upon which to feed and thrive. After discussing the various theories as to the formation of the Great Reef, Mr. Saville-Kent proceeds to treat of and describe its corals, coral animals, and allied organisms; the pearl and pearl-shell fishery; the Bêche-de-mer or Trepang fisheries; commercial oysters of the Barrier district; turtles and the turtle and tortoise-shell fishery; the Dugong fishery; commercial sponges; food and other fishes, &c.

That which imparts photographic interest to the work is a series of forty-eight large collographic plates illustrating the text. It is safe to say that few, if any, recently issued books are more indebted to photography for the beauty and technical charm of their illustrations than Mr. Saville-Kent's splendid volume. The pictures are from Mr. Saville-Kent's negatives, which have been collotyped by the London Stereoscopic Company and Messrs. Waterlow; and, while paying every tribute to the undoubted excellence of the originals, we are free to declare that seldom have we met with such delicacy, fidelity, finish, and studied carefulness of printing as in the work of the firms named. Views are given of coral structures of various kinds under natural conditions, of the pearl and pearl-shell fisheries, the Trepang fishery, anemones, oysters, the fishing industries generally, marine fauna, &c. Of many of these illustrations it is claimed that they represent the first occasion on which the camera has been employed for the systematic delineation of such subjects. It is only at rare and uncertain intervals that the reefs are uncovered to the extent in which in many instances they are here depicted. Two of the illustrations show Mr. Saville-Kent with his camera, the lens of which is pointed to the object contained either in a small pool or in an improvised aquarium in a bucket, with other objects of interest scattered about. To employ the camera in this manner, it is fitted in a frame to which the stand is attached. In addition to the collotype, sixteen chromo pictures of fishes, &c., from Mr. Saville-Kent's own water-colour drawings are given, these being by Messrs. Riddle & Couchman.

We have no doubt Mr. Saville-Kent's finely got-up work will take

* *The Great Barrier Reef of Australia: its Products and Potentialities.* By W. Saville-Kent, F.L.S F.Z.S. London: W. H. Allen & Co. Limited 13, Waterloo-place, S.W.

high rank in the library of the biologist, and in contributing to this result it is pleasant to note that, both in his own camera work and in the reproductions from his negatives, the part played by photography is conspicuously paramount.

News and Notes.

NORTHERN PHOTOGRAPHIC AND SCIENTIFIC ASSOCIATION.—July 22, Richmond.

HACKNEY PHOTOGRAPHIC SOCIETY.—July 25, *Exposure Meters and Tables*, by Mr. W. F. Fenton-Jones.

GOSPORT PHOTOGRAPHIC SOCIETY.—July 22, Bishopstoke; leave Gosport at twenty-four minutes past two, p.m.

MR. C. CRESCENT, of 20, Paternoster-square, E.C., has sent us a small sample of the "Crescent" sensitised paper, which we have found to be of good quality.

PHOTOGRAPHIC CLUB.—July 26, *Collodio-chloride Printing*. August 2, Report of the Convention Delegates. 7 (Bank Holiday), Outing to High Wycombe.

MESSRS. PERCY LUND & CO., St. John's-street, Bradford, have sent us a sample of gelatine, which retails at 1*s.* 6*d.* per pound, which is intended for collotype work. It appears to be suitable for the purpose.

EAST LONDON PHOTOGRAPHIC SOCIETY.—August 8, *On the Desirability of Suiting the Printing Process to the Negative*, with illustrations, by Mr. Bennett. 22, Demonstration upon *Chloride Printing and Toning*, by Mr. Copping.

"THE PRINCE of WALE'S SMILE."—Mr. F. G. Smith, photographer, of the Quadrant, Richmond, S.W., sends us a cabinet size portrait of the Prince of Wales, in which H.R.H. is lifting his hat and smiling heartily in acknowledgment of a salute. The picture is evidently an enlargement from a small negative.

BIRMINGHAM PHOTOGRAPHIC SOCIETY.—July 25, Social Evening. Members are invited to bring prints and negatives to all the Tuesday evening meetings when no special paper is announced. 26, Last day for sending in photographs for the Charlecote Excursion Competition.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.— On July 25 there will be a Technical Meeting at No. 50, Great Russell-street, when a discussion will take place on *The Use of Uncorrected Microscopic Objectives with Colour-corrected Plates*. Mr. Pringle will introduce the subject, and show specimens.

MESSRS. J. BISHOP & CO., of 19, Princess-road, Regent's Park, N.W., were recently honoured with a letter from Princess Victoria Mary of Teck, accepting a picture, a platinotype enlargement of the Royal Family in Windsor Park, framed complete, as a wedding gift, and they have just received from the Duchess of York a letter thanking them for it and saying that it gave Her Royal Highness great pleasure to receive it.

MR. W. T. WHITEHEAD, of 7, St. Paul's-churchyard, formerly with Messrs. Downey, Mr. Van der Weyde, &c., is making a speciality of designs for the backs of card mounts, headings, initial letters, &c., of which we have seen many artistic and tasteful examples. Photographers who may desire to have designs specially prepared for them could not do better than communicate with Mr. Whitehead, who also undertakes the working up of bromide enlargements, and tuition of the Air-brush, in the use of which he possesses a very high degree of skill.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.—The following are the arrangements of the London and Provincial Photographic Association during July and August:—July 20, Members' Open Night. 22, Outing to Totteridge Station, three o'clock; over Mill Hill to Hendon. 22, *Less Customary Orthochromatic Photography*. August 3, Members' Open Night. 7, Bank Holiday Outing to High Wycombe. 10, *Film Working*, by Mr. W. H. Barnes. 12, Outing, the Zoo. 17, Delegate's Report of the Convention, by Mr. W. D. Welford.

MIDLAND CAMERA CLUB.—The first Annual Exhibition of the Club will be held at the Botanical Gardens and College Grounds, Moseley, Birmingham, to open on Monday, October 2, 1893, and close on Saturday, October 14, 1893. It will be under the patronage of Right Hon. Joseph Chamberlain, M.P., Sir John Jaffray, Bart., Sir Walter Foster, M.P., Sir James Sawyer, Right Hon. Jesse Collings, M.P., Austen Chamberlain, Esq., M.P., &c. There will be classes open to professionals, amateurs, and manufacturers. Particulars and entry forms may be obtained of the Hon. Secretary, 4, Woodstock-road, Moseley, Birmingham.

"MANY people," says *Dry Plates* for July, "are greatly in doubt as to the correctness of the H. and D. method of speed readings through a series of densities, instead of the last faint indications of deposit in the feebly exposed portions of the plate. To them we would ask: Why did speed-testing with the Warnerke sensitometer fail to give even an approximate indication unless the last few faint numbers visible were *not* taken into account? Yet such was the case, and this point generally agreed on. Negatives, as a rule, consist of a series of densities extending over a considerable range; surely, then, a system which reads through the whole extent of that range must, as a matter of common sense, be the right one, and to the point."

THE CONVENTION EXHIBITION.—In our notice of this Exhibition last week, the enlargements from negatives by Messrs. Byrne, Richmond, and Messrs. Cox & Durrant, Torquay, should have been included among the exhibits of Messrs. M. & T. Scott, Edinburgh, instead of those of Messrs. O. Sichel & Co.

A PRIZE MEDAL FOR BEE SLIDES.—At the Royal Agricultural Society's Show at Chester, in Class 345, "The most interesting and instructive exhibit of any kind connected with bee-culture," a silver medal was awarded to Messrs. Newton & Co., of 3, Fleet-street, for an exhibit of lantern slides of bees and bee-culture, made from negatives by Mr. T. E. Freshwater. We have before referred to this series of slides as being of great interest, especially to bee-keepers, &c.

THE Imperial Dry Plate Company announce the following awards in the competition for negatives on Imperial plates, which closed June 30:—First prize of 4*l.* 4*s.* to Mr. F. Cherry, Vice-President North Middlesex Photographic Society; second prize of 3*l.* 3*s.* to Mr. P. H. Lamberts, Amsterdam; third and fourth prizes are divided between Messrs. A. H. Duncan, Glasgow, and F. G. Heseltine, Leeds. A series of competitions, closing October 30, will be announced during the month.

MR. J. HUBERT, the well-known photographer, of Mare-street, Hackney, ha become the editor of the *Hackney Record*, a small local sheet from which we extract the following unique obituary notice:—"On Monday, July 3, Mr.—— was solemnly conducted to his last resting-place, accompanied by thirty-five carriages, whose occupants ought to feel deeply grateful to the departed for having been permitted to don their best holiday attire, and pass in state through an admiring multitude."

THE "TALMER" HAND CAMERA.—Messrs. Talmer & Eamer, of Blackburn, have issued an illustrated price list of the various forms of the "Talmer" cameras which they are now manufacturing. These include hand, stereoscopic, field, and studio cameras. An eight-page pamphlet supplies a clearly written guide to the use of the "Talmer" hand camera, from which we make the following extract relative to the means employed to avoid the omnipresent enemy, dust:—"In most hand cameras the plates are contained in roughly blackened tin or zinc sheaths, which, during the operation of changing, are shot up or down, or fall from the vertical to the horizontal, rubbing against each other, raising an incredible amount of dust, and filling the interstices of the camera, and finally settling on the plate. Nor is the amount of dirt reduced by the continual scraping of the sheaths against the bare wood of the interior, nor by the wear and friction of other working parts inside the body of the camera. Comprehending these drawbacks, and following the adage that prevention is better than cure, we have adopted sheaths of thin pen steel of smooth and dull surface. Being made by special tools, they are absolutely uniform in size, and hold plates of any thickness up to register. The inside of the chamber in which the sheaths are contained is faced with brass plates, the sheaths and other metal parts work metal against metal, ensuring absolute freedom from dust and uniformity and certainty in action."

Our Editorial Table.

SNAP-SHOTS AT THE CONVENTION.

J. A. SINCLAIR.

THE hand-camera views taken by Mr. Sinclair at the Convention at once indicate the hand and head of a master—the head to select and the hand to manipulate. These *chefs d'œuvre* of hand-camera work are printed in platinum. The first to claim attention is a small group taken on board the boat the *Princess Royal*, in which, on the memorable rainy Tuesday's excursion, such a large number of members availed themselves of the kind invitation of the local camera clubs to visit the Yealm and Tamar rivers. The scene represents the President of the Convention with a surrounding of ladies, to whom he has been engaged in telling one of his ever-ready, genially funny stories. The amusement depicted on the ladies' faces shows that the humour of the story is being well appreciated. This, we venture to predict, will turn out to be one of the most popular of all the pictures taken during the Convention week. Others represent *Holes Hole*, a landing-stage on the Tamar. In this picture the steamer is seen made fast to the pier to afford the members an opportunity of visiting Cotehele House, a venerable ivy-clad mansion dating from 1485, and its very beautiful grounds. This is the most perfect example extant of the Tudor fortified mansion. Mr. Sinclair's collection includes a charming view of this mansion, which is buried in oak, ash, and chestnut-trees. Other pictures—for they are pictures rather than mere snap-shot photographs—represent Saltash and its famous Bridge, the Pool, Plymouth, and its shipping. These were all taken with an "Ideal," with a five and a half inch lens capable of focussing.

WALTER D. WELFORD.

MR. WELFORD is well known as an expert snapshotist, and he has employed his hand camera with excellent effect in carrying away reminiscences of many humorous groupings. Here we have a group of five members listening to the eloquence of Mr. Birt Acres, who, with

animation, is adducing reasons why this scene rather than that other should be selected for a short walk out. There is a fine view of the steam launch and the little flotilla by which the members were conveyed from Totnes down the Dart to Dartmouth. Another shows one of the most modern men-of-war at anchor in the Hamoaze. Here we have a great concourse of people assembling on the Hoe to secure good places from which to witness the fireworks that are to be let off after dark, and there we have individual specimens of the *genus homo* armed with camera and stand, or of ladies with hand cameras. These are all in Mr. Welford's usual excellent style.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

JULY 13,—Mr. J. S. Teape in the chair.

The Chairman showed results of a recent outing to Fobbing, Essex.

GETTING RID OF HALATION IN A NEGATIVE.

Mr. T. E. FRESHWATER asked the best way of getting rid of halation in a negative of an interior with a large window.

Mr. P. EVERITT would vignette the window in the frame. He had found the use of methylated spirit unsatisfactory for reducing purposes.

Mr. G. W. ATKINS had used emery powder in oil with satisfactory results.

Mr. FRESHWATER asked whether it was essential that the halation should be got rid of. In the photograph to which he referred he got the window just as looked in the subject.

The CHAIRMAN suggested the reduction of halated negatives and working them up with a pencil. He had tried the use of a knife for scraping away parts of a negative, and said that it seemed to make those parts much denser.

Mr. W. E. DERENHAM remarked that varnish restored the parts to their ordinary density.

The meeting was largely occupied in the arrangements for outings and subjects for discussion.

Hackney Photographic Society.—July 11, Mr. R. Beckett in the chair.—A question was asked, "What is the best way to restore old negatives stained yellow?" Mr. HUDSON advised the use of a weak hydrochloric acid bath. Mr. MOORE thought bleaching with mercuric chloride and redeveloping with ferrous oxalate better. The CHAIRMAN said often stains were caused by insufficient fixation. A question was asked as to the approximate exposure for enlarging on slow bromide. The HON. SECRETARY said there were many things to consider, such as stop, rapidity of paper, &c. If for lantern enlarging with slow Eastman paper, aperture *f*-4 for a fairly developed negative, enlarging from a quarter to 10×8, he would give about two minutes as a standard from which to work. Mr. HARVERSON had (by daylight) on rapid paper given one minute with *f*-16, enlarging from a half plate to 15×12. Mr. GRANT advised testing by using one piece of paper and giving varying exposures. Mr. NUNN then read a paper on *Reduction of Lantern Slides*. He preferred always to reduce his slides as grain was lost, and to do them by daylight, as they could be done much quicker. In developing always be clean—have clean dishes, fingers, and filter the developer; dust your plates. He then showed a long tunnel-shaped apparatus which he used for reduction. When using daylight a white reflector was placed so as to reflect evenly on negative. Aim at full exposure and full density; forcing was a mistake. Clearing was advisable. Mr. GOSLING asked if much advantage was gained by reduction rather than contact, and was informed that every defect was reduced correspondingly. Mr. PENRY asked whether thin negatives were better than dense ones. Mr. NUNN said he had found them so. The CHAIRMAN said copying always sharpened up more than when in contact. The HON. SECRETARY thought Mr. Nunn's apparatus too cumbersome, and advised a bellows, as it could be shut up and take less room.

Ashton-under-Lyne Photographic Society.—On Saturday last, July 15, the above Society's ramble was to Chew Brook, near Greenfield, with Mr. C. E. Redfern, J.P., as leader. The party, consisting of twenty-five ladies and gentlemen, left the Society's rooms, Henry-square, a little before two o'clock. The day was not very promising, but a good number of plates were exposed, and the party enjoyed the outing very much.

Leicester and Leicestershire Photographic Society.—July 13.—A number of the members of this Society went, by special train, to Warwick, where special permission had been obtained, through the kind permission of the Earl of Warwick, to photograph the Castle grounds; as, however, the party arrived rather late, the Castle itself was left out of the programme, and the interesting bits in the immediate vicinity occupied the attention of the members, and offered quite sufficient work in the quaint buildings and streets, and the river, and its ancient associations. In spite of the dull weather, some good work was done by time exposures, snap work being out of the question. After the members had exposed their plates, an adjournment was made to the Dale Temperance Hotel, the members being in fine trim for a substantial tea, after which they took the train for Melverton station, about a mile from Warwick proper, and, there taking the train, were soon at home again, after an enjoyable outing and a promise to revisit the place and Castle at an early date. The President, Mr. J. Perritt, was leader of the party, and the next meeting was arranged for Belvoir Castle on Saturday, July 29, and the President cordially invited any members of the sister Societies, who may wish to join the excursion, to this historic mansion.

FORTHCOMING EXHIBITIONS.

1893.	
August	*Welsh National Eisteddfod. The General Secretary, Pontypridd.
September 5	*Royal Cornwall Polytechnic Society, Falmouth. W. Brooks, Laurel Villa, Wray-park, Reigate.

LIGHT INTENSITY AND CHEMICAL ACTION.

To the EDITOR.

SIR,—After reading in your periodical of last week the law of photography stated by Captain Abney, "that, when the products of the intensity of the light acting and of the time of exposure are equal, equal amounts of chemical action will be produced," it appeared to me this supposed law was directly opposed to the universal law propounded by our best physicists, "that there is a preliminary resistance to be overcome before chemical change of any kind can take place." The experiments of Captain Abney give another illustration of this universal law, and there can hardly be a doubt the luminiferous energy could be so dealt with, that no effect whatever would be produced on the most sensitive recipient surface, however often the interrupted exposures were repeated in the manner suggested by him.

The luminiferous energy is now supposed to be an electro-magnetic vibration, and the rapidity of the vibration which influences the sensitised surface of the bromide of silver is calculated to be five hundred billion times in one second. Thus, in Captain Abney's experiment, where he employed time exposures of one-thirty-thousandth part of a second, there still remained over sixteen thousand million vibrations which were received at every exposure; so it is not to be wondered at that his experiments are still far removed from that exposure which would not suffice to overcome the preliminary resistance to chemical action, although they

appear to have been sufficient to indicate the failure of the supposed law of photography.

The wonderful achievement of Professor Boys in obtaining an image of the shadow of a bullet in its flight was rendered possible by this enormous number of vibrations contained in one second, because, although the time element was even reduced to the millionth part of a second, there still remained the energy from five hundred million vibrations. Professor Boys used the shadow produced from an intense light; if, instead, he had used the light passing through the objective of an ordinary camera, it may so have turned out that, however often the shot was fired, no image would be produced.

Another instance of the influence of the five hundred billion vibrations in a second is shown by stellar photography. The intensity of the vibration often is too feeble to influence the optic nerve, and yet the uninterrupted continuance of the vibration is capable of producing the chemical change on a sensitised recipient surface. It probably would be quite different if the exposures were interrupted in the manner adopted by Captain Abney's revolving sensitised drum.

An element of uncertainty is introduced by Captain Abney using slits and small holes for the introduction of the light to his revolving drum, because the luminiferous energy is changed in a very remarkable manner when so confined, and up to the present time the real nature of the change remains shrouded in mystery; but this much can be safely asserted, luminiferous energy passing through narrow slits and small holes will come under the universal law of a preliminary resistance to the change which is produced. From my own observations upon the luminiferous energy through small holes which give photographic images in cameras, it is perfectly evident there is a wonderful change produced; otherwise how are we to account for the difference of the effects of the energy through these holes, and those so large that no object is delineated in the camera?

A little investigation will indicate that the great difference between the holes is owing to the action of the edge of the small hole upon the axes of the luminiferous vibrations. These vibrations do not pass into the camera upon the same axes as is the case with large holes, but the axes in some way become transferred to new centres ranged round the edge of the hole; but whether this is owing to the molecules on the edge taking up the electro-magnetic vibrations of the ethereal medium, and transmitting them to the recipient sensitised surface inside the camera, yet remains to be proved.

The fact of the change in the axes of vibration is most apparent by the change which takes place in the illumination of the field. Suppose the hole be $\frac{1}{10}$ of an inch in diameter, and the focus of the camera two inches, and the angle of the field 120°, and the object a large sheet of white blotting-paper equally illuminated—then it can be demonstrated that the quantity of light from each point of the object which could enter the hole becomes less and less as the points in the object become further removed from the axis passing through the hole at right angles to the metal plate to the central point of the object. This arises from the plate in which the hole is drilled, and the axes of these cones of light between points of the object and the hole presenting a front at right angles to only one point in the object, that is its central point.

If the quantity of light from the central point be called ten for the maximum, then the points on the extreme edge of the object at an equal distance from the central point only admit four parts of light instead of ten, where the field embraces an angle of 120°. The image of the sheet of blotting-paper with the axes of vibration passing through the hole unchanged would be a circle, white in the centre, and gradually shaded off to more than half between black and white at the margin; but, because all the axes of vibration are changed, the image barely shows a trace of gradation at the edge. No doubt, if the hole be made very much smaller than $\frac{1}{10}$ of an inch in diameter, then gradation becomes more and more apparent as the hole is reduced in size; but this arises from the hole becoming more and more a cylindrical tube rather than from any other circumstance, and, if it were possible to reduce the thickness of the metal plate in the same proportion as the hole became reduced in diameter, there does not appear to be any reason why the field of illumination should be altered with holes even of $\frac{1}{100}$ of an inch in diameter.

The conclusion is thus forced upon the mind that the edge of the hole is the dominant factor, and that this edge has produced an enormous change in the distribution of the luminiferous energy inside the camera, a change so vast that these edges can be so formed as to produce photographs of objects of any degree of texture which may be desired. From these considerations the success of Captain Abney's experiments is owing to the preliminary resistance to change produced on the luminiferous vibrations by the edge of the hole, or the edges of the slits he employed, as well as to the preliminary resistance to chemical change on the sensitised recipient surface.—I am yours, &c.,

Parkstone, Dorset, July 10, 1893. ARCHD. C. PONTON.

PROFESSIONALS AND AMATEURS.

To the EDITOR.

SIR,—A lively controversy has been started in your columns under the above heading, especially the first-named being angry with the second. Allow me to put a question which is a great puzzle to me: What is the percentage of professional photographers, who are only professionals and not amateurs in other business lines, in London or any other given town? Search through your list of photographers, and you will find photography combined with picture-dealing, hair-dressing, teaching, painting, picture-frame making, or newsagent, dealer in antiquities, fancy warehouse, cigar and sweet shop, stamp-dealer, dancing-master, music-teacher, lodging-house keeper, and other more or less artistic or sweet by-occupations; in fact, amateur in any other business beside his own.

I will now give you an idea of how the best-known professional photographer in a town I could mention is carrying on his business. Those persons who can afford to pay, such as members of Parliament, clergy, doctors, &c., are invited for free sittings and presented with one dozen cabinet copies free of charge. Well, if a man like the above-named gets, say, six free sittings a year in this way, what would you call him if he spent his money on it? Outdoor groups 12 × 10 are supplied at 2*s.* 6*d.* per copy, or at a push they are taken free rather than let another photographer do the work; the same business charges 30*s.* per dozen cabinets in the front of the shop, and in the back 8*s.*, or perhaps not even that—all in all, a way of business which is killing not only opposition, but also himself.—I am, yours, &c., AUDACIOUS OPERATOR.

To the EDITOR.

SIR,—About ten years ago it was required to keep a record of certain subjects by means of photography. A professional photographer was employed to do the work at his own studio, but the result was unsatisfactory; the subjects were badly displayed, and the prints, on albumenised paper, showed evidence of early decay. The person employed would be rated as a good second-class professional, he was remunerated according to his own estimate, no bargain was struck. It was suggested that the platinotype process should be substituted for the evanescent silver method, a proposal which was declared to be not practicable, to the request that negatives might be supplied instead of prints a flat refusal was given. The employer then determined to obtain the necessary material and knowledge to do the work himself. About fifteen hundred negatives have been produced, the work is still in progress, the results are being permanently recorded in platinotype; the cost so far has been under forty pounds, the professional's charges would have amounted to over three hundred and fifty pounds.—I am, yours, &c., F. R. C. S.

To the EDITOR.

SIR,—Hurrah for No. 1730 of THE BRITISH JOURNAL OF PHOTOGRAPHY! That is what we call in French "une levée de boucliers." At last the professionals say something in retaliation to the lofty presumptions of amateurs. Let us hope they will keep it up some, and maybe the amateurs will get a little more modest, and not always think that they are the almighties to whom all is due, even the free use of the professional photographer's dark room, which they think they own too. Why, with their knowledge and (superior to all) ingenuity, can they not make up anything portable to change their plates in, &c.? Of course, there are some already made, but they are not above saving expenses and trouble, being satisfied with troubling the professionals they so much despise; otherwise, however, not slow to ask their advice when they are cornered by some trouble.

Some of this sometimes insufferable overbearing of amateurism, you will probably admit, is due to the modesty of some photographers, and not only with the six best professionals in every large city, but also to some of the smaller ones, beginning with the seventh, &c. When speaking of some very fine results obtained, very often the professional will say, "Yes, I am using Mr. So-and-So's plates," and then, "Mr. So-and-So's lens, and Mr. So-and-So's paper," &c., so that he really admits that he is no more than a mere tool, using plates, lenses, and paper, leaving only to him the posing or choice of subject. Not so with Mr. Amateur. If you praise him for some chance good work a professional would probably be ashamed of, nine times out of ten you can see his high satisfaction, but he never mentions the article he uses as having anything to do with it, except perhaps the cheapness of them. To the contrary, he takes not only credit for the pictures he takes, but also it is on his sole account that all improvements up to date are due. Photography has been made by him alone what it is to-day. And to think that the amateur as he is to-day, with his button-pressing, does not exist since ten years. I well remember that, before that time and even well into that time, amateurs used a tripod and ordinary camera, even for instantaneous work.

Time is money, and I advise every professional that is asked to lend his dark room, convenient or not, to charge a fee, and do the same for his advice, and am sure the amateur will have more respect in the future, and find it quite as natural to pay as he does when he uses a wash room or asks the advice of a doctor or lawyer.

By the way, I have read of a certain Club allowing free use of dark room, &c., in Chicago to all visitors. This is very kind of them indeed; but how about the grand generosity of not allowing any amateur, with his little square box, on the Exhibition grounds? Then, what is the use

of dark room, as the principal views to be taken in the windy city are smoke and black buildings, and may be an endless perspective of flat lands on one side and a lake on the other. Perhaps next winter an exhibition of all views taken by amateurs will be interesting, especially those of Chicago, which, if superposed, as is sometimes done with portraits to get a family type, will probably be very successful to show Chicago as it is week days, with so much smoke and dirt that going out fresh and clean at eight a.m. you can return at six p.m. to play minstrel without cork, and linen to match.—I am, yours &c., A. Levy.

July 3, 1893.

To the Editor.

Sir,—I am greatly at a loss to account for the recent outburst of vituperation on the part of a portion of the professional photographers against the amateurs of photography. It is natural, in envious natures, to hate a man who either does better work than theirs, or who has gained a success which they begrudge him; but a little sense of justice would show them that what they complain of is only a proof of their own inferiority in some respect, and that it is the amateur who has always led the way to the improvements in photography, and who has made by far the greater part of the discoveries which have brought it, from the black art it was once—so difficult and uncertain that the masters of it in any city could be counted on the fingers of one hand—to be a process so simple than anybody can practise it; so that probably three-fourths of the professionals, and most of the grumblers, who are the least successful of them, could not have gained a bare living at it if the amateurs had not made the sailing smooth for them. Will any of the grumblers give us a list of the processes, dry or wet, perfected by all the professionals in Europe and America? Did one of them discover photography? Did one of them, before becoming a professional, discover wet collodion? Are not all the dry processes known by the names of amateurs? Did a professional discover the bromide process, the use of tannin, and other preservatives, the collodio-bromide emulsion, the washed emulsion, the gelatine process? Did the professional invent the camera which made outdoor photography a practical affair? I remember well a clever professional, in the days when I was groping about for the perfecting of dry collodion, thirty years ago, and, though not in easy circumstances by any means, spending from 50*l.* to 100*l.* a year in experiments and material to attain this purpose, replying to my question why he did not take up the processes, that "he was not going to waste his time in experiments, but should stick to what he knew;" and he did, but in the course of time, marrying a wife with money, he forgot that he had ever been a professional, and took to working dry plates, not even then making improvements, but, as he could then afford it, buying his plates. I should like to see the brave list of the contributions to the present state of photography which have been made by professional photographers—not those who having been successful amateurs for a time, or artists, finally decided to adopt photography as a business, being unable to spend any more on it with nothing coming back, and being fascinated by it, but those who, having taken it up as a business, had set themselves to perfecting it for the good of the profession. I do not say there have been none, and in the discovery of chemical agents, developers, &c., there have been some I know, but how many? This uproar of indignation at the amateur, because he is supposed, by taking the portraits of his friends for nothing, to be keeping a hypothetical piece of bread out of the mouth of a professional, or because he brings home from his travels some collections of negatives which are absurdly supposed to interfere with the sales of the views of some needy landscape photographer of some quite other views of quite other lands, is not only supremely ridiculous and silly, but it is ungrateful, for what the photographer does in this way to injure the interests of trade is purely conjectural, and, even if actual, is so little that no evidence of it can be found. I can speak with intelligence on this subject, for I have been one of the worst offenders, if offence there has been. I went to Greece some years ago, and amused my idle days with photography instead of sticking to my painting as I ought; but, finding that there was not to be got in all Athens a photograph of the ruined temples there which was taken with the most elementary knowledge of what was needed for the archæologist and architect, I set to work and made a complete set of the ruins on the Acropolis, and presented them to the Hellenic Society. The same I did in Sicily. Now, if I had so interfered with any professional gaining money, it must be on one of two grounds—either I have done better work than any professional had done before me, or I had found a field no one had cared to occupy. In the former case I only interfered with a man who did not know the business, and, in the second, I found a field which interfered with that of no photographer. If my fancy were to photograph my friends, I should come into collision with the local photographer in one of two ways—I should make a better photograph of my friend than he would, or I should prevent him from having the work done by the local by doing it more cheaply. In the former case, again, I should benefit the profession by showing them how to do better work, and should only interfere with them by becoming a professional like the sculptor Salomon, which would be still worse for them. In the second case I should only interfere materially by having a large circle of friends and spending a great deal more on them than they could get the portraits done for by the professionals, for this kind of amateur work costs more than it comes to, and helps the apparatus-makers and dealers more than it injures the photographer. But, in fact, the friends of a man who can afford to waste his time and money in taking their photographs are not likely to be so poor as to go to him to save money, or is he likely to spend a crown for them to save them two-and-sixpence? To compete with a tolerable professional, one must have a good studio and lenses adapted, and there are very few amateurs in this position—not enough to talk about.

No, friend professional, business is dull because it is an easy one to follow, and, if the amateur has done you any harm, it is precisely in making photography easy for you as well as for the others, and this has led too many men into it. Raising your prices will only draw more competitors. If you really love it as an occupation, be content with the sacrifice it demands; if you don't, then drop it, and go to a business where there is less competition. But don't make a fool of yourself by talking about the amateur taking the business away from you, for all he can do is not a drop in the bucket, and my own experience is that I have made twenty times the work for the printer that I have taken from the maker of the negatives.—I am, yours, &c., W. J. Stillman.

Rome, July 4, 1893.

To the Editor.

Sir,—It has amused me to notice, in the recent correspondence on photographic depression, how many despondent professionals trace their troubles to that *fons et origo mali*, the much-abused amateur.

"Find us some process which the amateur cannot imitate." "Put an annual tax of ten pounds on the owner of every twelve-and-sixpenny hand camera." "Let no professional worthy of the name supply either chemicals, apparatus, or advice to one of the hated tribe." "Let all photographers plying for hire be numbered and licensed like so many hackney cabmen.' These are some of the more practical suggestions made by those of your correspondents who abstain from mere ill-tempered and inaccurate diatribes against amateurs in general.

May I, as an amateur who has never poached on professional preserves, and whose productions merely serve, prove—if proof were necessary—the immeasurable inferiority of amateur as compared with professional photographs, offer one or two suggestions.

When your house is on fire, do not begin to abuse the man over the way because his building interferes with your ancient lights. On the contrary, take off your coat and look around for a bucket.

Take the first of the proposals quoted above, the wail for a process beyond the skill of the amateur. I *have* heard that the carbon process of printing is very cheap, very permanent, very artistic, but not very easy, and only suitable for good negatives such as amateur negatives seldom are. Yet look through any photographic album and how many carbon prints do we find? and when we do find them in how many cases were they produced by the man whose name appears on the mount? In nine cases out of ten they are the work of some firm of trade printers, done to the order of some sitter possessed of discrimination in matters photographic.

Here, then, is a process ready to the hand of the photographer who wishes to distinguish his work from that of the run of amateurs. But unfortunately it is a process which requires skill and judgment, and printing cannot be delegated to boys and girls of tender years.

On the other hand, there is a process which the professional would in ninety-nine cases out of a hundred be far better without. How many young girls who could not draw a ball in a saucer well enough to satisfy the assistant master at the Stoke Poges School of Art, are allowed to work their sweet wills with the lineaments of Tom, Dick, and Harry to them unknown. Your photographic retoucher will not hesitate to rush in where Sir John Millais or Mr. Shannon would fear to tread, and with a light heart destroys all trace of character and likeness, at so much per square inch.

Let the professional photographer no longer confine himself to the simplest and most mechanical operations, but take advantage of many beautiful though difficult processes which will lend distinction and character to his work. Let him do away with ignorant and tasteless retouching and hackneyed and unmeaning accessories. Let him adhere less rigidly to accepted canons of posing and lighting, and become a little more unfaithful to the gospel of "sharpness." In short, let his least considered production show evidence of individual thought and taste, and we are likely to hear less about "bad times" and "shammateurs," in the future.—I am, yours, &c., L. C.

54 *Loftus-road, W., July* 17, 1893.

To the Editor.

Sir,—There has been lately a rather long and altogether one-sided correspondence on this subject.

The dark side has appeared long enough; let us look at the bright side. What good has the amateur done for us? Let our memories go back eighteen years or so, when there were no amateurs of the sort we get now, and see what the state of things was. There was pyro, 4*s.* per ounce; half-plates (dry), 6*s.* 6*d.* per dozen; 10×8 dry plates, 23*s.* per dozen nett, and many other things in proportion. There were only two

(or three) dry-plate makers altogether! How times are changed now—how, every reader knows—and I am fully of opinion that we have only to thank the much-abused amateur for all these changes. It is quite true that our prices rule somewhat lower, but when the cost of production is reduced to about one-third of what it used to be we must naturally expect prices to drop.

It is desirable, with so many at work, to strike out in some special line as a specialist, and not mix too deep in the general crowd.—I am, yours, &c.,

SILEX (PROFESSIONAL).

London, July 17, 1893.

Answers to Correspondents.

*** *Several Answers are held over through lack of space.*

SPECIMENS.—We have written to the man.

F. G. SMITH.—No directory of London and provincial photographers is published.

B. O. (Burton-on-Trent).—1. Yes, quite safe, if you can get an even coating. 2. It is better to have the sitter's consent.

R. MICHELL.—Heliotype is simply collotype under another name. This process has probably more names than any other process that is worked.

NOVICE.—A simple way of "matting" the gelatino-chloride prints is to squeegee them on to ground glass, or the matt side of a sheet of celluloid.

FAIRPLAY.—So far as we can see, you will have to do the necessary repairs as you have the premises on a lease, and, presumably, it is a repairing lease, like most leases.

PUZZLED.—The markings are not flare spots, and, indeed, do not seem as if due to lenticular agency. Possibly there is a minute hole in some part of the camera which has escaped observation.

WEST.—If the practice of photography is prohibited in the grounds without a special permit, of course a hand camera will not be allowed. Is not a hand camera for taking photographs the same as any other camera?

T. A. W.—So far as photography is concerned, we believe the labour market in America is quite as much overstocked as it is here. There is really less opening for mediocre work in the States than there is here.

A. H. WILLOTT asks: "Should I incur any pains or penalties by publishing photographs of *The Light of the World*, as I have seen them on sale in stationers' windows?"—Yes, you would render yourself liable to be sued.

E. A. RAY.—A lens with an aperture equal to *f*-16 will do for a hand camera, but it can only be used with very rapid plates, or when the light is exceptionally good. A lens with an opening of *f*-8 will be far more generally useful.

G. R. A.—We should think the print was washed for an excessively long time, and that may have something to do with the yellowness, although we are inclined to think, as the markings chiefly show in the backgrounds, that the mounts may be at fault.

DEVON.—The two groups are decidedly good, and the price charged is very low; indeed, very much lower than would be charged by second or third-rate houses in London. We should say you would have no difficulty in recovering the amount in the County Court.

GLASS.—Your customer is under a misapprehension. The bill, though printed, did not become law. It was crowded out at the end of the session, like many others that are introduced. But is it wise, from a business point of view, to say nothing of the morality of the thing, to exhibit a portrait for which you have been paid for taking against the sitter's protest?

G. S. R.—Surely, as you have supplied the portraits of the clergy, and those taking an active part in the church, as well as local views, to the bazaar, and taken payment for them, although you have only charged a little more than half what the local photographer would have done, you can no longer honestly style yourself an amateur. You are a professional in disguise, and are underselling the established local photographer.

A. MCANDREW writes: "Please tell me why many of my vignettes are stained in the whites like those enclosed. The stains do not show in the unmounted prints, and only show after they are mounted and dried. The mounting is done with the best starch made fresh every morning."—The stains are produced by the mounts. The colouring matter on the surface of the card is soluble in water, consequently when moistened with the starch it stains the paper.

T. BIGGS says: "I have two lenses—the largest stop of each is *f*-8. One is by a London maker, and for which a high price was paid; the other is a cheaper one, has no name, and is, presumably, of foreign make. On working them under the same conditions, I find that, to get the same amount of exposure in the negative, the latter requires quite fifty per cent. more time than the former. Why is this the case?"—Many cheap foreign lenses we have seen, although the largest stop has been marked *f*-8 has really been *f*-9 or *f*-10, and we surmise that is the case in the present instance.

ALEXIS writes as follows: "A few months back I bought some mounts from another photographer here, who was giving up business. They have his name and address printed at the back in gold, and over this I have mounted my pictures. In nearly every case, after the pictures have been mounted two or three months, the imprint shows through in the form of fading; also the prints become very spotty. Why is this, and how can it be avoided, as I have a large quantity of these mounts, and, of course, they are no use to me unless I mount the prints over the other man's name?"—The cause is that the imprint is not in gold but in bronze powder. If it were in real gold it would be inert. The only remedy we can suggest is to paste a piece of thick paper over the imprint, and then mount the print on that. But then this would probably involve more trouble than the cards are worth.

T. A. COLE says: "On adding sulphate of iron to a large quantity of old toning baths (acetate) I can only get a very small quantity of gold, far less than I ought to get, considering the paper I use is said to tone with half a grain of gold to the sheet, and I never get more than a sheet and a half toned with a grain of gold. Is there anything that will throw down more gold than sulphate of iron?"—Sulphate of iron will precipitate any gold there may be in the solution. As one and a half sheets of paper have been toned per grain of chloride of gold, we should say there is no gold left to precipitate. Anyhow, the iron will throw down all there is, that may be relied upon.

H. W. L. writes: "Some two months ago I sent you up a print covered with spots, same as enclosed two, to see if you could give me any reason for them, but then you were not able to account for it. We have not had them so bad since then till this day, when nearly every print is so marked. I have tried everything I could think of, such as fixing longer or shorter time, hypo weakest and stronger, new toning bath, and fresh dishes. I thought perhaps the water running on them all night might be something to do with it, so used to turn it off, but all to no good purpose. You will see also the backs are yellow as well. Any suggestion you can make I shall be glad of, as it is a great hindrance to business."—Whatever may have been the fault with the previous prints sent, though we do not remember them, there is no question as to the cause of the defects in these. It is imperfect fixation. Either the bath was too weak, or the prints were allowed to stick together while in the solution. The spots are due to air bells being allowed to adhere to the paper while in the fixing bath. More care will avoid the trouble in future.

OUR CONVENTION.

AND so the time has come and gone,
Our "eighth" is now a finished story,
There only rests when all is done
The recollection of its glory.

This to us all will surely prove
One of the brightest recollections,
And give us, as apart we move,
Food for the pleasantest reflections.

The kindness of our Southern friends,
Our happy trips by road and river,
Heightened by charms that distance lends,
Will dwell within our mem'ry ever.

And thoughts of friendly faces near,
Now severed by a dreary distance,
Be with us through the coming year,
And haunt us with a sweet persistence.

Though "art" is still its highest aim,
Photography its first intention,
I think not least in "friendship's" name
We greet with pleasure our Convention.

While we who loving Scottish skies,
Breathe native air 'neath smiling heaven,
Remember still with pensive sighs
Your leafy lanes, sweet, sunny Devon.

Good-bye; accept from Northern parts,
Kind English friends, this hearty greeting.
We look with hopeful, trusting hearts
To such another pleasant meeting. LASSIE.

THE CONVENTION GROUP.

With this week's JOURNAL *we present a collotype reproduction by Messrs. Morgan & Kidd, Richmond, S.W., of the group of members of the Photographic Convention of the United Kingdom, assembled at Plymouth on July* 5, 1893. *The negative was taken by Mr. R. L. Kidd.*

We also give a key with names of members. In the cases where we have been unable to identify members, we should be glad if our friends would supply the omissions, for mention in the next number of the JOURNAL.

By an unfortunate error we are made, on the picture of the group, to describe the Plymouth Convention as the "seventh" that has been held, whereas, as will be seen by dating from the Derby meeting of 1886, *it should have been the "eighth."*

CONTENTS.

Collotype—Morgan & Kidd, Richmond, S.W. *Negative by R. L. Kidd, Richmond, S.W.*

MEMBERS OF THE SEVENTH ANNUAL PHOTOGRAPHIC CONVENTION OF THE UNITED KINGDOM.

HELD AT PLYMOUTH, JULY 3-8, 1893.

KEY TO THE CONVENTION GROUP TAKEN AT PLYMOUTH, JULY 5TH, 1893.

1. Mr. G. Mason (*President*).

THE BRITISH
JOURNAL OF PHOTOGRAPHY.

No. 1734. Vol. XL.—JULY 28, 1893.

CORRECTING MICROSCOPIC OBJECTIVES FOR PHOTOGRAPHY.

The *American Journal of the Medical Sciences* for this month coutains a paper by Professor Henry G. Piffard, M.A., "On a Suggested Improvement in the Correction of Lenses for Photo-mierography, Photography, and Photo-astrography," a copy of which he has kindly sent to us.

Twenty-five years ago, while mieroseopie object-glasses are admitted by the learned author to have been of excellent construction and well adapted to the revelation of the strueture of minute objects to the eye, yet he says the photographs made by them were greatly inferior in clearness and sharpness to the virtual image appreciated by the retina, this being due to the lack of coincidence of the visual with the actinie focus. Dr. Piffard reminds us that, at the period mentioned, the art of photography was almost exclusively practised on iodised collodion plates, which, while very sensitive to the blue, violet, and ultra-violet rays, were but feebly so to the rays of less refrangibility. But, as these latter are more luminous, they impress the eye so forcibly, that the effect of the more refrangible rays is almost obscured when mingled with the others as in ordinary white light. It follows that, in order to obtain a sharp photographic image, it was necessary to either shorten the anterior conjugate focus or move the plate to a point nearer the lens where the actinie rays came to their posterior conjugate foeus.

Dr. Piffard, who is an expert photo-micrographer, is doubtless well aware of the system that was—nay, still is—practised by some in this country to utilise their objectives so as to ensure their acting both visually and photographically; but, as he does not mention it, we shall, pending the publication of his excellent paper *in extenso* on an early occasion, take occasion here to describe it, in the interests of those who are entering this fascinating branch of photography for the first time.

For reasons deduced from the foregoing, microscopic object-glasses must be slightly over-corrected for colour. We are now referring to such as are constructed of ordinary flint and crown glass, and in which eategory is to be found the majority of those in use at the present time. But under-correction for colour is a condition for obtaining the sharpest photographic image.

It is just forty years since the subject of photo-micrography was brought before the Society of Arts by the Rev. W. Towler Kingsley, and he met the then acknowledged difficulty of the non-coineidence of foci by recommending that a new front lens be made for the objective, so that it might be employed visually with the original one, and photographically with the new under-correeted one. This system is, however, very costly as compared with one which was suggested several years afterwards by Mr. F. H. Wenham, if we remember aright. By it the object-glass itself is not altered; but from its upper end, in which is usually serewed a diaphragm to prevent reflections from the interior of the brass mount of the objeetive, this diaphragm is unserewed, and its place taken by another cell, containing a simple convex lens, usually cut out from the centre of a speetacle glass.

By having a few of these of different focal power it is then easy to select one which, when screwed in, shall, by its non-correction, impart to the objective the requisite amount of under-correetion to ensure the coincidence of the chemical with the visual focus. When onee the correcting glass has by trial been found, it is marked, and is always afterwards used when the special object-glass for which it was selected is employed for photo-micrography. The angular aperture of the latter is very slightly inereased by this adaptation, but no one will consider this as a disadvantage.

The system here deseribed for seeuring the desired coincidence of the foci is, in our opinion, greatly superior to that for attaining the same end by displacing either the anterior or posterior conjugates. Any working optician will, at a moderate cost, supply such a cell as we have described, and adapt to it a variety of uncorrected lenses of sueh variety of focus as will serve to correct, photographically, one's whole stock of objectives.

Dr. Piffard says that the photographs of microscopic objects made twenty-five years ago "were crude and unsatisfactory, and were all made with what we would call low-power objectives." In justice to an eminent worker on this side of the Atlantic, Dr. R. L. Maddox, we must point out that this gentleman had, considerably anterior to that period, achieved great suecess in photographing, with a one-fifth of an inch objective, *Polycystina* from Barbadoes, together with several *diatomaceous* forms which accompany them; several frustules of the *Triceratium favus;* front views of the *Surirella bifrons;* various speeimens of *Coscinodiscus*, and other objects. We mention this *àpropos* of Dr. Piffard's remark as quoted above, for we feel assured that this American scientist would be the last to withhold credit to an equally eminent English brother for what he has achieved in the early days of our art-science.

COMPARATIVE DEVELOPER EXPERIMENTS.

A LARGE number of earnest workers in the field of photography find a pleasure in the class of work indicated by the title of this article; but in too many cases the results are either worthless or too indefinite to be placed on record as serious results. Some hope of remedying such a state of affairs is the motive for the remarks that follow. The causes are mainly to be placed in two categories. First and foremost must be placed that most detestable—no other word is so suitable—method adopted by so many platemakers and writers of instructions and formulæ, of giving the proportions of the ingredients in a manner that renders comparison of one with another most difficult, and wasteful of time to a degree that is most irritating. This is, of course, no new complaint; but, if constant iteration will lead to its destruction, then "Delenda est Carthago" should be the watchword of all who would put an end to its inconsistencies and its annoyances. We have lately set ourselves to try a series of experiments with one of the later developers—metol—and a good share of half an hour was wasted in arranging for ready comparison the various instructions published, either by the makers themselves or in other ways. Percentage formulæ were useful; but, until the metric system is more commonly employed by the public generally, we think that grains per ounce will be understood and felt to be most practical by a larger number of working photographers. The manner in which every formula is set down should show at a glance how many grains per ounce, or per pint, or half-pint if preferred, of the various constituents are contained in the given quantity of developer when mixed ready for use. What a boon this would be, if all makers and formula-producers would adopt it, those only who are in the habit of making comparative experiments can say. To all such it is a familiar experience to find a couple of rival formulæ being argued about which, upon being reduced to a standard, are found to be practically identical.

The second of these two main causes is the hasty and incomplete manner in which conclusions are drawn, or rather jumped at, from the briefest of premisses. An experimenter tries, say, a new developer side by side with the one he usually employs; the new solution flashes out the image at once, the conclusion is rushed at and published that it is a "find," excellent for under-exposed pictures. Another is tried, and the image is only beginning to appear when the plate by its side is finished. The new solution is worthless, requires too long exposure, &c. Yet in each case the ultimate developing power may turn out to be the same, and no more exposure value can be got from one than the other.

Then, again, it must be remembered that the experience of many years has so narrowed down the range of formulæ for pyro that the working limits are well known—strength of pyro, proportion of alkali to same, as also the value of alterations in the amount of bromide permissible. But to obtain such ready command of proportions of the various ingredients and their effect on results when an entirely new substance is used would require many trials, and it is the absence of trials of these variations that may make or mar—for a time, at least—the future of any newly introduced developing agent. Before any decision can be fairly made as to the merits of such new substance, it should be tried in various strengths, with varying proportions of alkali and of bromide, and notes made as to the rapidity or slowness with which the image appears, and of all phenomena varying from ordinary experience. Let us now refer to one of the latest developers, metol. Any one trying it for the first time would be very apt at the outset to think that exposure could be reduced when it is used, for the image will flash out, and the surface of the plate present an appearance to that given by a fully developed pyro negative, while a companion pyro-developed plate has scarcely begun to show the high lights. How very needful to avoid rash conclusions here. Then, taking the published formula, we have been at the trouble to extract the data and reduce to an ounce standard (avoiding complex fractions by giving the nearest small one) the formula sent out by the maker, and those given in the reports of eminent experimenters.

	Formulæ by				
	Agents.	Agents.*	Sexton.	Eder.	Pringle.
	New.	Old.			
Water	1 oz.	1 oz.	1 oz.	1 oz.	1 oz.
Metol	1¼ gr.	3¼ gr.	3⅗ gr.	3⅓ gr.	3⅓ gr.
Carbonate of potash ..	7½ „	15½ „	11 „	11 „	11 „
Sulphite of soda	3¾ „	10⅔ „	33 „	31 „	31 „
Bromide of potassium..	¼ „	None.	⅓ „	None.	1 „

By this means a glance shows the peculiarity of each. In the first formulæ published, the metol is to be used at a little over three grains per ounce, but now the agent recommends only one-third that strength. Messrs. Eder, Pringle, and Sexton give formulæ almost exactly alike, save in the use of bromide. The first-named uses none, the second one grain per ounce, and the third a third of a grain. The new formulæ of the agents in this country give six times as much potash as metol, the others only three times as much. There are two conclusions that might be drawn from these fluctuating and varied formulæ: First, that metol is so valuable that it can be worked almost hap-hazard; second, that its actual value is not yet ascertained, as the proportions of the given ingredients for a particular purpose would not have such wide limits as above shown. Let pyro and ammonia be taken, for example; if the ammonia of some formulæ were doubled, hopeless fog would result; if it were halved, the utmost value would not be obtained.

We conclude by saying these remarks are neither for nor against metol; they are made to show the necessity for care in forming judgments, and for varying the modes of using or mixing the developer before a logical conclusion can be justly formed.

City and Guilds of London Institute.—Our attention has been called to several alterations that have been introduced in the programme of examinations for the session 1893–4, and other arrangements. Some new subjects are added, and others divided into two sections. The honours examination in photography is one of them: (1) pure photography, and (2) photo-mechanical processes. And the practical examinations will be held in connexion with the honours grade only. There are several other alterations with regard to the examinations and regulations. For example, the practice of returning, or giving credit for, half-fees is to be discontinued. Some fees have been reduced while others have been revised. Furthermore, the list of teachers has been revised and rearranged. The Institute is making strenuous efforts with regard to technical education, and it is to be anticipated that the new regulations will strengthen them particularly with reference to the really practical side of subjects taught.

* For ordinary use; variations are given for hard or soft negatives.

Art in Business Centres.—Since Sir John Gilbert gave several of his fine works to the Guildhall Art Gallery, several other presents of pictures have been received. Now Mr. W. A. Murphy-Grimshaw has given his picture of the *Haunted Mill*, at present in the Royal Academy, to increase the collection. The Birmingham Art Gallery has also lately been enriched by the acquisition of some fine examples of art metal and wood work, not in this case by donation, but by purchase at the late Spitzer sale. Manchester, as is well known, owns a large collection of fine works of art. While on the topic of art, *The Academy* says that the famous collection of drawings and sketches by old Masters, formed by the late Mr. John Malcolm, has been deposited on loan by his son in the British Museum, where it will soon be made accessible to students. A present of a colossal cartoon by Michael-Angelo has also been made by Mr. Malcolm's son. If good photographs of such works as these were forthcoming, they would be of inestimable value to students; many are, it is true, but they are usually issued at such a price as to be prohibitive to the ordinary struggling art student.

Discoloured Glass Positives.—Amongst the odd work that photographers are frequently called upon to do is to produce copies or enlargements from old glass positive portraits. If the picture happens to be in a good state of preservation, nothing is easier to copy in camera than a glass positive; but, in the majority of instances, it is not. These pictures, from being carelessly produced, and seldom or never being varnished, after a time become discoloured unevenly by a highly non-actinic tint, which causes camera copying to be very unsatisfactory. Most old hands know, though the new ones evidently do not, that, if the black varnish be cleaned from the back of the glass, the stains show but little, if at all, by transmitted light. Therefore they then use the positive as a negative, though a weak one, to print a transparency by contact on a dry plate, and from that make a negative for the end desired. The other day we were consulted as to the best way to produce an enlargement from a badly stained positive. On removing the black varnish, we found, as we expected, that the stains scarcely showed in the centre of the picture when it was looked through. At our suggestion the positive was placed in the enlarging camera, and an enlargement made direct from it, as a vignette, on bromide paper. The result was a picture quite as good as if it had been made from an average ordinary negative. So good was it, that the method deserves a passing note for the benefit of novices.

Metric Weights and Measures.—The vexed question of weights and measures as regards photographic formulæ seems to be as far off a settlement as ever. Whenever any new formula appears from the Continent, whence, by the way, the majority come, it is given in grammes and cubic centimetres, while English ones are written in grains and ounces. Now, notwithstanding that tables are given in the ALMANACS of the equivalents in one system to those in the other, we, and perhaps other journals also, are being continually asked by correspondents to convert a formula according to one system into that of the other. A few years ago the Photographic Club went to some considerable trouble to get other photographic societies to adopt the metric system entirely; but this has not been generally followed. We were recently shown a set of gramme weights stamped with their equivalents in English grains, but we were told by the owner of them that he had to do it himself. Of course, beyond the gramme weight, for photographic purposes, the nearest whole number is near enough. Fluid measures are to be had at some shops graduated on one side with ounces and drachms, and on the other with cubic centimetres. Thermometers are regular articles of commerce with the Fahrenheit scale on one side and the Centigrade, or Réaumur, as the case may be, on the other. Why, then, should not weights and measures marked with the two systems be universal? The additional cost, particularly with the weights, would be merely nominal, and that would be repaid to many photographers by the general convenience.

Photographs of the Milky Way.—Professor E. E. Barnard, who has recently been on a visit to Europe, has brought with him some wonderful photographs of the Milky Way, which are simply a revelation to many of us. These photographs (says the *Observatory*) were taken at the Lick Observatory with a lens made by Mr. Willard, of New York, in 1859, which is one of large aperture (six inches) and short focus (thirty-one inches). Such a lens tends to compress, as well as intensify, the characteristic features of these stellar clouds, the large field allowing one to embrace any of these forms as a whole, and not in detail, as is the case when they are viewed with a telescope. The first photographs, showing the cloud forms, were taken in August of 1890, the portion of the sky being that situated in Sagittarius, and the exposure three hours fifteen minutes. A most interesting picture is that of a section of the constellation of Cygnus, near γ Cygni; this photograph shows some of those curious and almost weird dark spots and dark lanes the origins of which are very doubtful. Mr. Ranyard supposes them to be due to an obscuring medium between us and that part of the Milky Way, but Professor Barnard's opinion is that they are real holes in the cloud structures themselves. Two photographs, with different lengths of exposures (two hours forty-five minutes, and four hours thirty minutes), of the region about M. 11 in the constellation of Sobeski, raises an important point as regards the different structure of the Milky Way. The second picture exhibits details which considerably altered the configuration, not at all brought out in the first one. Not only in these photographs, but in several others of the Milky Way, this fact has been noticed, and Professor Barnard suggests that there may be different orders or kinds of cloud structure implying distance or nearness, or possibly an entirely different order of stars in point of actual size.

Chicago Exhibition.—A recent telegram informs us that the jurors in the Fine Arts Department have elected an Englishman, Mr. W. B. Davis, as president, and Signor Delnero, of Italy, and Signor Delcampio as first and second vice-presidents, with Mr. Dielman, an American artist. Mr. Thacher's plan of awards has been rejected *in toto*, and the following adopted:—A member of the jury will propose a medal to a certain artist. Then this motion must be seconded and supported by a majority of the jurors before the medal can be awarded. As, however, the French, Danish, Russian, and Norwegian Commissioners were not present when the President of the Committee on awards made these concessions, it is understood that the countries named have decided not to enter their fine art exhibits for the jury's examination. This decision will, of course, to an extent, rob the competition of its international character. This "big thing" among international exhibitions seems to have been a more or less unfortunate affair from the very beginning. There have been the strikes and accidents during its building throughout, its chaotic state at the time of opening, and the allegations of "jobbery." Then there was the irritating monopoly with regard to photography, and the unpleasant friction about the awards. Next, the late lamentable fire. Lastly, and that will weigh heavily with our American cousins, the prospect of a financial failure in proportion to the magnitude of the undertaking. By the way, we learn that the American liner companies are not reaping the harvest they expected from British visitors to the West. Last year, in almost every family circle, some one was going to Chicago; now, it is surprising how many, for some reason or other, have abandoned the idea.

RATIO OF GRADATION ON POSITIVE PAPERS.

THE invaluable researches of Messrs. Hurter & Driffield in connexion with the exposure and development of negatives should stimulate photographers to inquire more closely into the character of the various descriptions of films employed in the production of their prints or positives. Not only do these, as is well known, vary in actual sensitiveness, but also in the way in which they render the gradations of negatives of different densities, some giving the best rendering of generally dense images, others again behaving better with thin or delicate negatives.

With no printing surfaces with which I am acquainted does this difference exist to so great an extent as with gelatino-chloride paper

which can be made by varying the formula to work to perfection with either hard or delicate negatives, though generally it may be accepted that the commercial papers work better with a rather thin negative, and give a good result with negatives too thin to print satisfactorily upon albumen paper. The latter of late years, since the introduction of ready-sensitised papers, has materially changed its character, being both more sensitive and more generally applicable to thin negatives than was the case when the home-sensitised article was in use, the alteration being, no doubt, due to the introduction of new organic salts of silver.

But, though the positive papers are known to thus vary, little or no attempt has ever been made to adapt the paper to the character of the negative. In days gone by, if a man had to print from very thin negatives that were worth the trouble, he would use a stronger sensitising bath than usual, perhaps also employing a more heavily salted paper if obtainable. That was about the only direction in which the chemical treatment was varied, except perhaps in carbon printing, where exactly the reverse means were adopted to produce the same result; in other words, for thin negatives a weaker bichromate solution is employed in sensitising. Beyond this, there were various methods of shading the negatives with tissue paper, or matt, or coloured varnish, when the image was too thin to print satisfactorily; but, though many, myself among the number, believe that improvement results from such treatment, others strenuously deny any advantage.

It is many years since the idea first struck me to apply direct measurements to the printing gradations of various papers, but the more I thought about the matter the more I became impressed with the magnitude of the task and the inutility of only half doing the thing. The accounts of Messrs. Hurter & Driffield's researches, and even of the experiments reported in his paper before the Convention by Mr. W. K. Burton, only prove that I was right, though, what a single individual may not do, photographers collectively might very well undertake, especially as in the case of positive paper the requirements in the matter of apparatus are not so great as for the more sensitive negative films, nor is the task one of such intricacy. In the case of all print-out films, for instance, we are spared the complications surrounding development as distinguished from exposure, while, with developed prints, in all probability the same laws established by Messrs. Hurter & Driffield would be found to hold. In fact, the work might be confined entirely to a study of the relative gradations produced upon papers of different kinds, and by light of varying strength.

For this purpose it would be necessary to establish a scale of gradations representing those of a "perfect" negative—if there be such a thing—but at any rate a scale of some sort by which to compare results; and here again Messrs. Hurter & Driffield have already supplied us with the necessary data upon which to proceed in constructing such a scale, as well as the details of its construction, for which I would refer to the two diagrams given in connexion with their Convention article in last issue. Although no detailed description is given, the diagrams, I think, sufficiently explain the principle, which may, of course, be modified in a variety of ways to suit circumstances.

The apparatus there figured is intended for the exposure of plates to the light of the standard candle, but for use in connexion with paper, and almost necessarily to daylight, a different and much simpler arrangement will suffice. Such a one I constructed some years ago consists of a printing frame or dark slide, with closed front, in which a revolving disc, similar to that in Messrs. Hurter & Driffield's diagram, is fitted, the motive power being a driving wheel and band, attached to the instrument after the manner of a chromotrope slide. The disc is arranged to carry movable masks, having openings representing different series of gradation, so that either the general sensitiveness of the sensitive film may be tested or its capability of rendering gradations, either coarse or delicate. The importance of this power of varying the character of the gradation is more important in the case of paper than of films.

With such an arrangement it is only necessary to place strips of the papers to be tested or compared side by side in the printing-frame portion of the apparatus, and to cause the disc to revolve for a given time, or until a given depth of tint is obtained, as the case may be, when not only the relative sensitiveness but also the relative power of rendering gradations will be shown at a glance. Absolute sensitiveness is of no importance in such an experiment; if it be required, of course a standard light will have to be chosen, and this is rather more difficult for slow exposures on paper than for negative work.

Such an apparatus might be constructed and put on the market at a very small cost, and would prove useful in a variety of ways in connexion not only with papers but with negatives, but more especially would it assist the amateur in selecting the best paper to suit his general style of negative.

W. B. Bolton.

CONVENTION NOTES.—II.

What a blessing it is that Plymouth is not nearer to London than 216 miles! If it were, we tremble to think of the inundation of its streets and surroundings by the metropolitan photographer, who would invade the place in shoals. In the history of Convention outings, there is no one place which can offer, in its immediate vicinity, so many delightful scenes for camera work as can Plymouth.

Contrasted with Edinburgh, the town of Plymouth has so few objects of quaint historical interest as to be nowhere in affording food for the camera of the archæologist; but, unlike Edinburgh, one has only to take a comparatively short walk to reach Sutton Pool—the whilom harbour of Plymouth. This Creek of the Cattewater was formerly protected by having a chain stretched every night across its entrance. In this vicinity the Barbican, with its innumerable fishing boats and other shipping, affords excellent themes on which to practise with either the stand or the hand camera, and during Convention week it was difficult to walk many paces in this locality without running against one or the other of these.

It is, however, outside of the town wherein lies the great value of Plymouth to the photographic tourist. It would be difficult to find a more enchanting place for an excursion than the river Yealm (pronounced indifferently Yem or Yam). On the second day of the Convention the kindness of the local Clubs in providing a steamer enabled some seventy or eighty members to visit this river, the entrance to which is two or three miles outside of the Breakwater, an artificial, strongly built erection which stretches well across Plymouth Sound for more than a thousand feet, and protects its shipping inside from the heavy ocean waves. No sooner, however, had the steamer got inside the Yealm, and realised the placidity of its waters compared with the turbulence of those outside, than rain began to fall, and, although soon this was accompanied by lightning and thunder, it failed to damp the spirits of the excursionists, who, well sheltered from the storm, beheld with admiration the beautiful stream with its romantic turnings and richly wooded banks. Had there come a glimpse of sunshine, if but for a minute, many mementoes of that visit would have been carried away, for there were over sixty cameras on board, and their owners were only too anxious to have a shot at such scenery, but the Fates did not so will it. Having cast anchor, advantage was taken of a stay of over an hour to have a lunch, of which it is enough to say that, in excellence and variety, it surpassed all that could have been expected at any well-appointed hotel on shore. We do not know what local arrangements exist for visiting the Yealm, but our advice to all artistic tourists who find themselves in Plymouth is not to return without seeing this river, and selecting for their visit a day on which there are neither rain nor thunderstorms.

Returning to Plymouth *viâ* the Mount Edgcumbe end of the Breakwater, and being thus afforded an opportunity of seeing the grounds of this far-famed place, which we may remark, *par parenthèse*, are generously thrown open to the public by the Earl of Mount Edgcumbe, we picked up a few who could not, either from business arrangements or anticipated *mal-de-mer*, take part in the forenoon excursion, and proceeded up the Tamar, the mouth of which is contiguous to the town. Here let us pause for a moment to say how

much the excursionists owe to Colonel Barrington Baker for his assiduous attention throughout the day. His intimate acquaintance with the Royal Navy, with which he is officially connected, enabled him to impart valuable and interesting information respecting the numerous war ships through which we threaded our way up the Hamoaze. A temporary cessation of the rain permitted of several exposures being made at some of these ships, and of Brunel's masterpiece, the Royal Albert Bridge, which at Saltash connects Devon with Cornwall. Much rain fell during the passage up the Tamar, but towards evening, after tea, the weather cleared, although too late for much good work.

If the weather was unpropitious on the occasion of the Tuesday's excursion, ample amends were made on that of Thursday. At a moderately early hour a very large party left Plymouth by train for Totnes. The town was *en fête*, and the sun shone brightly. After witnessing local processions in honour of *the* marriage, we embarked on a steam launch in waiting on the Dart to convey the party to the pretty town of Dartmouth at the mouth of the river. The launch proving totally inadequate for the accommodation of the large party, a second boat of like dimensions was provided and also filled, the surplus finding accommodation in a third boat. These were taken in tow by the launch, and a merrier party was never seen on the Dart. When a few miles down still another boat, with a small contingent which had preceded the main party, was seen waiting for us in the middle of the river, and it, too, was taken in tow to swell the goodly procession, which, when we reached Dartmouth, must have presented a singular, if not a semi-formidable, appearance. What numerous pictures may be obtained here! But to secure them one must go alone, or, at any rate, with a much less numerous party than constitutes a Convention outing. On the boat nothing but hand cameras could be used for sheer lack of room in which to erect a stand, but on shore, and with stand cameras, pictures will be found everywhere, lying as thick as the proverbial blackberries.

Plymouth and the adjacent towns have given many good men to the world. Mention has already been made of Robert Hunt. He was one of the early investigators into the photographic properties of several substances. We owe to him the knowledge, *inter alia*, of the developing powers of ferrous sulphate. He was the earliest and most competent historian of things photographic that we have had. His *Researches on Light* is a classical work; so, for that matter, is his *Poetry of Science*, together with other equally charming works. His memory will always be green in the recollection of all photographers worthy of the name. To Plymouth also we owe such early Fellows of the Royal Society as Joseph Glanville and Dr. Yonge; such painters as Sir Joshua Reynolds, Sir Charles Eastlake, James Northcote, Benjamin Robert Haydon, Samuel Prout, Samuel Cook, and others. In fine, in mathematics, surgery, horology, electricity, engineering, and literature, Plymouth, with its immediate surroundings, has produced many gifted and eminent men.

In naming some men of mark belonging to Plymouth, we must not omit special mention of J. T. Towson, subsequently Marine Examiner at the Sailors' Home at Liverpool, and the discoverer of Great Circle sailing. He was early engaged in prosecuting photographic experiments, and in 1838-9, along with Robert Hunt, H. Fox Talbot, and Sir John Herschel, was probably the only one so engaged. Dissatisfied with the slowness of the achromatic lenses of that period, he wrote a paper, which appeared in the *London and Edinburgh Philosophical Magazine* for November, 1839, on the proper way to focus for Daguerreotyping with simple lenses, in which he pointed out the difficulty of using the common achromatic lens, the luminous focus being different from the chemical. Towson was also instrumental in preventing the success of Talbot's application for a patent for photographing on glass; for, in 1838, he (Towson) had produced a photograph on glass which, with the knowledge of Hunt, he had sent to Herschel at the time. This was referred to by both as a proof that Mr. Talbot had no claim to an exclusive enjoyment of the privilege of producing photographs on glass.

TELE-PHOTOGRAPHIC SYSTEMS OF MODERATE AMPLIFICATIONS.

If the positive element of a tele-photographic system have a large angular aperture or a high intensity, say *f*-3 or *f*-4, it is possible to produce a combination of considerable magnification (in a short compass), maintaining at the same time sufficient rapidity for all ordinary purposes. With such a positive element, however, it becomes necessary to introduce a means of correction for spherical aberration when the compound system is used for any but one extension of camera and one particular distance of object. The advantages of this type of lens have already been described, as also the manner in which the necessary corrections referred to have been carried out.

Now, if the positive element have only a moderate intensity, say *f*-8 or less, and the magnification required be not great—in other words, if the focus of the negative element combined with it to form the tele-photographic system is not too small a fractional part of the focus of the positive element—the compactness of the tele-photographic system is maintained; and, further, the amount of spherical aberration introduced for planes other than that for which it is constructed becomes a negligible quantity. Again, with a comparatively weak negative, the latter can be made of considerable diameter, so that there is the compensating advantage of a greater angle than it is possible to include as against the loss of magnification.

I was at first inclined to think that a special construction involving comparatively weak magnification in ordinary lenses of the rapid rectilinear type was unnecessary, as most cameras, for a given size of plate, will permit of sufficient extension to utilise one combination only of the doublet designed to cover that plate, and so obtain an image of double the linear dimensions. Further consideration, however, has led me to think that there are advantages of sufficient weight to merit a special construction. The chief disadvantage of using one-half of a doublet is that it requires stopping down in order to cover the plate properly, and, again, there are, of course, only the two definite focal lengths possible with the one lens, *i.e.*, both combinations or one alone.

By the use of a negative attachment to the doublet lens the full aperture can be maintained, and a wide range of foci can be obtained by the employment of one negative lens only, in conjunction with it, controlled only by the separation of the nodal planes of the two elements (but in practice by the camera extension). Moreover, the one positive lens, used in conjunction with a battery of several negative lenses each of different foci, can be made to give any focus one chooses longer than that of the positive used alone, and to include any less amount of angle that one may choose.

After careful investigation I recommend that the rapid rectilinear type of lens (*f*-8, or even *f*-7) should be combined with a negative lens of half its focus, to form a really useful tele-photographic system. (If the negative is less than half the focus of the positive, there is danger of introducing outstanding aberration for any but one extension of camera, and for other than parallel rays; this aberration is only removed by stopping down the positive lens, reducing both angle included and rapidity.) Negative lenses, in this proportion of foci, can be made of larger diameter than lenses of the positive element, and a considerable angle can be included, and necessarily greater equality of illumination is attained than when the negative lens is of smaller diameter than the positive. With the proportion of foci recommended, the attachment to the positive lens is not inconveniently bulky. Weaker negative lenses can also safely be employed, or, in other words, the focus of the negative lens may be more than half that of the positive; in this case the attachment is shorter, the magnification less, but the angle included greater.

The figure illustrates the combination of a six-inch focus rapid rectilinear combined with a three-inch focus negative combination. When the foci are known, it is only necessary to know, or set the separation of the nodal planes N_1 N_2 to completely determine the equivalent focus and back focus (*i.e.*, the distance of negative lens to screen).

If f and f^1 represent the foci of the positive and negative lenses respectively, a the separation, F the equivalent focus, and BF the back focus, then the following simple *numerical* formulæ give the required information:—

$$F=\frac{ff^1}{a+f^1-f} \qquad BF=\frac{f^1(f-a)}{a+f^1-f}$$

for the case in the illustration;

$$F=\frac{6\times 3}{3\frac{3}{4}+3-6}=\frac{18}{\frac{3}{4}}=24$$

$$BF=\frac{3(6-3\frac{3}{4})}{3\frac{3}{4}+3-6}=\frac{6\frac{3}{4}}{\frac{3}{4}}=0$$

Rule I.—To FIND THE EQUIVALENT FOCUS of the combination: *Multiply the foci of the two elements together and divide the result by the sum of the focus of the negative lens and the separation, after having subtracted the focus of the positive lens from this sum.*

Rule II.—To FIND THE BACK FOCUS: *Multiply the focus of the negative lens by the difference between the focus of the positive lens and the separation, and divide the result* (as in the last case) *by the sum of the focus of the negative lens and the separation, after having subtracted the focus of the positive lens from this sum.*

[Note the importance of the separation as affecting the equivalent and back foci. If, instead of making the separation $3\frac{3}{4}$", we had chosen $\frac{1}{4}$ of an inch more—*i.e.*, 4"—the equivalent focus of the lens would be 18", and the back focus 6" only; and if, on the other hand, we had made the separation $\frac{1}{4}$ of an inch less, or $3\frac{1}{2}$", the equivalent focus becomes 36", and the back focus 15". If the sum of the focus of the negative lens and the separation is equal to or less than the focus of the positive lens, then no focus is formed.]

It is interesting to examine the capabilities of combinations by the above rules, and thereby to determine for one's self the suitability of the ratio that must exist between the foci of positive and negative lenses for any particular purpose. The separation between the nodal planes of the two elements is easily *written* for this purpose, but in practice is more difficultly measured.

The object of this paper is to place the matter in the simplest light possible, and happily there is a simple means of setting to work without any fear of mistake as to the conditions under which the instrument is used.

It reats on the determination of the *magnification* of the image *as compared to the positive lens used alone.*

Calling M the magnification, v *the back focus*, and f^1 the focus of the negative lens:—

$$M = 1 + \frac{v}{f^1}$$

in the particular case

$$M = 1 + \frac{9}{3} = 4$$

So that, calling F the equivalent focus and f the focus of positive lens as before,

$$F = f M$$
$$= 4 \times 6''$$
$$= 24''$$

as illustrated in the diagram.

Rule III.—To FIND THE MAGNIFICATION for any chosen extension of camera: *Divide the distance from negative lens to screen by the focus of the negative lens, and add one.*

Rule IV.—To FIND THE EQUIVALENT FOCUS of the combination for any chosen extension of camera: *Multiply the focus of the positive lens by the magnification.*

Having readily determined the magnification, as also equivalent focus for a given extension of camera, the next step is to find the intensity of the tele-photographic combination. This is measured by the clear aperture of the positive element divided by the equivalent focus, as in all cases. The intensity values or their equivalents are now always marked upon the diaphragm notation of positive lenses, so that the intensity of the compound system is most readily determined by reference to the intensity of the positive system and the magnification. It is expressed thus:—Calling I the intensity of positive lens and M the magnification as before,

$$\text{Intensity of system} = \frac{I}{M}$$

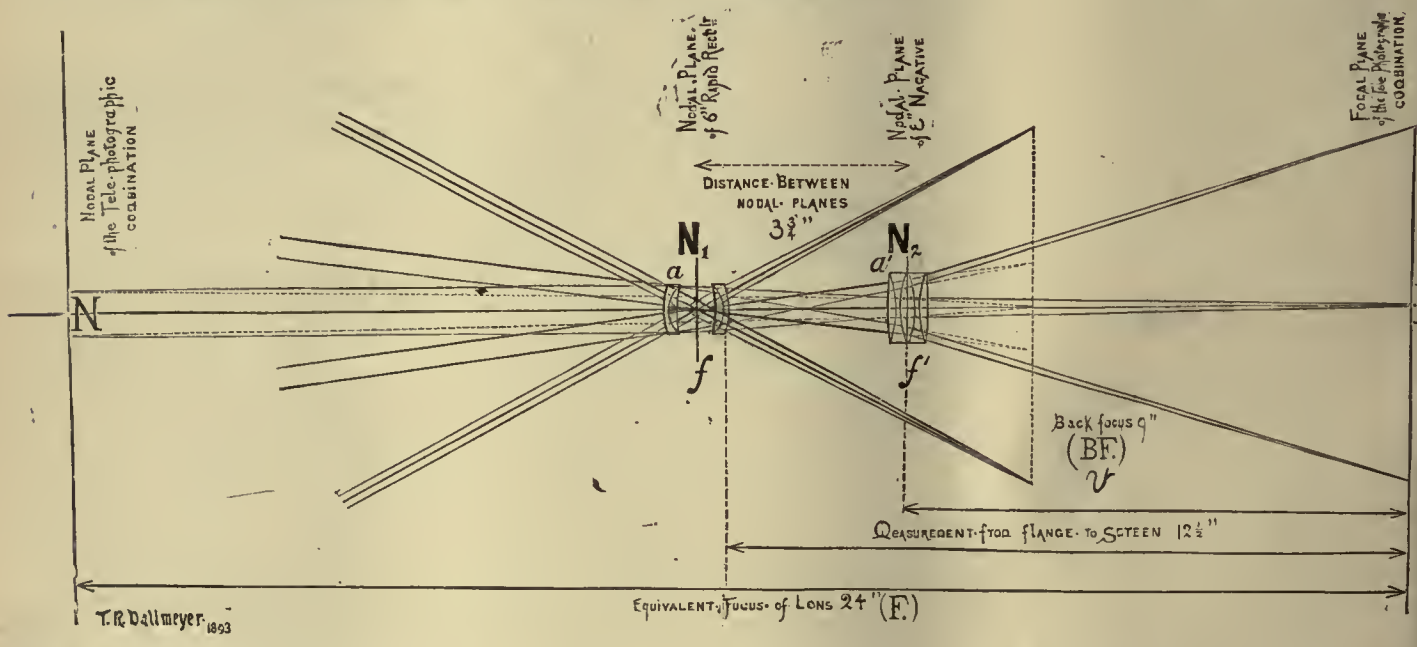
in the particular type of case illustrated;

$$\text{Intensity} = \frac{\frac{1}{8}}{4} = \frac{1}{32}$$

In the actual example illustrated, the intensity of the rapid rectilinear is *f*-7, and the intensity of the tele-photographic system *f*-28, for the particular extension.

[Note.—With less magnification and less camera extension, the intensity increases.]

Rule V.—To FIND THE INTENSITY for a given extension of camera when magnification is known: *Divide the intensity of positive lens by the magnification.*



Simple rules cannot, unfortunately, be given for the remaining two data that should be known to fully determine the capacity of the lens system—viz., the plate that can be covered and the extreme angle included—but the formulæ to obtain them are readily used.

I give them applied to the case illustrated.

(1) To DETERMINE THE DIAMETER OF THE PLATE COVERED:—

Calling D the diameter of the plate,
a the full aperture of positive lens $\frac{1}{8}$",
a^1 " " negative lens $\frac{5}{4}$",
and v, as before, the back focus, 9",

$$D = (v + f^1)\frac{avf^1 \times a^1 f\,(v \times f^1)}{f^1[v(f - f^1) \times ff^1]}$$
$$= (6 \times 3)\frac{\frac{1}{8} \times 9 \times 3 \times \frac{5}{4} \times 6 \times 12}{3[9 \times 3 \times 6 \times 3]}$$
$$= 12 \times \frac{113\frac{5}{8}}{3 \times 45} = \frac{909}{90} = 10{\cdot}1''$$

Thus it appears that with an extension of 9" from negative lens to screen, a circle of 10" is covered at full aperture—nearly sufficient to cover a "whole plate." In the diagram I have indicated the lens as covering only the diagonal of a 5×4 plate, but it will be seen that half of the whole pencil incident upon the front of the positive lens is received by the extreme margin of this plate. To find the covering power for any smaller stop inserted in the positive lens, it is only necessary to measure its diameter and substitute its value in place of a in the formula given.

(2) The extreme angle included by the combination is given by the following formula:—

Calling a the angle, and F the equivalent focus, as before,

$$a = 2\tan^{-1}\frac{D}{2F}$$

$$= 2\tan^{-1}\frac{10{\cdot}1}{48} = 2\tan^{-1}{\cdot}210416$$

From the table of natural tangents we find tan 11° 53″ = ·21043, and hence the extreme angle that can be included is 24° nearly.

When the lens is used to its utmost limits, it will be found that the angle included is approximately a constant for any extension of camera, *i.e.*, with a fixed aperture of the positive element.

It may be well to point out, in reference to the diagram, that a back focus (measured from the negative lens to screen) of only 5½″ is really necessary to cover the plate indicated (viz., 5×4) if full aperture be used.

To work the matter out practically, we have for this a back focus of 5½″. The magnification $M=1+\frac{5\frac{1}{2}}{3}=2{\cdot}8$, and the equivalent focus $F=M\times f=2{\cdot}8\times 6=17''$.

$$D=(v+f^1)\frac{avf^1+a^1f(v+f^1)}{f^1[v(f-f^1)+ff^1]}$$

$$=(\tfrac{1}{2}^1+3)\frac{\frac{7}{8}\times\frac{1}{2}^1\times 3+\frac{5}{4}\times 6\times(\frac{1}{2}^1+3)}{3[\frac{1}{2}^1\times 3+18]}$$

$$=\tfrac{1}{2}^7\times\frac{1251}{24\times 69}=\tfrac{1}{2}^7\times\frac{139}{8\times 23}$$

$$=\frac{2363}{368}=6{\cdot}4,\text{ the diagonal of a } 5\times 4 \text{ plate.}$$

Further the angle taken in is—

$$2\tan^{-1}\frac{D}{2\times F}\,2\tan^{-1}\frac{6{\cdot}4}{34}=2\tan^{-1}{\cdot}1882.$$

And, from table of natural tangents, tan 10° 40′ = ·1883, and thus the angle included is 21° nearly.

I have given a formula for the distance from the *flange to focussing screen* in my paper before the Society of Arts (published March 3rd of this year), but have not given it here, as the "back focus" is most readily measured, and this measurement, as already pointed out, is the simplest cue to all further information that is desired or necessary.

I hope that the very unpopular "formulæ" contained in this paper may not detract from its interest to the ordinary reader, for the formulæ are *readily interpreted* by any one with a knowledge of arithmetic.

In conclusion, I may add that the effect of the form of negative lens adopted is one that tends, by its moderate power, to flatten the field of ordinary aplanatic lenses without introducing "reverse" curvature; it minimises the tendency, in tele-photographic systems generally, to introduce pincushion distortion, it eliminates the violent chromatic fringes brought about by negative lenses of the double concave type, and diminishes the astigmatic aberration in the eccentrical pencils.

T. R. Dallmeyer, F.R.A.S.

CONTINENTAL NOTES AND NEWS.

Clearing Negatives Developed in Impure Water.—M. E. Forestier, in *L'Amateur Photographe*, says that the quality of the water used in making up developing solutions is not always irreproachable, which causes the lights and half-tones of a negative to have their transparency degraded. In order to remove this veil, he recommends that the plate, after fixing and washing, should be immersed in a solution of—

Water	1000 c.c.
Oxalate of iron	20 grammes.
Alum	80 „

This clears the negative, which should then be well washed.

The Fluorides of Sodium and Potassium for Stripping Purposes.—These two salts, which are prepared by saturating commercial hydrofluoric acid with sodium or potassium carbonate, take the form of white crystals, easily soluble in water, and present no danger in handling them, while they form excellent substitutes for hydrofluoric acid, which requires to be used with considerable precaution. The alkaline fluorides in the presence of an energetic acid, such as sulphuric acid, set free hydrofluoric acid, the alkaline sulphate being formed at the same time. Taking advantage of this reaction to produce a trace of hydrofluoric in a film of gelatine attached to a glass plate, the gelatine will be found to leave its support with as great facility as if hydrofluoric acid were employed. To produce the minute quantity of hydrofluoric acid necessary for the operation, M. L. Mathet says he first places the plate in a solution of alkaline fluoride, leaving it therein for three or four minutes, then, without washing, immerses it in a ten per cent. sulphuric acid solution, when the film will soon commence to regularly detach. He suggests that the plan would be available for cleaning off old negatives. In order to prevent the film, when detached, from expanding, the negative, before being stripped, should be soaked for about an hour in a five or six per cent. solution of chrome alum, being afterwards washed in several changes of water before the application of the fluoride and sulphuric acid.

The Boiling Water Reducer.—A writer in a contemporary advises the immersion of over-toned prints [presumably albumen, although it is not stated] in boiling water until they have toned back sufficiently. The prints are then placed in cold water.

Toluol Matt Varnish.—Toluol is a product of the distillation of coal, from which it is obtained at a temperature of between 100° and 130° C. It is analogous to benzine. According to Lainer the following formula with toluol gives a good matt varnish:—

Ether	100 c.c.
Sandarac	100 gr.
Toluol	350 to 400 c.

The powdered sandarac is dissolved by agitation in the ether, and, after filtration, the toluol is added. The varnish is employed in the usual manner.

Photography without Light.—Captain Colson states that in a picture on albumen paper of a bronze object, such as a coin, can be obtained by moistening the paper and placing the coin in contact with the surface, a reduction of silver takes place, and in a few minutes an impression similar to that producible by light is obtained, which may be toned and fixed.

Flexible Glass.—The following is the formula given by *Science Illustrée* for a flexible substance as transparent as glass. Dissolve four to eight parts of pyroxyline in alcohol and ether in the proportion of a one per cent. solution. Then add two to four per cent. of oil of rice or any other non-siccative oil, and four to ten per cent. of resin or Canada balsam. Coat a plate of glass, and dry in a warm current of air at 50° C. This will give a sheet of a durable, unbreakable, transparent substance, impervious to acids and alkalies, and less inflammable than ordinary collodion, and of any desired thickness or colour. With zinc oxide it has the appearance of artificial ivory.

A Very Rapid Collodion Process.—Having experimented with Dr. Hill Norris's process, which was patented some four years ago, without obtaining satisfactory results, M. P. David, of the Service d'Identification de la Préfecture de Police, Paris, has introduced some modifications of his own, and gives the following method of preparing a dry-collodion plate of a sensitiveness about 22° or 23° Warnerke. He coats a plate, 180×240 cm., with 25 c.c. of collodion, containing eighteen grammes of silver nitrate and seven to eight grains of pyroxyline per litre. The film being set, the nitrate is bromised in a bath of

Potassium bromide	80 to 120 grammes.
„ iodide	0 01 „
Gelatine	2 „
Distilled water	1000 c.c.

Sensitiveness is obtained by immersing the plate for a greater or less time in a solution of

Potassium bromide.....	18 to 25 grammes.
Gelatine	1 "
Distilled water	1000 c.c.

The sensitiveness increases with the temperature of the bath. At 70-75° the plate is left in for about two hours, at 90-95° for one hour. The figures are, however, approximate. The plate is then washed and dried. Contrary to what might have been supposed, says M. David, the collodion film does not show any tendency to leave the support even at a temperature of 100° C., provided that the surface of the glass has been carefully prepared.

No more Double Exposures.—For the modest sum of three francs a Bavarian gentleman undertakes to impart particulars of a method whereby the amateur may discover whether a plate has been exposed or not, and this without impairing the original quality of the plate. They should render impossible the oft-accomplished feat of "securing thirteen pictures on a dozen plates." The catchpenny trade is always with us, it seems, even in photography.

Black tones in Ferro-prussiate prints.—A contemporary says that ferro-prussiate prints acquire black tones by treatment with a solution of silver nitrate followed by development with iron oxalate. The print fixed and washed as usual is placed in a solution of silver nitrate, in which it is left until it has bleached, when it is placed in the developing solution. If, after development, it is placed in a solution of hypo, the black tone will tend to disappear, passing back to the blue stage. Thus, with a little care, a print may be obtained, in which the deep shadows are black, while the half-tones are blue.

PHOTOGRAPHIC INDUSTRIES.

The Lantern-slide Factory of F. York & Son.

It was our privilege, on returning home from the Photographic Convention at Plymouth, to be permitted to break the journey to visit a very important photographic industry, of which a brief account will interest our readers.

Very few there are who are not more or less intimately acquainted with the lantern slides, either individually or in series, so well and so long associated with the name of F. York & Son, of Notting Hill, London; but it is not equally well known that these slides are produced in the town of Bridgwater, Somersetshire, for here is situated that factory from which emanate in hundreds of thousands those little gems of art whose function it is to delight, instruct, and amuse.

It is no figure of speech to say that more slides are issued from the offices and distributing centre of this firm at 67, Lancaster-road, London, than from any other centre of operations in the world; and even several years ago, when writing some notes of a visit to this distributing centre of the firm, we spoke of their negatives and output as being measurable by the ton weight; but since that time these have been very greatly increased. Some years have now elapsed since, with a sentimental regard for his native town, Mr. F. York decided upon selecting it as his place of manufacture.

Under the guidance of the veteran chief, whose wonted energy does not seem in the slightest degree to be impaired, and his resident local manager, we have been privileged to inspect the whole of the Bridgwater factory and witness the various operations there carried on. Mr. York himself was, nay, still is, a great traveller, and, when he visits scenes or towns either at home or abroad, he rarely terminates his visit without carrying away with him negatives representing every salient feature of the locality thus visited, whether such be in the West India Islands, Monte Carlo, and other Italian towns, or even places of equal or greater merit, although of less distinction at home, such as those selected for Convention meetings. His camera and his aim are true; he selects his subjects by instinct, and, while having a pardonable love for the civic palaces now to be found in every town of any pretensions, still he is not averse to

> "Loiter by the peasant's cot,
> And pot it with unerring shot."

The Bridgwater factory occupies two houses in a quiet street, with out-houses erected in their gardens behind.

We first visited the negative room. This is a fireproof structure, strongly built and slightly isolated from the other buildings. Humanly speaking, there seems no chance of the valuable contents sustaining damage from fire. These are arranged in boxes on shelves around the walls, the numbers on each corresponding with those in the catalogue of negatives in the possession of Mr. King, the manager; so that, when an order from any subject is received by letter or telegram from headquarters, he can, by referring to his negative catalogue, lay his hand at once upon the package in which the required negative is contained, and to which it is immediately returned when done with.

The only kind of glass used is Chance's Crown, which York & Son find to possess certain advantages over others in respect of brilliance of surface, flatness and freedom from certain defects, which, although small to the eye, are visible in a marked manner when the picture is shown on a scale of great magnification on a fifteen or twenty foot screen.

The negatives in most cases are taken on 5 × 4 plates and, as we have said, there are many thousands of these in stock, for during the twenty-five years that this business has been carried on the number has been ever constantly increasing. The process of reproduction is wet collodion, which is supplied mainly by two makers if we judge of this by the enormous number of large labelled bottles we saw in a repository of "dead men." The transparencies are all taken on plates seven and a half inches square, this being of the best quality supplied by Chance Brothers, of Soho, Birmingham, and already alluded to. Of this glass thirty gross per month are regularly supplied. There are four transparencies printed on each plate.

There are three dark rooms in which the plates are coated and developed. These, when coated, are sent by a lift into the room above, where they are exposed in cameras which point upwards to the sky. But, as even Somerset skies often vary in their brightness, the exposers above are in verbal communication with the developers below, who occasionally call out to give so many seconds less or more exposure to the next lot according as the light gets brighter or grows more dull. In the exposing room are four cameras with repeating backs, which slide both vertically and horizontally, and they are adjusted so as not to necessitate focussing. After exposure the plates are sent down for development and subsequent treatment.

When the rush of work or the darkness of the weather necessitates it recourse is had to artificial light. This consists of a kerosene lamp as a source of illumination, the light from which is concentrated upon the negative by a five-inch compound condenser, and is then transmitted through an objective to the sensitive plate, an average exposure of twenty seconds being given. As there are quite a number of these copying lanterns, the firm is rendered independent of the weather, seeing that work may be carried on by night as well as by day.

The developer employed is a ferrous-sulphate one, so prepared as to give the utmost clearness and gradation with purity of the whites. After being fixed in hyposulphite of soda, the transparencies—of which, as stated, there are four on the plate—are toned. It is no secret that a solution of a salt of platinum is the toning agent employed by York & Son. Seeing that platinum behaves in a whimsical and unreliable manner in the hands of many, bleaching in some cases and giving an exceedingly heavy and black image in others, investigations were long ago gone into by the firm, the result of which is that the platinum toning bath now and for some years employed is stable and reliable, its erratic tendencies being eliminated. In this lies the chief secret of the uniform tone, which is such a characteristic of York's slides that they can be distinguished from most others at a glance. The platinum toning also confers such stability, that we are not aware of any case of fading of the image ever having been known to occur with these slides. Varnishing follows toning, the varnish being a colourless spirit one.

The system adopted in severing the plate, which is seven and a half inches square, ensures identity in the four transparencies impressed thereon. After a considerable pile has been prepared, the examiner then takes them in hand, and unceremoniously rejects every transparency on which there is the slightest blemish, or which in any respect falls short of what in his estimation a transparency ought to be. Owing to the experience of the workpeople and the care taken throughout, the number rejected is but few, and these, after having had the films stripped off and being cleaned, are employed as cover glasses.

Concerning the mounting, it is not necessary we should describe it further than to say that starch paste is invariably used as the mountant. When gum is employed, it is found that, sooner or later, it ceases to adhere to the glass and leaves it. Each picture has its title printed in small type on a slip of paper, which is pasted on the edge of the finished slide. This is convenient for reference when a quantity are packed in

grooved boxes, as the subjects are thus known without the necessity of withdrawing them for inspection being experienced. It is also useful in selecting and arranging subjects for lectures or miscellaneous entertainments.

Some of the rooms are devoted to silver printing, and there is also a large carpenter's shop on the premises, for, as may be readily supposed, the packing and sending away of goods forms no inconsiderable item in the day's work of a busy establishment like this.

We have said that the factory is in Bridgwater, and may incidentally observe that the river on which this town is situated is the only one which supplies the material out of which "Bath" bricks (so called from the name of the originator of the industry of that well-known domestic article) are formed. Each tide deposits a large quantity of the sand suitable for the purpose for a mile above and a mile below the town. Beyond these extremes the deposit is either too fine or two granular for this industry. The finer deposits are, however, utilised in America and elsewhere in the manufacture of sapolio and kindred soaps.

Returning for a moment to York's lantern-slide factory, there were twenty-six hands employed at the time of our visit.

PHOTOGRAPHIC CONVENTION OF THE UNITED KINGDOM.*

The following paper was taken as read:—

ANASTIGMATIC APLANATISM AND THE ZEISS ANASTIGMATIC LENSES.

By Dr. Paul Rudolph (Jena).

[Translated from the German MS.]

The anastigmatic lenses of Zeiss made their first appearance scarcely two years ago; nevertheless, they have attracted the general attention of the photographic world, and, despite considerable adverse criticism, proved a great success. It would, therefore, be interesting to examine the special features to which these new objectives owe their popularity.

Over 7000 lenses have now been sold, and though there are still many professional photographers and amateurs who have not had an opportunity of testing the powers of the anastigmatic lenses from personal experience, it may be assumed that nearly every one has heard of them or has seen photographs produced by them. The Zeiss anastigmatic lenses are well adapted for portraits and groups, for copying and enlarging, for interiors and flashlight exposures, and for outdoor instantaneous photography, for architecture, landscape, and photogrammetric work.

Experts unanimously pronounce the Zeiss anastigmatic lenses to be superior to the older objectives, and praise their extensive range of applicability. We may refer to the respective writings of Koster, Faber, Wallon, Eder, Vogel, and others.

The following remarks are based upon the criticism of these experts, and, in particular, upon a paper read by me in March, 1892, in the Free Photographic Association of Berlin.*

The Zeiss anastigmatic lenses are dissymetrical doublets, consisting of an achromatic anterior part whose *flint* has the higher refractive index, and an achromatic posterior part in which the *crown* has the higher refractive index. These two cemented parts of the doublet possess, therefore, opposite differences of refractiveness in the crown and flint glasses employed for achromatisation.† This embodies the important principle by which it became possible to effect anastigmatic aplanatism of a system of lenses corrected spherically and chromatically for large apertures.

The series of new glasses produced about six years ago by the glass works of Messrs. Schott & Co., of Jena, rendered it possible to practically realise this principle in the construction of the Zeiss anastigmatic lenses.

Let n_f, n_c, n_d be the refractive indices of a certain glass corresponding to Fraunhofer's lines, F, C, and D, then the ratio $\frac{n_f - n_c}{n_d - 1}$ represents the relative dispersion for the interval C-F. With the older series of glasses this value increased in a measure as the refractive index increased, *e.g.*,

Crown of $n_d = 1{\cdot}5166$ had $\frac{n_f - n_c}{n_d - 1} = 0{\cdot}01643$.

Flint of $n_d = 1{\cdot}6129$ had $\frac{n_f - n_c}{n_d - 1} = 0{\cdot}02708$.

In order that the anastigmats may be constructed, it is, however necessary a range of glasses in which any given refractive index may be coupled with any desired dispersion. This postulate is realised, *e.g.*, by the following glasses made by Messrs. Schott & Co.

The sodium lead glass, flint $n_d = 1{\cdot}5205$ of relative dispersion, 0·01956.

The barium-silicate glass, crown $n_d = 1{\cdot}6112$ of relative dispersion 0·01747.

The refractive index of the former, viz., 1·5205, would, in the older series of glasses, necessarily imply a relative dispersion of 0·01700, while to obtain a refractive index of 1·6112 with the other glasses the relative dispersion would have to be about 0·02700, *i.e.*, sixty per cent. higher.*

All photographic lenses preceding the anastigmats had either a very much curved field, or, if flat, an astigmatic field. In the latter case the image was perfect in the centre, but the quality of the image declined towards the edge.

It may be useful here to define what is meant by a curved, flat, and astigmatic image.

Let the object be placed in a plane which is accurately vertical to the axis of the objective, or let all the object be at so great a distance from the objective as compared with the focal length of the objective, that the difference of the distances of the different objects may be neglected. Then *the field of an objective is* considered to be *curved* if different positions of the focussing screen are required for *sharply* focussing an object point in the axis (centre of the image), and an object point lying outside the centre of the image.

The whole of the older photographic lens types exhibit curvatures of the image, such as to necessitate the distance of the focussing screen being shorter for marginal points of the image than for axial points. The points of distinct delineation are, therefore, situated upon a curved surface, whose concave side is presented to the objective. Fig. 1 represents a section of the image surface, and a plane passing the axis of the objective. The dotted line *a* represents the ideal image plane, which intersects the axis in the axial image point, and is at right angles to the axis of the objective, while curve *b* represents the actual surface of the image.

Fig. 1.

The *field* is *flat* if the position of the *focussing screen* is *the same* for central and extra-axial points, *i.e.*, if the sharply focussed points are all contained in a plane which is at right angles to the axis of the objective, or if these points lie in the ideal plane of the image.

The image is *astigmatic* if sharp images of *lateral*, *i.e.*, extra-axial, *points* may be obtained by *two different* positions of the focussing screen. The two images are not exactly similar to the object; one of them shows distortions in the direction radiating from the axis (radial distortion), while the other exhibits distortions in the directions at right angles to the radii (tangential distortion). This fact may easily be demonstrated by means of an "aplanatic" lens, say, by using a small circular disc having a diameter of only a few millimetres situated *outside* the axis and attempting to sharply focus it. With the nearer position of the focussing screen, the image of the disc appears as a radial line of a breadth proportional to the diameter of the disc. With the longer distance of the screen, the image is an arc of a circle concentric to the axis of the objective (tangential distortion). The lengths of the radial and tangential portions of a line are essentially dependent upon the difference of the two positions of the screen, and increase continuously from centre to margin in the case of the "aplanatic" lens. With objectives yielding astigmatic images, there are thus two image surfaces conjugate to one and the same object plane. These two image surfaces touch each other in the axial image point, and the distance between them increases continuously from centre to margin. "Mean curvature" may be defined as that surface which represents the arithmetical mean of the deviations of the two image surfaces from the ideal surface. The dissimilarity between the details in the two image surfaces *inter se*, and the original increases from the centre to the margin. The following is an interesting experiment:—

* *Photogr. Wochenblatt*, Berlin, 1892, Nos. 18 to 21.

† "Crown" and "Flint" are here placed in opposition, not with respect to their chemical composition, but are considered with respect to their *optical properties*. The same glass may, therefore, appear in two different achromatic combinations as lenses, either as "Crown" or "Flint" (*vide* Eder's *Jahrb.*, 1891, p. 221., Rem.). In the following remarks "Crown glass" is always understood to refer to that glass of a binary lens, which is less in *relative* dispersion, while the term "Flint glass" refers to that glass which has the greater *relative* dispersive power. Relative dispersion is the value represented by the expression $\frac{\Delta n}{n-1}$, Δn being the difference of the refractive indices for two lines of the spectrum, as a refractive index within these limits.

* Refractive and dispersive power was, with the older glasses, dependent upon each other in a certain manner. If n_d and $\Delta n = n_f + n_c$ were respectively made to represent abscissæ and ordinates, the points so represented formed a fairly straight line inclined to the axis (*vide* Dr. J. Czapski, "Optical Lenses," *Zeitschrift fuer Instrumentenkunde*. Berlin, 1886, pp. 344 and 345); n_d was, therefore, a linear function of Δ_n or—

$$n_d = a + C\,\Delta n$$

Arrange in one plane (fig. 2), along the radii of concentric circles, bright discs. The angles between the radii should be chosen according to the astigmatic aberrations and the focus of the objective. Direct the axis of the objective at right anglea towards the centre of the system of radially grouped discs, and focus one of extra-axial discs. The image obtained at the shorter diatance of the focussing screen from the objective is, as fig. 3 shows, a portion of a radial line which, in proportion to the curvature of the image plane, becomes more and more indistinct towards either side, and is more or less interrupted radially in proportion to the degree of astigmatic deviation. Fig. 4 is an image obtained by focussing a disc on a circle, situated midway between the axis and the outside circle. It will be seen that images of all the discs grouped along the same circle are of the same degree of distinctness or indistinctness, and also exhibit the same amount of distortion.

Focussing at the greater distance of the screen shows the object (fig. 2) tangentially distorted. The image becomes thus composed of a series of circles concentric to the centre of the image, which are more or less

Fig. 2. Fig. 3. Fig. 4.

interrupted, or perfectly uninterrupted. The discs grouped along another circle, which had not been sharply focussed, are similarly distorted, though in a less marked degree.

If, now, a screen having drawn upon it concentric to the axis of the objective circles and radii be substituted for the system of discs, the astigmatic objective would reproduce the original with partial similarity, but both systems of lines could *not simultaneously* be delineated with the same position of the screen. The shorter distance would yield sharpness of the radial elements, the circles at the same time being badly defined; the longer distance would show the circles sharply, and at the same time the radial elements badly defined.

A sufficiently large screen bearing the two systems of lines, radial and concentric circular lines, appears thus to form the most natural test for astigmatism. Such a screen would, however, be too uniform and too little adapted for exhaustive tests.

The screen of 2×2 metre area, as it is used in the photographic laboratory of Carl Zeiss of Jena, is for this reason arranged somewhat differently, and it may not be uninteresting to here give a short description of it. Upon strips of paper of 18×21 in area two systems crossing each other at right angles of parallel lines of varying thickness, and placed at varying distances from each other, and the strips themselves are fixed to the screen with one of their ends at the centre of the screen, and their sides parallel to the sides of the screen in such a manner that in each strip the radial and tangential lines alternate. The middle of the screen contains a field consisting of rectangular cross lines, which is intended for testing sharpness of definition. The tangential parallels form substitutes for the system of concentric circles, while the radial parallel lines take the place of the radii proceeding from the centre. The difference between the two positions of the focussing screen for sharp delineation of the marginal portions of the systems of straight lines represents the astigmatic difference. For the purpose of demonstrating the incorrectness of the image caused by astigmatism, the screen has square fields of more or less fine rectangular cross lines diagonally attached to it in such a manner that in one case the system of lines is parallel and at right angles respectively to the diagonal, while in the other case they are inclined at 45° to the diagonal. The screen has also samples of writing and printing attached to it.

When focussing square cross lines at the edge of the image, the astigmatic objective produced in the two characteristic cases furnished by the test screen the following deformations:—

1. The straight lines composing the net at the edge of the image are parallel and at right angles respectively to the direction of the radial lines.

In this case—represented by fig. 5, in which A is the point of intersection of the axis of the objective and the plane of the object, A′ that of the axis and the plane of the image—sharp focussing of the tangential lines causes the lines which are at right angles to the radius to appear nearly sharp, while the lines which are parallel to the radius are almost entirely invisible (image *a*). Focussing of the radial lines produces the converse of the last test. The lines parallel to the radius appear sharp, the lines at right angles to it disappear (image *b*). Mean focussing results in a totally ill-defined image, and eventually in more or less marked reversion of the cross lines, such as a black net in a white field.

2. The straight lines of the net are inclined at 45° to the radial direction. In fig. 6 let A and A′ again be the point of intersection of the objective axis with the plane of the object and image respectively. Tangential focussing causes the rectangular cross lines to be distorted so as to present the appearance of tangentially elongated hexagons, and, in the

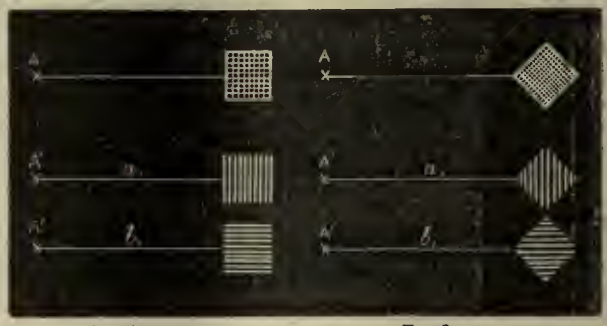


Fig. 5. Fig. 6.

case of great astigmatic difference, it may result in almost precise commutation of the cross lines into a *single* system of tangential lines (image *a*, fig. 6).

If we focus between these two limits, the net may, similarly as above, eventually be reversed so as to appear as black points in a white field; the same effect may also be produced in anastigmatic images by unsharp focussing. Similar results of a more or less marked character may be obtained by replacing the quadratic net by one formed of oblongs, rhombi, circles, &c.

In order that these relations might be objectively fixed, photographs were taken in the photographic laboratory of the optical works of Carl Zeiss of the test screen, and the photographs so obtained were reproduced by photo-lithography. There are four plates, of which we show the two most characteristic ones, Nos. I. and IV. (shown). Here an "aplanat" and "anastigmat" are subjected to direct comparison Plate I. has been taken with an "aplanat," made by a renowned firm. The objective had a focal distance of 14 cm. and a relative aperture of 1·6, and was stopped down to *f*·12·5. Image and object are in the ratio of 75 to 1000, and the angle subtended by the object is about 67°.

The centre of the screen is sharply focussed. In this part the delineation is extremely good, a sufficient proof that the objective, *per se*, was a good specimen of its kind. As the margin is approached, the definition, however, loses more and more in distinctness, and astigmatic distortion increases more and more. While the tangential lines are fairly sharp up to the edge, the radial lines rapidly decrease in definition past the third field. In the diagonal squares, the bounding lines of which are at right angles and parallel respectively to the radius, it will

Fig. 7.

be noticed that the tangential lines are markedly sharper than the radial lines, the latter being almost invisible, and in the squares, whose sides are inclined at 45° to the radial direction, the distortion at the margin of the tangential lines may readily be observed. The squares appear, in fact, as hexagons.

Plate IV. has been taken with a Zeiss anastigmat, viz, anastigmat 1·6·3, 14 cm. focus, all other conditions being the same as those existing in the former case. There, too, the centre was accurately focussed; but barely any traces of those details which point to astigmatic imperfections of the margin of the image will be noticed.

Plates II. and III., which are not shown here, were taken with the

same "aplanat" as that used for Plate I. In the first case the tangential marginal lines were focussed, in the second case the marginal radial lines formed the critical part of the object. While in the former case the centre appeared to be fairly sharp, in the latter case it was totally worthless. The characteristics of astigmatism, as above explained, become apparent in both plates.

The older types of lenses (aplanatic, antiplanats, portrait lenses, single lenses, &c.), admitted of astigmatic correction, but they could not at the same time be corrected for flatness of field. The Zeiss "anastigmat" was the first lens in which, as we pointed out, anastigmatic aplanatism was combined with the realisation of other requisites of a good photographic lens.

A lens having *anastigmatic curvature* yields sharply defined points from centre to margin. These cannot, however, simultaneously be fixed upon the *plane* negative plate of the photographic apparatus whenever the points constituting the object are nearly in one plane at right angles to the axis, or when they are at a relatively great distance from the objective. If it be desired to simultaneously fix these sharp points upon the plate, it would be necessary to use a *curved sensitive surface* corresponding to the curvature of the image. Clearly the use of such curved sensitive strata is impossible, for it must not be forgotten that for each lens type, each focal length, and even each degree of magnification or reduction, there is a distinct corresponding curvature, to say nothing of the practical inconvenience attaching to curved photographic plates. At present we are, at any rate, limited to flat negative plates. From an optical point of view, this is an undesirable limitation, which seriously affects definition and depth of the curved image.

The flat plate must be covered nearly uniformly sharply from centre to edge, unless the objects are grouped on a curved surface corresponding to the curvature of the image. With portrait groups photographers had a means of compensating the anomaly by arranging the persons in a semi-circle, in the centre of which the objective is placed. With landscape and instantaneous photographs, however, such an expedient is only rarely, if at all, applicable. In order to obtain tolerable distinctness in the image from centre to edge, it would be necessary to work with narrow angles or to stop the lenses down considerably.

In working in this manner, it must be borne in mind that both in the centre and at the edge near and far objects are to be depicted simultaneously; the objective yielding a curved image causes, however, on the photographic plate distinct objects to appear indistinct, and sufficiently near objects sharp at the edge when the focussing is sharp for the centre. On the *oblong* flat negative plate, A B C D (fig. 7), let near objects be depicted at AB, distant objects at CD; then, if the *centre*, M, be accurately focussed, the points of sharp delineation are situated upon a curve, and are represented by E, which intersects A B in two points, and is symmetrical with respect to A B. By stopping the lens down we obtain, as is well known, greater depth for distant objects than when focussing for near objects. In the present case the depth necessarily diminishes, therefore, from the centre to the margin. The limits may be graphically represented by curves, T_1 and T_2, which, being symmetrical with respect to E, have their greatest distance apart at M. The depth of focus is represented by the area contained between T_1 and T_2. By this area the imperfections of the marginal image may readily be ascertained. When it is important to improve the distinctness at the edge, it would be necessary to sharply focus a point situated at a distance from the centre, and to sacrifice the distinctness at the centre.

The deficient depth of focus of lens yielding a curved image does, under certain conditions, not become apparent in street scenes. In such cases it may happen that the position of the camera is such that the rows of houses are delineated simultaneously on both sides of the street, the distant houses being thus shown in the centre, the near ones at the edges of the plate. In such a case the curvature of the image may even become the very cause of greater marginal distinctness than is obtainable with the flat field. With all other, and nearly always existing, cases distant objects have to be shown simultaneously at centre and edge, and in such cases it is absolutely necessary to have a flat field.

It is possible to partly flatten the field of the aplanat. This is most conveniently done with those points of the image which are due to the meridional rays, *i.e.*, for the tangential directions in the image. Under these circumstances, one would, however, have to abandon the anastigmatic correction of the image, and to rest content with partial distinctness. These points of the image which are due to rays contained in a sagittal section yield another image surface (image points of radial directions), which touches the former surface in the axis of the objective, and deviates from it with continuous curvature towards the edge, as already explained.

With angles of 50° this deviation amounts to one-fifteenth; with 70°, to one-sixth; and to 90°, even nearly one-third of the focal length of the lens. The section of these image surfaces by a plane passing through the axis of the lens would present the appearance shown in fig. 8. Curve *a* appertains to the image points in the meridional section (tangential distortion), *b* to those of the sagittal section (radial distortion). H_o represents the axis of the lens H_n a principal ray.

This result may be obtained with aplanatic lenses if their halves be sufficiently widely separated. The marginal distinctness is then very

FIG. 8.

FIG. 9.

defective, and the stopping down has to be carried very far if it is at all desired to obtain sharp definition at the edge or fair definition extending over a considerable field.

An objective having an anastigmatically flat field, such as the "anastigmat" produces, however, a sharp image upon the flat plate, which, as fig. 9 shows, is bounded by lines T_1, T_2, the latter being parallel to the focussing line E. This objective delineates near and distant objects with the desired uniform sharpness and centre at edge.

The Zeiss anastigmats yield, therefore, a uniform depth of focus from centre to margin without necessitating the same amount of stopping down that is imperative with the "aplanats." *The anastigmats have in proportion to their covering power a considerably relative rapidity.*

A paper read by the author in the Free Photographic Association at Berlin was accompanied by two instantaneous photographs reproduced by the lithographic process, which served for comparing the "anastigmat" with a normally corrected "aplanat." The two lenses used in the tests had the same maximum aperture, and were stopped down to 1-9. The anastigmat 1-6·3, $f=21$ cm., gave a circle of 25½ cm. diameter of fair definition (62½°), while with the aplanat 1-6 of 20 c.m. focus stopped down to 4-9 the same circle of 11 c.m. at most (31°). The aplanat,* which was the make of a renowned firm, was in itself a good specimen, the definition being excellent in the centre.

In order to obtain with the aplanat a sharp image of the same extension it would have been necessary to stop the lens down to about *f*-36, and thus to seriously diminish its rapidity.

Professor Roster, of Florence, who, in his own interest, subjected the anastigmats to exhaustive practical tests, found that the anastigmats, with a given angle, admit of five to eight times more rapid exposures than aplanats and antiplanats of best make.

Dr. Chinaoli, of Ravenna, speaks equally favourably of the anastigmats, and Professor Fabre, of Toulouse, writes, in his *Aide-mémoire* of 1891, "The anastigmat is eleven times more rapid than the comparable objectives of older types."

The author himself compared an anastigmat 1-6·3 $f=170$ mm., with an excellent specimen of the *aplanat* 1-9, $f=145$ mm., and found that the *anastigmat* covered the test screen of Zeiss with almost the same degree of definition that could be obtained with the *aplanat* working at *f*-32, *i.e.*, the anastigmat working at 1-6·3 with a *twelve times greater rapidity* than the aplanat 1-9 was found to do the same as the latter. Owing to the better concentration of light in the anastigmatic flat image, as compared with the anastigmatic curved or astigmatic flat image, with an objective of the former type, the intensity necessarily diminishes less from centre to edge than a lens belonging to either of the last-named types. This advantage of the Zeiss anastigmats cannot be overrated, as the oblique incidence of rays at the edge of the image is, in itself, productive of a continuous diminution of intensity towards the edge. The anastigmats yield a negative which is *uniformly exposed* from centre to margin. The advantages resulting from the anastigmatic flatness of field greatly extend the range of applicability of these lenses.

The advantage of being permitted to use a large stop when a certain size of plate is prescribed, and the advantage of the uniformly bright

* By "aplanat" we understand the well-known type of symmetrical doublets of four lenses introduced by Steinheil. Previous to the invention of the anastigmats, it was the best type, and appeared in the market under many names, such as aplanat, eurycope, rectilinear, symmetrical, lyncéinoscope, paraplanat, &c.

field, assists in the solution of the problem of using short focus lenses for relatively large plates; *i.e.*, with a given rapidity of the objective, essentially shorter foci may be used in the case of anastigmatic lenses than is admissible with other types, *e.g.*, anastigmat 1-6·3 (Series II.), of a focus of 105 to 120 mm. is *quite* sufficient for sharply covering a plate 9 × 12 c.m. (3½ × 5 inches) at *f*-9; with the older types, the focus would have to be 120 mm. (7½ inches) at least. In order to cover 13 × 18 cm. (5 × 7 inches) at *f*-9, it was necessary to employ a lens of, say, 350 mm. (14 inches) focus, whereas, with the anastigmats, this result may be obtained with a focus of 210 mm. (8¼ inches), and even with 170 mm. (7 inches). Short foci give, however, at equal distances of the object, a better depth than long foci; they yield a sharper image of objects situated at *different* distances from the position of the apparatus. The anastigmatic lenses have, therefore, in another sense, greater depth of focus than the older lenses.

These advantages become particularly apparent in instantaneous and wide-angle lenses, and in the photography of architecture and interiors, and in copying. Detective cameras may be made of smaller dimensions, as they may be fitted with short-focus lenses. Photographs of architecture and interiors, and reproductions of maps and paintings, may be taken by means of rapid lenses, *i.e.*, at short exposures.

The tables published by the author in *Eder's Jahrbuch*, of 1893, in his paper on "The Astigmatism of Photographic Lenses," which are based upon calculation, show the extent to which anastigmatic flatness has been obtained with the *various* series of the anastigmats.

TABLE I.

Mean Deviations of Image Curvature for Objectives at 100 mm. Focus.

Objectives.	Deviations for Inclinations of a Principal Ray of—						
	10°.	15°.	20°.	25°.	30°.	35°.	40°.
	mm.	mm.	mm.	mm.	mm.	mm.	mm.

Aplanat 1-7	+0·8	+2·0	+4·0	+7·0	+12·2	+19·4	—

Table I. shows the deviations of the mean curvature of the various anastigmats for every interval of 5°. The table gives also the corresponding value for an aplanat of relative aperture 1-7, as it may be interesting to directly compare the correction of this hitherto best type of lenses with the Zeiss anastigmats.

Table II. gives the astigmatic deviations. The figures are reduced to a focus of 100 mm.

These two tables suffice to give an adequate idea of the correction of the anastigmats. Studying them more closely, we find that the long-focus lenses at the series 1-18, the typical copying lenses, are at the head of the table. In computing these lenses, the greatest possible pains were taken to render anastigmatic flatness as perfectly as possible without in the least neglecting accurate spherical correction.

The greatest deviation of the mere curvature in an objective of 100 mm. focus of this type, with an inclination of a principal ray of 30°, *i.e.*, with a field of 60° is 0·5 mm., and the astigmatism 0·6 mm., amounts which may be practically neglected.

Next to this type comes the anastigmat 1-9, which, up to 70° of field (35° inclination of a a principal ray), has a maximum deviation of curvature of 1·2 mm. and a maximum astigmatic differerence of 0·5 mm.

After these come the shorter focus lenses of anastigmat 1-18, anastigmats 1-6·3, 1-12·5, 1-4·5, and 1-72.

The aplanat 1-7 has up to 30° a deviation of curvature of about 1 mm., while with the more rapid anastigmat, 1-6·3, it is only 0·6 mm. The former has 12·2 mm. astigmatic difference, the latter only 3·6 mm., *i.e.*, less than one-third of that amount. The difference is still greater with wider angles.

In conclusion, the other advantages which the Zeiss anastigmats combine with anastigmatic flatness may be shortly enumerated. They are the following:—

1. The reflection images have a most favourable position.
2. They admit of the most colourless glasses being used, and
3. The two parts of the doublet are in close proximity.

The images formed by reflection at the boundary surfaces between glass and air are all at a considerable distance from the plane of the image. By this means the appearance of fogged images, which generally increases with the number of isolated lenses, is reduced to a minimum, and thereby the image rendered exceedingly brilliant.

The existence of this property is amply proved by photographs taken with the anastigmatic lenses.

None of the anastigmatic lenses can be shown to have a *flare-spot*, even when dazzling light enters the objective.

The use of colourless glasses is an advantage which cannot be overrated. Apart from sensitive plates, this is the only means of satisfying the universal postulate, *depth of definition with short exposures.*

With objectives of the same type, a certain desired amount of depth can, with a given focal length, only be obtained by corresponding stopping down of the lens. The further, however, this stopping down is carried, the less becomes the light which can pass through the lens. If, in addition to this, the scanty light thus admitted is further impaired by detrimental colouring in the glasses, as was the case with the glasses formerly used in the construction of aplanats, it becomes naturally impossible to work at short exposures.

The anastigmats, when applied to outdoor photography at *f*-18 give fully exposed negatives, the usual commercial instantaneous dry plates being used. Before the application of the Schott baryta glasses to the construction of photographic lenses, this belonged to the province of impossibilities. Even with stops *f*-25 and *f*-36 instantaneous photographs are still obtainable.

The *short structure* of the anastigmats favours the *diminution of the rapidity with which the intensity decreases from centre to edge.* It diminishes that part of the decrease of the intensity which is caused by partial stopping of these oblique pencils by the edges of the lenses.

Let L_7 and L_2 (fig. 10) be the lenses forming a doublet of a diameter 2·D, let B be the plane of the diaphragm, and let the diaphragm be

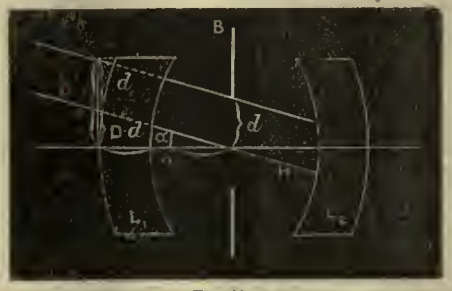

FIG. 10.

situated midway between L_1 and L_2. Let a be the distance of the diaphragm from the apex of the anterior surface, and let $2d$ be the diameter of the aperture of the diaphragm.

If for the sake of simplification the collective effect of the parts of the doublet be neglected, *i.e.*, if it be assumed that the diameter of the pencil passing through the diaphragm $2d$ is also $2d$ previous to the passage through the lens, and also if we disregard the curvature of the external surfaces and the thicknesses of the lenses, then the oblique pencil passing through $2d$ is stopped in that particular moment when the principal ray, H, is of that degree of obliquity which is represented by a straight line contained in a plane passing through the axis of the objective, and connecting the edge of the lens with the diaphragm edge on the same

side of the axis. Let the angle between this principal ray, H, and the axis be a, then it will easily be seen that $tg\,a = \frac{D-d}{a}$. This limit is increased in a measure as the difference $D-d$ increases, *i.e.*, In a measure as the aperture of the diaphragm d becomes less.

When $D-d$ is constant, then a increases in a measure as a decreases.

From this we infer: *The shorter the distance of the diaphragm from the extreme apices of the lenses, the later is the moment of the stoppage of oblique pencils by the edge of the lenses.*

The following table contains a few results derived by actual measurement of some of the best known lenses:—

When $D - d = \frac{1}{2} D$.
Or $d = \frac{1}{2} D$.

the double limiting scale, *i.e.* the field illuminated without stop, has the following values in the cases of the lenses so measured:—

Let $d = \frac{1}{2} D$.

Objective.	Greatest relative aperture of the objective.	Field without stoppage of pencils by edge of lens.
Busch Aplanat (No. 4)	1-8·5	31° 2′
Goerz Rectiplanat (Rap. Lync.)	1-6·5	33° 22′
Zeiss Anastigmat 1-4·5 ...	1-4·5	36° 40′
Euryscope IV. von Voightlander	1-6	38° 18′
Group Antiplanat von Steinheil	1-7 bis 1-6·5	40° 6′
Zeiss Anastigmat 1-6·3 ...	1-6·3	41° —
Goerz Landschafts Aplanat ...	1-8·5 bis 1-9	44° 14′
Zeiss Anastigmat 1-7·2 ...	1-7·2	45° 15′
Zeiss Anastigmat 1-9	1-9	50° 6′
Zeiss Anastigmat 1-12·5 ...	1-12·5	58° —
Zeiss Anastigmat 1-18 ...	1-18	58° —

According to this table, Busch's aplanat is last in the order of excellence. It has, with relative aperture of 1-8·5, an unstopped field of 31° 2′ only, the anastigmat 1-4·5, which is four times as rapid, having an angle of 36° 40′, or 5° 38′ more, while anastigmat 1-9, which is about equally rapid, has 50° 6′, *i.e.* 19° 4′ more. Better results are obtainable with the rectiplanat of 1-6·5 aperture; still it falls short of the doubly rapid anastigmat 1-4·5. None of the above-named aplanats, and even the group antiplanat, which is noted for its shortness, possess the same angles as anastigmats of corresponding apertures.

It must again be stated that the figures here shown are not quite correct, inasmuch as the refractive power and the thickness of the combined lens, and the curvature of the external surfaces of the lenses, have not been considered. This does, however, not materially affect the *relative* position of the lenses as compared with each other.

The short structure of lenses has also the advantage of permitting of instantaneous shutters being adopted before or behind the objective, without the risk of thereby causing detrimental stopping of the incident rays when no shutter is being used. The localisation of the shutter between the lenses of the anastigmat is not, therefore, of the same importance as with long-bodied aplanats.

News and Notes.

Manchester Photographic Society.—July 29, Southport (Hand Camera).

Gosport Photographic Society.—July 29, Shanklin, Ventnor. Leaves Portsmouth Harbour twenty minutes past one p.m.

Hackney Photographic Society.—July 29, Excursion, Belvedere Park August 1, Open Night. Members are requested to bring up questions, &c.

We have received the trade price list of Mr. J. Furnell, New Malden, S.W., who undertakes silver, carbon, platinotype, and bromide printing, enlarging, copying, and lantern-slide making.

Mr. C. J. Whittaker, of Station-road, Penrith, informs us that he will be happy to grant the use of his dark room for purposes of changing and developing to amateurs (tourists, &c.). The studio is next the station entrance.

Birmingham Photographic Society.—July 29, Half-day Excursion to Salford Priors and Cleeve Priors. Leader, Mr. William Rooke. Train leaves New-street at fifteen minutes past two. Returning from Salford Priors at five minutes past nine.

Will Louis William Green, Photographer, formerly of 18 or 22, Dennetsroad, S.E., and also a member of the 3rd Middlesex Artillery (2nd Division), please send his present address to Mr. H. M. C. Sprunt, 192, New Cross-road, S.E., as his father is anxious to hear from him?

On Thursday, August 3, before the London and Provincial Photographic Association, Messrs. F. B. Grundy and A. Haddon will read a paper *On the Amounts of Silver and Hypo left in Albumenised Paper at Different Stages of Washing*. We understand that the paper is the outcome of much experimental work.

The International Union of Photography.—The second session of the International Union of Photography will be held from August 21 to 26 next, in the Electoral Palace, Geneva, the session being opened at ten o'clock on the morning of the 21st. Several important communications are expected. The address of the Secretary is 33 Rue Rembrandt, Antwerp.

A catalogue of the library and museum of the Photographic Society of Great Britain has just been issued. It extends to thirty-two pages, and is well arranged. The library of the Society, considering the short time that has elapsed since its formation, appears to be in a creditably forward state of completion, and, as it includes most of the standard text books and sets of periodicals, should be of great interest to members of the Society.

On Saturday evening last, and on the occasion of a garden party given by the Canonbury Constitutional Club, the novel experiment was tried of having a lantern entertainment out of doors. This was under the auspices of the North London Photographic Society, which meets in the premises of the Constitutional Club (Canonbury Tower). The exhibition was highly successful, the lantern being worked by Mr. B. J. Grover. Although the "Constitutional" is a political Club, the North London has nothing to do with party politics.

The results of Messrs. Wormald's third "Photomnibus" Prize Competition are as follows:—First prize (two guineas and bronze medal), awarded to Mr. Frank W. Robinson (age fourteen), 140, High-street, Lewes, Sussex, for his photograph of *A Sussex Farmhouse*, 1570. Second prize (one guinea) awarded to Miss A. L. Walker, 38, South-parade, Southsea, for her photograph of *Corner of a Drawing-room*. Third prize (half-a-guinea) awarded to Mr. Charles Hunter, 30, Clifton-street, Margate, for his photograph of *John Sanger's Tomb*, Margate Cemetery. Three extra awards were made. A fourth competition is announced.

Assistants and their Specimens.—A correspondent writes: "Lately you have written about the annoyances that assistants are put to by the detention of their specimens and references, &c. Through your columns, lately, I have engaged, first, a retoucher, and, secondly, a printer; but, on or about the day they should have commenced work, I have received a letter, coolly saying they had made other arrangements. On both occasions I had written to the unsuccessful applicants saying that I had engaged one, and that their services were not required. Among these rejected ones several would have suited my requirements; but, having destroyed their letters, I was unable to write to them. The last one I engaged sent me the enclosed letter, saying that the writer had made fresh arrangements with his employer and would stay on. I had paid 1*s.* 6*d.* for advertisement, about 2*s.* 6*d.* in telegrams and postage, and he has the impudence to send 2*d.* for his specimens to be returned. I have written, asking him who is to recoup me the expense I have been put to."

What the Photographers are Doing in New Zealand *re* Free Portrait System.—The following draft petition, which is being circulated amongst the photographers in New Zealand, should be of peculiar interest in connexion with the correspondence on "Depression in Photography" now appearing in our pages:—"To the Honourable the Members of the House of Representatives of New Zealand in Parliament assembled. The humble petition of the undersigned photographers, resident and practising in New Zealand, sheweth:—1. That your petitioners approach your Honourable House with a sincere desire to maintain and advance the character and excellence of photographic art in New Zealand. 2. That your petitioners are discouraged, and in many instances ruinously affected, by the competition of travelling pretenders to the art, and by the unrestricted sale of foreign photographs by the agents of foreign companies, whose pictures and enlargements are introduced and sold in the colony at prices or remuneration ruinously competitive with the work of your petitioners. 3. That your petitioners would respectively submit to your Honourable House that the existing New Zealand Customs Tariff is not calculated to foster colonial excellence in photography, or to prevent the introduction and sale by itinerants of cheaply produced articles, to the discouragement of the investment of capital in improved photographic apparatus and materials by qualified members of the profession permanently resident in the colony. 4. Your petitioners would therefore pray your Honourable House to abolish the *ad valorem* duty on imported photographic materials; to permit bromide, chloride, and platinum papers the same privilege of free entry granted to albumen papers; to enact that persons practising photography in New Zealand as a profession, and particularly all itinerants engaged in the art or in the sale of photographic pictures, should be subject to registration and a licence fee, and all imported photographic pictures of New Zealand scenery and photographic enlargements be subject to a protective duty of not less than twenty-five per cent. And your petitioners will ever pray," &c.

PATENTS COMPLETED.

Improvements in or connected with Doublet Lenses for Photographic Purposes.

No. 23,378. Carl Paul Goerz, 7A, Hauptstrasse, Schöneberg, and Emil Von Hoegh, 60, Prinzregentenstrasse, Wilmersdorf, Berlin, Germany.—*June* 13, 1893.

Our invention relates to doublet lenses for photographic purposes, and is illustrated in the sectional views (figs. 1, 2, and 3 of the accompanying drawing).

Within the last few years, as the result of the labours of the scientific glass-

laboratory in Jena, there have been made available for optical industries new kinds of glass, which by reason of their optical properties, differing from those of the kinds of glass which alone were previously to be obtained, have given rise to improvements in optical instruments, and especially in photographic objectives. The conditions of the elimination of the astigmatic errors of pencils of rays entering obliquely require that the crown glass should be of a refractive power higher than that of the flint glass combined with it. Varieties of glass which render combinations of this kind possible have been regularly manufactured since 1886, and since that time attempts have been made in various quarters to utilise the new kinds of glass for the elimination of the astigmatic error in photographic objectives. Thus, for instance, amongst others, the "anastigmat" of Hartnack, calculated by Dr. Miethe, was introduced in the year 1887. This objective is free from astigmatism when the image is approximately plane; but, like all other objectives manufactured by various opticians upon the same principle, it has the disadvantage that the spherical error cannot be eliminated, and hence the system has an illuminating power too feeble for most of the needs of practical photography, and is especially ill adapted for instantaneous exposures.

The reason for this fact is that in order that, the spherical error may be compensated for, the refractive power of the crown glass must of necessity be lower than that of the flint glass which is combined with it. The construction of an "anastigmat" of good illuminating power, with the spherical error corrected, that is to say, without injury to the sharpness of the image, thus appears to be prevented by the interposition of two incompatible conditions, standing in opposition to each other, and, as a matter of fact, it has been customary in the best-informed scientific circles for a long time to consider it impracticable to devise a method of construction which should combine the two properties above referred to.

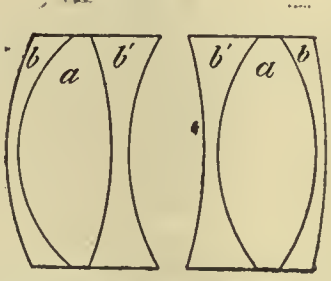
Dr. P. Rudolph, of Jena, the inventor of the recently introduced "anastigmat" of Zeiss, forming the subject of a German patent, No. 56,109, was the first who succeeded in bringing forward proof of the possibility of constructing "anastigmats" of good illuminating power.

We have endeavoured to gain greater approximation to the ideal form by a method differing essentially from that adopted by Dr. Rudolph.

For this purpose we have made extensive calculations, directed at first to the single object of determining whether, as a fundamental principle of a new objective, the astigmatic error could be reduced as far as possible, in the expectation, which appeared, humanly considered, to be justifiable, that, even if it should prove to be impossible to eliminate the astigmatic error absolutely, it might yet be hoped to effect important improvements in the direction indicated.

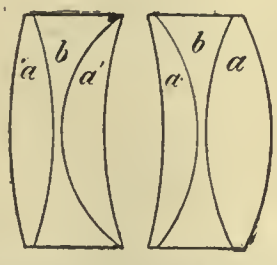
Starting from the above-mentioned facts, well established theoretically, in accordance with which a crown glass of lower refractive power than that of the flint glass combined with it must be used to eliminate the spherical error, and a crown glass of higher refractive power than the flint glass component for the elimination of the astigmatic error, it was sought to determine, by strict calculation, how far a doublet, each half of which was built up of three lenses, would be able to fulfil the conditions required for the elimination of the two aberrations, the spherical and the astigmatic. The separate components of such a system might, with reference to the result, be conceived to be so made up that they should consist either of a negative flint glass (*b*, fig. 1), enclosed

Fig. 1.



between two positive crown glasses, *a* and a^1, in such a way that one of the two latter, say *a*, should have a higher refractive index, and the other, say a^1, a lower refractive index, than that of the enclosed flint glass, *b*, or be made up of two negative flint glasses, *b*, b^1 (fig. 2), enclosing a crown glass, *a*,

Fig. 2.



in which case one of the two flint glasses, say *b*, should have a refractive index higher, and the other, say b^1, lower than that of the enclosed positive crown glass, *a*.

It was found to be possible in both methods of construction, whilst compensating for the spherical and chromatic aberrations, not only to reduce the astigmatism, but to eliminate this last in a manner theoretically perfect. Of the two methods of construction under consideration, the latter (crown glass between two flint glasses) is found to involve unfavourable forms for the separate components, and the employment of such kinds of glass as have their practical applicability limited by disadvantageous peculiarities, so that the former combination (flint glass between two crown glasses) was exclusively adopted in the further working out of the problem, and the determination of the constants of an objective capable of being carried out in practice. As an example, there is depicted in fig. 3 of the appended drawing an objective of

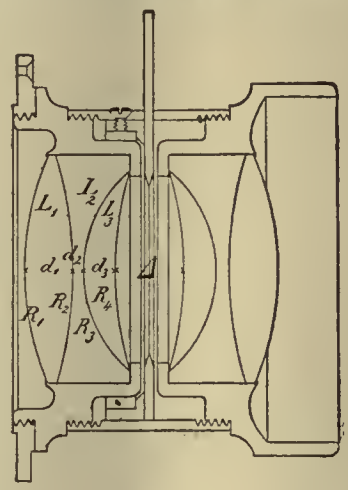


Fig. 3.

the kind described, of an equivaleut focal length of 240 mm., and a free aperture of 36 mm., of the natural size, and in axial section.

The maximum effective aperture is 30 mm., corresponding to one-eighth of the focal length.

The constants required for the construction of the objective are as follows:—

Radii of Curvature.	Thickness of Lenses.	nD Kind of Glass.	nG Kind of Glass.
R1 = − R8 = 45·835	d1 = d6 = 7·334	$L^1 = L^6$ 1·61310	1·62883
R2 = − R7 = 54·324	d2 = d5 = 1·833	$L^2 = L^5$ 1·56804	1·58182
R3 = − R6 = 19·853	d3 = d4 = 4·584	$L^3 = L^4$ 1·51497	1·52663
R4 = − R5 = 49·088	Δ (distance apart) = 11·00.		

All measurements, radii, thickness, distauce, &c., are expressed in millimetres; the kinds of glass are designated by their exponents of refraction for the line D (nD) of the solar spectrum, and for the line H_8 (NG^1) of the spectrum of hydrogen.

If a principal ray, inclined at an angle of 30° to the axis, be calculated through the system, and the position upon it of the image point of the sagittal rays, and those of the meridional rays, be determined, a measure of the residual astigmatism is found in the distance of the two points. This distance amounts, in the case of the objective chosen as a specimen, to 1·2 mm. when the image formed by the meridional rays is flat, and this residual amount of astigmatism has no greater unfavourable effect upon the sharpness of the image formed by the marginal rays than that caused by the secondary spherical aberration in the axis.

The lens just referred to as an example, based upon strict calculation, is symmetrically constructed, but the combination of two absolutely identical halves is not to be regarded as a special characteristic of the objective system under consideration. The only characteristic mark of objectives of the new kind is rather the combination of separate systems independently corrected for spherical, chromatic, and astigmatic error, each made up of three lenses, the glass of these last having refractive indices properly graduated in the manner described; indeed, one system of the objective might have an external form differing from that of the other, or in the same objective one system might be built up as in fig. 1 and the other as in fig. 2. Any such modifications may be undertaken by a calculating optician without difficulty; but, from a practical standpoint, they are to be regarded as purposeless, since the more simple symmetrical form satisfies all the conditions herein taken into account to a sufficient extent. Furthermore, since each of the two separate systems constitutes in itself an objective corrected for spherical, chromatic, and astigmatic errors, each may be employed alone as a simple photographic objective.

Having now particularly described and ascertained the nature of our said invention, and in what manner the same is to be performed, we declare that what we claim is:—

1. A photographic doublet, the two component systems of which are each corrected for spherical, chromatic, and astigmatic errors, being to this end made up of three lenses, as follows:—either

(*a*) of a negative lens enclosed between two positive lenses, one of which has a higher, and the other a lower, refractive index than the enclosed negative lens, or

(*b*) of a positive lens, enclosed between two negative lenses, of which one has a higher, and the other a lower, refractive index than that of the enclosed positive lens.

2. The employment of a single system of the kind described in claim 1 as an independent photographic objective, substantially as hereinbefore described.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

July 25, Technical Meeting, Mr. W. E. Debenham in the chair.

Mr. A. S. C. Forbes, of the Blair Camera Company, exhibited the "Bull's-eye" hand camera, which takes films. It can be loaded in daylight with a cartridge of film for twelve exposures. Mr. Forbes also showed the "Hawk-eye" No. 3 Columbus camera, for taking a 5×4 roll-holder.

A New Photometer.

Mr. A. Cowan exhibited the photometer of Messrs. Franz Schmidt & Haensch, the principle of which is based upon reflection from an opaque surface of plaster of Paris. In his experience it was a great deal better than the grease-spot photometer. It was specially good for weak lights.

Mr. T. Bolas said Mr. A. P. Trotter, who first introduced a photometer of that form, claimed that its great advantage was in being used with a weak light.

Tele-photography.

Mr. T. R. Dallmeyer exhibited a rapid rectilinear lens, with negative attachment, and said that, by remembering the following formula, all tele-photo calculations would become easy:—

$$M = 1 + \frac{v}{f1}$$

m = magnification.
v = distance of negative lens from screen.
f = focus of negative.

Knowing the intensity of the positive lens, and the magnification being determined by the formula, the intensity of the tele-photo lens under the given circumstances $= \frac{I}{M^2} = \frac{\text{Intensity.}}{\text{Magnification.}}$

He said that, when a negative was used with the rapid rectilinear, the ratio could exceed two to one without introducing spherical aberration. In such a construction the diameter of the circle of illumination was always as large as the back focus of the tele-photo combination.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

July 20,—Mr. W. E. Debenham in the chair.

The Adams' New Hand Camera.

Mr. J. A. Sinclair exhibited the new Adams' hand camera of Messrs. Adams & Co., Charing Cross-road, W.C. It has a swing back and rising front, and rack-and-pinion focussing movement, the shutter having a range of speed of from one-hundredth of a second to one second. There was an arrangement for enabling the finders to be cleaned, they being hinged and lifting out of the front. The rising front moved both vertically and horizontally, and the swing back was brought into use by loosening clamping screws at the top and bottom of the camera. The changing back differed from all others in that it would take twelve plates or twenty-four films, or some of both. An indicator stop prevented more than the proper number of exposures being made, so that an exposed plate could not be exposed a second time. The lifting was done by pulling up the lifter at the back, the plate coming up at the front, and being then carried to the back instead of a plate being lifted from the back to the front, as in some changing backs.

The Chairman remarked that he thought a swing back objectionable, and preferred a high rising front.

Miscellanea.

Mr. T. E. Freshwater (Hon. Secretary) showed photographs of Fleet-street and Temple Bar on the day of the Royal Wedding.

Apropos tele-photo lenses, Mr. R. P. Drage said that a few days previous he was out photographing with a friend who had a Dallmeyer tele-photo lens with him, and, after waiting an hour and a half, found that the state of the atmosphere prevented him from using it.

Mr. Freshwater asked if there was any advantage in using pink or mauve albumenised sensitised paper over white? He also inquired how it was that the pink colour washed out more in some instances than others in prints taken from the same sheet of paper?

The Chairman thought the latter might be due to the thickness of the coating of albumen, the thick coating retaining more colour.

Mr. Freshwater had seen it stated that pink and mauve papers retained their colours better than white paper.

Several members thought the contrary was the case.

Uranium Toning of Platinum Prints.

Mr. J. S. Teape said that Mr. Haddon had, at a previous meeting, stated he was unable to tone platinum prints with uranium on paper made by himself, and suggested that, as he (Mr. Teape) had toned some of the Platinotype Company's cold-bath paper in this manner, there might be some silver in the paper which accounted for the toning action. To test the point, he had placed platinum prints in a saturated solution of bichloride of mercury, acidified with hydrochloric acid, for eighty minutes, washed them for two hours, and then put them in a hypo bath (four ounces to the pint) for twenty-five minutes. They were again washed for two hours, and then toned for thirty-five minutes in a uranium bath. He showed the prints, some of which were of a full sepia colour. It had been said that uranium-toned prints faded; he showed prints toned eighteen months ago to show that they had not undergone any alteration. Toned prints which had the uranium removed by washing took a much longer time to tone a second time.

Mr. A. Mackie inquired if Farmer's reducer would reduce platinum prints?

Mr. Drage said that he had tried it, and found that it did not reduce the prints, which, however, turned mealy.

After other discussion the meeting closed.

FORTHCOMING EXHIBITIONS.

Correspondence.

THE CONVENTION GROUP.

To the Editor.

Sir,—In your issue of July 21 you refer to the collotype copy of the Convention group "from a negative taken by Mr. R. L. Kidd." Permit us to state the following facts:—

1. The group was entirely arranged by our operator, and is a *facsimile* of our official 18×15 group taken at the request of the Committee.

2. It was exposed by the writer, Mr. Kidd being in the group.

3. It was developed in our dark room by our operator, Mr. Kidd being present.

4. It was dried, packed, and sent off by us.

We presume that Mr. Kidd was unaware that he would be honoured with your commendations of "his" negative, or he would doubtless have suitably acknowledged our connexion with the picture. We heartily agree with you in commending the promptitude of Mr. Kidd's firm in producing the bromide prints, and in admiring the excellence of the collotype prints.—We are, yours, &c.,

W. Heath & Co.

24, *George-street, Plymouth, July* 24, 1893.

THE QUEEN AND "PROFESSIONAL" PHOTOGRAPHY.

To the EDITOR.

SIR,—For the information of other professionals, I think it only right to draw attention to the following: An operator and retoucher who has recently left my employment, having possessed himself of a copy of my photograph of their Royal Highnesses Prince and Princess Henry of Battenburg, taken at Windsor Castle for Her Majesty the Queen, writes, apparently in their behalf, to a lady holding a responsible position in Her Majesty's household, forwarding a coloured copy of the photograph, asking that it may please Her Majesty graciously to accept the same, and, should Her Majesty desire to have it enlarged or obtain additional copies, he would deem it an honour to execute Her Majesty's commands in this respect, or as regards any similar work.

I need hardly say that Her Majesty the Queen refused to accept it, and ordered that the photograph and the letter should be handed to me, to take any action that I thought proper in the matter.

I feel sure that the profession will be glad to know of, and will appreciate, the action taken in the matter by Her Majesty the Queen.—I am, yours, &c.,

G. P. CARTLAND.

Windsor, July 19, 1893.

Answers to Correspondents.

PHOTOGRAPHS REGISTERED :—

Frederick Argall, Truro.—*Six photographs of J. Passmore Edwards.*

Richard Keene, Burton-on-Trent.—*Six photographs of Charles Frederick Claverhouse Graham.*

Thomas Maitland Laws, Darlington.—*Three photographs of the Wolverhampton Wanderers Football Team, with English and Birmingham Cups.*

H. J. CHANNON.—Received.

CHARLES JOHNSON.—We are inquiring into the matter.

YACHTSMAN.—The picture bears the appearance of a snap-shot.

SHAPOOR N. BHEDWAR.—The negatives were dispatched about a month ago.

W. AND F. VERNON.—We cannot well publish your complaint; it borders on libel.

M. F. B.—The address is Mr. H. N. King, 4, Avenue-road-villas, Goldhawk-road, W.

G. TUMLY (Battersea).—Unless putty or white lead, or a mixture of the two, will answer, we do not know what will.

W. M'DOUGALL.—Although of local interest, it possesses none for photographers in general. Thanks, notwithstanding.

G. BEAUCHAMP.—Ordinary lithographic ink answers every purpose. In some cases it will be desirable to thin it with litho-varnish.

J. YATES.—Communicate with Mr. Fallowfield, Charing Cross-road, who may be able to supply you with one of the automatic machines.

J. LEACH and F. ARNEY.—Our publishers will register the photograph for you if you will send them three copies of it and *1s. 7d.*

PHANTOM asks: "Is there a book published on Accessory Making? If so, where obtainable? Answer in this week's, if possible."—We know of no such work.

LIGHT.—We are unable to add any explanation to that given you by the Company, unless it be that possibly the water is contaminated with iron or some other deleterious substance.

NICHOLSON.—If another really holds a copyright in the picture, it will be illegal for you to copy it. As to whether the copyright is valid or not, depends upon circumstances. On this point, better consult a solicitor who makes a speciality of copyright law.

COUNTRYMAN.—Powdering the face of sitters to obliterate freckles is not much, if at all, practised by London photographers at the present time; they mostly rely upon retouching to effect the object. Of course, as you say, this takes up a lot of time in the case of some sitters.

T. COLMANE.—The lens in question is not very well known in this country. It is well adapted for the purpose for which it is designed, and gives excellent results with a large aperture; but it is very bulky and heavy, and, for this reason, for landscape work, it is not often employed.

M. HOUNSLOW.—Burton's *Printing Processes*, or Wilkinson's book, will give you a good idea of the process. Of course, that, like any other process, is not to be learnt by merely reading a description of it. If you really desire to learn to work it commercially, the best way is to apprentice yourself to a good house.

THOMAS GATES asks: "Could you state what power of electric light is required to take sitters?"—It all depends upon the exposures required to be given. You may calculate the power of the light from the fact that 1000 candle power necessitates an exposure of about ten seconds. Possibly a power of 5000 to 6000 candle power would be the most convenient to employ.

J. PAGE.—Enamelled iron dishes may be used with safety for washing prints on P.O.P. paper. Common brown-ware baking dishes can be also used, but the former are preferable as they are not liable to breakage.

G. FORBES.—Possibly a solution made up in the following strength per drachm would suit:—Hydroquinone, one part; sodium sulphite, two parts; sodium carbonate, ten parts; water, sixty-seven parts. Dilute each drachm of concentrated solution with four times its volume of water. Many other hydroquinone formulæ are given in the current ALMANAC, to which we refer you.

S. T. S.—Although the picture has been largely used as a "poster" for advertising purposes, it would be illegal to copy it, whether leaving out the advertisement portion or not. The advertisers paid a very high price for the painting, to use it in the way they do, and it is not at all probable that they would permit any one to copy the picture itself to be sold without the advertisement.

G. NEGRIO.—The negative was delivered to us in about a score of fragments and innumerable particles. So far as one is able to judge under such circumstances, the spots are due to air bubbles adhering to the film while in the developer. The plate was certainly old, as proved by the appearance round the edge. Evidently there was no fault with the plate when issued by the maker.

J. HETHRINGTON.—The article from which you quote is the one that contains the fullest description of that method of photo-engraving. You are not the only one that has failed to work it successfully, but that may be due to inexperience. However, as the inventor works the process commercially, it is scarcely likely that he has published the details of it with the greatest minuteness.

R. BLANE.—Bichromate of soda can be obtained from any operative chemist or dealer in electrical appliances. But it is not so good as the bichromate of potash as a sensitiser in carbon printing, neither is the bichromate of ammonia for general purposes. The tissue should be dried within eight to twelve hours, according to the temperature. The cooler it is, the longer the time it may take to dry without injury.

R T. says: "I have an old oil painting to copy, and I am told that to get the best effects I should rub the picture over with glycerine and water to improve it for copying. Is this so?"—Glycerine is employed by some, at times, as it shows up detail in old paintings nearly as well as a fresh coat of varnish; but it is what the owner of a valuable painting would not allow to be applied if he knew it. However, if the varnish is not cracked, we doubt if much harm will accrue to the picture if the glycerine is completely removed directly the copy is obtained.

R. SMART.—The work is only published in German. Its price is, we fancy, about three marks—equal to three shillings. If it is only the formulæ that are really required, we should advise you to obtain the work; for, although you are unable to read German, you will doubtless be able to understand them, as the names of the majority of the things mentioned are the same, or nearly so, in German as they are in English, and the proportions are quoted in grammes and cubic centimetres. Liesegang, Düsseldorf, Germany, will supply the book, if it is not published by him; or it may be obtained through any of the foreign booksellers in London.

A. R. (Berks) says: "I have, during the two years I have practised photography, taken some dozens of very pretty views of country scenery, which I should like to turn into money. I am an amateur, but do not care if I sacrifice my title to be considered as such if I can sell my negatives, as I find photography, though agreeable, an expensive hobby. Can you suggest a market, as the photographs are really good?"—The only thing we can suggest is to advertise the negatives, with a description of their character, for sale, or to communicate with one or other of the large publishing houses. Unless the views possess some interest beyond "country scenery," we fear they will not find a ready sale.

W. T. puts the following queries: "1. In using ferrotype plates to enamel P.O.P. paper, I find that the paper sticks occasionally in spots, and will not leave the plate without spoiling the print. How is this to be remedied? 2. How can I bring my silver bath to its senses? It has got dirty, and leaves dirty water marks on the albumen paper. I have used kaolin, too. 3. I am stationed on the high roadside in the country for the purpose of taking groups of pleasure parties. Can any one interfere with me if I don't obstruct? I have not been interfered with, but should like to know if they can."—1. If the plate be clean and is treated with French chalk, the prints will not stick. 2. Kaolin will decolourise the bath. Probably the "water marks" are due to scum on the surface of the solution at the time of floating: skim it with a strip of blotting-paper. 3. If the thoroughfare is not obstructed, we imagine no one will interfere. Better obtain the bye-laws of the highways authorities of the district.

*** EDITORIAL TABLE, many letters, and other communications, unavoidably crowded out this week.

THE BRITISH
JOURNAL OF PHOTOGRAPHY.

No. 1735. Vol. XL.—AUGUST 4, 1893.

THE FUNCTION OF SULPHITE OF SODA IN DEVELOPMENT.

From the time that sulphite of soda was introduced into the alkaline developer some twelve years ago by the late Mr. Herbert B. Berkeley, it has been the custom to regard it mainly, if not entirely, as a preservative of the pyro and preventive of staining; but since the advent of numerous new developing agents which exhibit no tendency to stain the negative, and which may be, if desired, used as pyro formerly was, without any preservative, the retention of sulphite of soda in the developing formulæ seems to argue that it possesses other functions besides those mentioned.

By very many of those who have used it in conjunction with pyro, sodium sulphite has been regarded as a restrainer or retarder of developing action, though it has over and over again been pretty conclusively shown that any such action is really due to the presence of sulphate, produced by the oxidation of the sulphite, which, in its pure state, has not been proved to possess any slowing action. On the other hand, from the value of the sulphites as reducing agents, quite the opposite tendency might be anticipated, and indeed, so far back as 1872, and later again by Mr. Sammann in 1877, a modification of the pyro developer was proposed, in which, by the action of zinc upon the acid sulphite, a new substance was formed which, in combination with pyro, possessed powerful developing action.

It was noticed at that period that both the so-called "neutral" sulphite of sodium as well as the acid salt frequently exhibited developing powers when mixed with pyro, without the action of zinc, though in the former case the effect was most probably due rather to the presence of free alkali in the sulphite. With the bisulphite, however, this was out of the question, and it became evident that chemical development in the acid condition was a possibility, as, indeed, was foreshadowed by Mr. M. Carey Lea about the same time.

All this, however, was in connexion with collodion films, which, as is well known, behave somewhat differently from gelatine. For instance, old dry-collodion plate workers were wont to commence development with plain pyro solution, and, when detail had been thus obtained, to proceed to obtain density by the addition of acid silver. Frequently, in cases of over-exposure, an image would be produced with acid pyro alone, without the addition of any soluble silver salt, but this might probably be set down to the presence of minute traces of nitrate of silver remaining on the film after sensitising. Similar results were also obtained with collodion emulsions prepared with excess of silver. With gelatine films, however, no such development had been known to occur until Captain Abney, Mr. G. W. Webster, and others, showed that pyro and sulphite in the neutral, or even the acid, condition were capable of developing an image, and, quite recently, the researches of MM. Lumière prove that acid development is possible, and even practical.

Up to the present, however, the matter can scarcely be said to have got beyond the experimental stage, so far at least as acid development is concerned, though in one case, that of amidol, we have a developing agent which acts in conjunction with sulphite in the neutral, or even, it is said, in the acid condition. But in this instance the necessity for the addition of sulphite to the amidol is recognised, which is not so with others of the newer developers, and in conjunction with which it is usual to employ alkali in much the same proportions as with pyro.

Seeing that the addition of sulphite is not rendered necessary for the prevention of stains, and that some of the newer agents are sufficiently soluble in water to be dissolved at the time of use, the question arises, of what utility is the sulphite? It undoubtedly adds very materially to the cost of development, besides increasing the trouble of preparation, and if merely an ornamental addition, serving no really useful purpose, it seems to us desirable to dispense with it if possible.

To put the matter to a practical test, a plain three-grain solution of metol was made, this being the developer that came first to hand, and this was applied to a plate that had received a rapid exposure in the camera—that is to say, a fraction of a second—an exposure that under the circumstances would have required the full strength of a pyro developer though without any forcing. The metol solution, without either sulphite or alkali, was applied to the plate for ten minutes without the least trace of an image appearing, when an addition of ammonia and bromide was made equal to three minims of the former and one-third of a grain of the latter to the ounce of developer. In about three minutes the image began to appear, but proceeded so slowly, that at the end of twenty minutes—half an hour altogether from the commencement—it was still not half out, and very thin. It was then placed in a dish of water and covered, to protect it from light.

Another plate was similarly exposed and treated with a solution containing three grains of metol and thirty grains of

sulphite of soda to each ounce of water. In a trifle over two minutes the image began to appear, and at six minutes it appeared to be fairly dense, though too clear in the shadows to be fully developed. At ten minutes it had apparently progressed no further, and was evidently finished, so it was washed and transferred to the fixing bath. The previously developed plate was then treated with the same solution, containing metol and sulphite, when in about three minutes the detail and density that had been wanting were obtained, and, on fixing and comparing with the second plate, there was no difference to be detected except in the colour of the image and a greater clearness in the one developed without alkali.

This experiment quite upsets the theory that sulphite of soda is a useless addition to metol, at any rate; on the contrary, it proves it to be a far more important adjunct of the developer than the alkali, for, while the latter in half an hour failed to more than half perform the duty required of it, the sulphite in one-third of that time, or probably less, had completed its work. Compared with the time occupied in developing with the usual metol formula, the action of the neutral solution is decidedly slow; but, judging it alongside an ordinary pyro development, we question whether there would be found any great difference.

The quality of the image, too, was very satisfactory; for, although before fixing it conveyed the idea of being either under-exposed or under-developed, that proved to be the result of the unusual clearness of the shadows even for metol. The colour was less black than that produced with the aid of alkali, and the gradations, especially in the higher lights, decidedly softer; on the whole, indeed, a better negative. Development without alkali where time is not an object, and especially in case of over-exposure or with subjects presenting strong contrasts, would seem to be worth trying.

The first experiment was made as much to test whether metol without sulphite showed any tendency to stain the film as to try the developing power of the former alone. In this respect the film proved as free from stain as if sulphite had been used, but the solution after use had become nearly as dark as pyro would have been under the circumstances, although clear and free from sediment. Where the developer is to be used repeatedly, then the necessity for sulphite is indicated.

Turning now to amidol, a plain five-grain solution was made and applied to a plate exposed similarly to the others for ten minutes, without the symptoms of development. A similar quantity of ammonia and bromide solution to that previously employed was then added, and development then proceeded very slowly, and after another quarter of an hour appeared complete. A second plate was treated for ten minutes with a fresh plain solution with no result. A crystal of sulphite of soda—perhaps five or six grains—was then thrown into the developing cup, and the solution poured backwards and forwards from the dish to the cup. In just two minutes the image began to appear, and in five minutes was strong, and vigorous, and full of detail, presenting an appearance of greater "pluck" than we are accustomed to with amidol. Here, again, the absolute necessity for sulphite seems evident, and the conclusion is forced upon us that it exercises an important and specific function in development altogether independent of any free alkali it may contain.

Whether the proportions of sulphite recommended in the different formulæ are the best or not remains yet to be seen; but, judging from the last experiment, and especially the character of the image produced, we are inclined to think that the proportions of 10 : 1 are far too high. Used in those proportions, we find amidol absolutely requires restraining bromide; whereas, if the proportion of sulphite were reduced, it seems likely that, in addition to the saving thus effected, the bromide might be altogether dispensed with.

DEPRESSION IN PHOTOGRAPHY.

THE article relating to photography as a business that appeared a few weeks ago has given rise to a large amount of correspondence, and, as all sides have now been fully heard, it is necessary to bring it to a close. During the discussion professionals have soundly rated amateurs for being the principal cause of the present unfortunate depression. This position certainly cannot be maintained, though, there is no gainsaying it, they have directly and indirectly conduced to bring some not inconsiderable proportion of it about.

From the correspondence it must be admitted that photographers themselves have greatly injured portraiture as a business by their own actions. They have, it is proved, been for years past competing with each other, not in the healthy direction, with quality of work, but in the suicidal policy of reduced prices, free sittings, speculative enlargements, and the like. To such an extent is the free-sitting phase now carried that many popular men, such as clergymen, doctors, and others, who used to be good customers to photographers, get what portraits they require by obliging different photographers with sittings from time to time, and accepting a few copies in way of compliment.

It has been pointed out that the introduction of gelatine plates has not been an unmixed blessing to the profession. Before their advent a certain amount of skill, only to be acquired by long practice, was undoubtedly necessary to work the collodion process under the ever-varying condition of the chemicals. Therefore the number of really good workers had always been limited. The difference between the productions of the skilful worker with collodion and the unskilful one was wide indeed, and, so long as this continued, ability counted for much. But with plates purchased ready for putting into the camera, and, as now, of uniform quality, the conditions are altered. A degree of proficiency that would be utterly inadequate to produce even a passable negative with collodion will now suffice to secure a really good one with a commercial plate. It was remarked to us during this controversy that greater ability is required in the "beach operator," who still has to prepare his own plates, than the present-day studio operator. Under these circumstances it is not surprising that there has been a great influx into the ranks of the profession, so that for some years past the supply has much exceeded the demand, and, as a result, competition has increased in all directions. It may be taken as a rule that any craft that is quickly and easily learnt does not, permanently, continue a very profitable one.

In the controversy amateurs have not been backward in retaliating on professionals. They say that the profession have done little or nothing for the advancement of the art, and that all the great improvements have been made by amateurs, and they have always freely given their discoveries to the world. There is undoubtedly a great deal of truth in this; but the reply is, that there is a wide difference between the amateur of the past, who was generally a good friend to the professional even as a customer, and the amateur of the present of whom he so loudly complains. The former took up photography as

a scientific pursuit, and was prepared to spend time and money in acquiring the necessary knowledge, and their number was limited. The latter, in the majority of instances, takes up the art as a fashionable pastime, and his name is legion. Some correspondents have said, in some instances, he is proud to give his work away; in others, to charge the cost of material, and often to make a profit for himself. In any case, the professional must suffer to some extent.

We can quite imagine that, in many cases, amateurs of the present day, unlike those of old, have an idea of the £ *s. d.* element, and do not give any improvements they may make so freely to the world as did their elder brethren. We find, on going through the specifications of patents in connexion with photography for the last few years, that by far the larger proportion of them are taken out, presumably, by amateurs, for it is rarely that the trade or profession of the applicant is described as "photographer." The patentees are of all manner of callings, most of them totally unconnected with photography, and not a few are entered as "gentlemen." Therefore the complaint that the modern amateur is of a different type from him of the past seems to be not altogether ill-founded, and therefore he is not entitled to trade on his predecessors' reputation.

Nothing is to be gained by professionals and amateurs decrying each other. That great depression does exist in the portrait business is undeniable, be the cause what it may, and the immediate question is how is it to be remedied. During the discussion various ways have been suggested, but whether any of them would be successful, or whether some of them are practicable, is very problematical. The idea of legislation on the subject, such as granting of licences to professionals or heavily taxing amateurs, as some have proposed, is of course out of the question; with this most business men will agree. It has been suggested that, if diplomas were conferred, it would raise the status of photographers, but that would not prevent the general public from going where they could get the work done cheaper if it were equally as satisfactory to their ideas, for it must be confessed that a portrait is by many better appreciated as a likeness than it is as a work of art or excellent example of photography.

Among the suggestions made, is that a union should be formed to regulate prices and other matters, including employing only certificated assistants and the like. But have we not the National Association of Professional Photographers, that was formed to carry out practically these objects? Of course any rules such a union might frame would not lie on those who are not members of it. Unfortunately many only consider themselves. If they want an *employé* the first consideration with them is, 'Can he do the work required and at the wages?' further accomplishments are too often reckoned as nothing. One of the suggestions made was at least worthy of attention, but the opportunity of putting it into practice has passed for a time. It was that the whole subject should be taken into consideration at the meeting of the Convention at Plymouth. At the Convention meetings, which are held but annually, are gathered together representative professional photographers, amateurs, manufacturers, and dealers from all parts of the kingdom; and one might have surmised that a subject of such vital importance to all concerned might have received some attention.

A New Light-sensitive Salt.—A considerable number of salts of sulpho-phosphoric acid, obtained in a pure state by Dr. Glatzel, of Breslau, are recently described by him in a foreign chemical journal, and among them is a new compound shown to be sensitive to light. This is the mercury sulpho-phosphate, which is acid, and very sensitive to light.

Detection of Halogens.—Still another method—this time a comparatively simple one—is described by Herr L. F. Kebler. A few drops of nitric acid, sg. 1·42, are added to the solution to be tested, and a few drops of bisulphide of carbon added. If iodine be present, the bisulphide will be coloured purple. A brownish yellow tint indicates bromine and no iodine. If iodine be found, more acid is added, the liquid heated for a few moments, and again tested with bisulphide. If the iodine has been all removed, the bromine colour, if any, will alone be seen. If bromine be present more acid is added, and the solution boiled till all the bromine is volatilised. Nitrate of silver solution is next added, and the presence of chlorine shown by the usual precipitate so well known to photographers.

The Manufacture of Oxygen on a Commercial Scale.—At a recent sitting of the Paris Academy of Sciences, the dissociation of calcic plumbate was discussed by M. H. Le Chatellier. This operation, it may be remembered, is the foundation of Kassner's process for procuring oxygen, described on a previous occasion in these columns, the reaction as follows: $PbO_2 2CaO = PbO + 2CaO + O$. Comparative experiments were made with this and the peroxide of barium method. It was found that with the new method there was the drawback that a temperature of 900° had to be reached as against 700° for the older method, for the dissociation of the oxygen at 0·1 atmosphere. On the other hand, the plumbate had an advantage in that, being fusible, it absorbed the oxygen more rapidly and completely, and, further, the air needed no special desiccation and decarbonation.

The Preservation of Pictures.—One of the conclusions of the Commission appointed to examine and report on the effect of light on water-colour paintings, was that every pigment is permanent when exposed to light *in vacuo*, and this indicates the direction in which experiments should be made for the preservation of water-colour drawings. Mr. W. S. Simpson has devised an apparatus for making use of this suggestion. He places the picture face down on a sort of glass trough, and then covers it at the back; all, of course, we presume, being hermetically tight. He then extracts the air by a Spreagel mercury pump, and completely seals the whole against air. The expectation is that, apart from accidents, the picture would then last for ever. The apparatus has connected with it a small manometer, somewhat like an aneroid, which, if there is any leakage, will exhibit the fact in a moment.

Uranium Toning of Platinum Prints.—An interesting discussion on this subject has recently taken place at the London and Provincial Photographic Association. Mr. J. S. Teape succeeded in toning some platinum prints with the ordinary ferridcyanide of potassium and nitrate of uranium intensifier, from which Mr. A. Haddon inferred that, as platinum has no reducing action on the ferrideyanide, silver must be present in the platinum paper, the more especially as he had failed to tone platinum paper of his own preparation. Upon treating the paper for the presence of silver with mercuric chloride and hypo, as well as with bichromate of potash and hydrochloric acid, Mr. Teape still succeeded in toning the pure platinum image; so that the silver theory falls to the ground, and we are led to believe that, after all, platinum does reduce potassium ferridcyanide to the state of ferrocyanide. The mysterious part of the matter is Mr. Haddon's failure to tone platinum paper of his own preparation.

Photography of the Shortest Ultra-violet Rays of the Spectrum.—Professor Schumann, in one of the reports of the Session of the Imperial Academy of Sciences in Vienna, discusses this subject at length, describes the present position of our knowledge on the subject, and while detailing the results of a portion of his inves

tigations, states that years may probably elapse before he completes his investigations. He describes how the earliest important results were dependent upon an examination of fluorescent effects, a method which has lost ground as sensitive plates have increased in efficacy. Becquerel's were the first investigations, but, being made on a basis of a spectrum-formed glass, they did not extend very far. Stokes, by using quartz, obtained a spectrum which, measured from Frauenhofer's H., was, in the ultra-violet, twice as long as the total visible spectrum. With the electric light it was from six to eight times as long. His results were given to the Royal Society on June 19, 1862, and on the same day was read a paper from Miller on "The Photographic Transparency of Various Bodies," both papers treating of the same subject in substance. Stokes, however, used the fluorescence, and Miller the photo-chemical power of the rays, the former being able to examine much shorter rays than the latter. Other physicists used fluorescence, and it would seem as though photography was insufficient to do the work. This, however, was shown not to be so, as Carnn, in 1879, published an account of what he could do with photographic aid. He used wet plates, but dipped them in distilled water to avoid stains through the long exposure, and so obtained at once photographic results superior to any. Schumaun, aware of all these difficulties, and cognisant of the advance in dry plates, determined to investigate, or "open up to photographic study," the remaining ultra-violet as far as 185·2 mm. (that is as far as Stokes had gone with fluorescent methods) by means of a more suitable process than those hitherto applied, and at the same time to consider the extension of this region of observation as the direction of greater deviation. The report we are giving in brief discusses the former portion of the plan, and also the preliminaries of the second.

THE INFLUENCE OF DEVELOPMENT ON GRADATION.

The papers read at the recent meeting of the Photographic Convention should be carefully studied by all who are interested in the matter of the influence of development on gradation. The questions at issue appear to be becoming clearer, and light is gradually being shed on some doubtful points. Mr. Bothamley, indeed, suggested that it might possibly prove that there was, after all, no real difference of opinion on the question among photographers, and that, when we came to properly understand each other, it might turn out that all thought alike; but I think that view of the matter will hardly bear examination. Between the opinions maintained by Messrs. Hurter & Driffield and those held by the majority of photographers a wide gulf seems still to exist. It is true that all agree that the ratios of the *opacities* of a negative *may* be modified in development, and Mr. Bothamley's diagrams showed how that follows from Messrs. Hurter & Driffield's principles. His explanation, put simply, merely means that a negative will print differently accordingly as greater or less density is given to it, by carrying on the development for a longer or shorter time. That the photographer has such control as results from that is a matter of course, but Messrs. Hurter & Driffield will admit the existence of no other. They deny that any practical alteration or improvement in gradation can ever be made by altering the *composition* of the developer, while nearly all photographers believe, on the contrary, that great and often valuable variations in results are to be obtained by that means. Mr. Bothamley touched on that point, and thought the different opinions might, perhaps, be reconciled by taking into consideration the greater or less amount of fog produced by the various developers; but here he appears to have fallen into a pitfall against which he has warned others, viz., that of confounding density with opacity (using both terms in Messrs. Hurter & Driffield's sense). The effect of general fog is to spread a certain proportion of reduced silver evenly over the film, and it therefore adds equal amounts to the *densities* at all parts, and so alters their ratios; but these densities are the *logarithms* of the opacities, and it is, of course, unnecessary to point out to Mr. Bothamley that equal additions to a series of logarithms make no difference in the ratios to each other of the numbers which they represent. The effect of the fog is, in fact, as Mr. Cowan suggested, just equal to placing a piece of thin paper over the negative. I see Mr. J. Sterry has already drawn attention to the matter.

Messrs. Hurter & Driffield's present position is becoming more clearly understood; they certainly do not now maintain all that a reader of their original paper would be likely to gather from it. Taken literally, it appeared to be there asserted, in several places, that the ratios between the densities were *altogether* unalterable in development, and that the only sort of control left to the photographer was to give a greater or less value to the development factor γ, according to the length of time employed in the process. This view has now quite broken down, and every one of the many sensitometer experiments of Professor Burton (as described in the valuable paper read at the Convention), in which the opacity curves (and therefore the density curves also) *crossed*, has given sufficient proof of its unsoundness. Messrs. Hurter & Driffield, however, are now themselves convinced that extreme alterations in the composition of the developer may bring about somewhat greater alterations in the density ratios than they at first thought was the case. This they candidly admit in their preface to the reprint in *Dry Plates* of their original article. The opinion they now hold appears to be that, in *picture-making*, no advantage can, in any case, be gained by varying the method of development, *because*, the difference in gradation to be so obtained, will be too small to be appreciable in the small range of intensities of light which they believe to exist in ordinary photographic subjects. Now, supposing this to be so, it is still important to know that the simple principles laid down in the original paper are not accurates and especially that there is so serious a weakness in the formulæ, a' other uses, besides mere picture-making, are every day being found for photography, and there are probably many cases in which a knowledge of such principles, if true, might have been most valuable. But even in ordinary photographic work I do not think Messrs. Hurter & Driffield's opinions regarding development are likely to be yet accepted. Mr. E. J. Wall's Convention paper and the discussion on it show how little impression has yet been made on the majority of photographers, not one of the members present having expressed any doubt as to the great influence which the choice and composition of the developer may have on the resulting negative. And even their most enthusiastic supporters are unable to fully agree with them on that point. I have previously referred to an advertisement of Messrs. Marion & Co. as evidence of that, and Mr. Ashley Cowan, who represents that firm, and has made a very large number of photometrical experiments, has since shown, in a discussion at the London and Provincial Photographic Society (April 20), that he considers that variation in the composition or temperature of the developer will seriously affect results. But the experience of Messrs. Cadett & Neall is a still more striking fact (see *Dry Plates*, No. 9, page 52); having now adopted the Hurter & Driffield system, they mix the developer used in testing their plates according to the standard formula agreed upon by those platemakers who use the actinograph speed numbers, while, in their instructions to the users of the plates, another formula is recommended. "The result (they write) is a general complaint of over-exposure" (of course, from users of the actinograph), and, since their attention has been called to the matter, Messrs. Cadett & Neall have undertaken a series of experiments, and now find that these two species of developers, neither probably differing extremely in constitution from normal proportions, yet differ so greatly in their action that the correct exposure is found to be twice as long when one mixture is used as it would be if the other were employed. These experiments, it should be remembered, were made strictly on Messrs. Hurter & Driffield's principles.

The every-day experiences of working photographers, including users of the actinograph, are apparently confirmed by the evidence of systematic experiments, such as those described by Professor Burton; but Messrs. Hurter & Driffield oppose the latter by the argument that, in ordinary photography, the range of intensities of light to be dealt with is far less extensive than is usually supposed, and that erroneous conclusions have been formed in consequence of a want of knowledge of that fact. That the range is confined to such narrow limits as they described will, they suspect, be news to Professor Burton. No doubt it will, and to others also; but the matter, I think, requires clearer proof than we yet have before these views can be generally accepted. The experiment described (in the paper which they sent to the Convention) by Messrs. Hurter & Driffield, in order to show the correctness of their opinion, seems scarcely satisfactory. To represent the range of illumination likely to be found in a landscape, they attached sheets of white card and black paper to each side of a folding screen, and, having placed it so that one side was in full sunlight and the other in shade, a negative was taken of the screen and the densities measured. By this means they arrived at the, no doubt, correct conclusion that the intensities of light reflected from the various parts only varied as much as 1 : 30. The questionable matter is whether that screen could fairly be considered to represent the differences of illumination existing in even an average landscape, for the shaded side was fully exposed to all the light coming from one half of the sky—equal in intensity, as the experiment showed, to direct sunlight itself—while in every

landscape there are places which receive light from only a small fraction of the sky, or often from no part directly. This is a matter likely to enormously extend the scale.

Messrs. Hurter & Driffield have previously expressed this opinion as to the shortness of the range in their article in THE BRITISH JOURNAL OF PHOTOGRAPHY of April 21 last, and I was much surprised on reading it. Since then, I have tried a few experiments to test the matter, but my results, being only negative, have been rather unsatisfactory; still, they appear to be very inconsistent with Messrs. Hurter & Driffield's conclusions. Opposite my dark-room window is a house, which I frequently use as a test subject for trying plates, &c. A nursery business is carried on there, and there are several outhouse and stable doors which are frequently open, showing spaces which furnish the darkest parts of the view, and in the foreground is a summer-house, the interior of which is nearly as dark. By taking negatives, and comparing on them the images of these dark spots with those of the sky, I found reason to suppose that there had been far greater differences in the intensities of the light during exposure than 1 : 8, which Messrs. Hurter & Driffield had given as the average, or 1 : 30, which they considered an extreme case; but, as the darkest parts covered too small a part of the negative to be measurable in the photometer, I afterwards took a negative of the summer-house from a few yards' distance, so that the interior covered a considerable space. That, however, was not quite the darkest part of the view, an open doorway in the opposite house being still darker. The experiment for which this negative was taken was my last and most satisfactory one, and I will therefore give fuller details of it. A backed "Ilford ordinary" half-plate was cut in two, and one half exposed, as mentioned, on the summer-house (eight seconds with *f*-45). To the other piece, cut into strips, a series of carefully timed exposures, to a standard candle, was given, varying from 1 to 64 C.M.S., and another series of from one to five minutes at a metre's distance, and all were developed together in a well-restrained solution. On examining the results in the photometer, I found that the sky part of the negative was slightly denser than the patch representing the five minutes' candle exposure. The means of several readings were :—

Exposure	180 C.M.S.	240 C.M.S.	300 C.M.S.	Sky in Negative.
Density	2·67	2·71	2·72	2·81

As these densities were all in the "period of over-exposure," the difference shown of ·09 may represent a large excess of exposure over 300 C.M.S. The densities shown by the summer-house interior, with those nearest to it, are given below :—

Exposure	1 C.M.S.	2 C.M.S.	4 C.M.S.	Summer-house in Negative.
Density	·14	·35	·68	·51

These densities, except as regards the 1 C.M.S. patch, were found to be included in the "period of correct exposure," and the value of the exposure of the summer-house interior could therefore be easily calculated, and was found to be equal to 2·8 C.M.S. That exposure, however, was the result of the action of all the light which fell on that part of the plate, but a considerable proportion of the deposit in the shadows of a negative (especially when, as in this case, bright sky covers a large part of the view) is generally produced by light scattered by the lens or reflected in the camera, which must be allowed for when judging in this way of the actual brightness of a dark part of the subject. I endeavoured to estimate the amount of the scattered light by comparing two negatives, which I exposed immediately after that of the summer-house, and developed with it. The parts compared represented the interior of a black box, which appeared in the foreground of each of them, a bright sky being included in one negative, but entirely cut off in the other, by hanging a black card in front of the lens.

It is, perhaps, unnecessary to give fuller details, so I will merely state that I concluded that the action of the scattered light, during eight seconds of exposure, might be taken as equal to ·6 C.M.S.; but, unfortunately, I found that I had included a much smaller amount of sky in the view in this experiment than appeared in the negative of the summer-house. Taking, then, 2·8 less ·6 as the proportion of light reflected from the deepest shadows when that of the sky was equal to 300, the intensities in the subject appeared to have varied from 2·2 to 300, or in the ratio of 1 : 136, and the only conclusion I could arrive at was that the difference was certainly no less than that; but, considering that the light of the sky and the scattered light had both been under-estimated, it was probably considerably greater, and the subject is by no means an exceptionally strongly contrasted one. I intended to have made another experiment, in which I should have given different exposures to sky and foreground, so as to bring both within the "period of correct exposure," but have not been able to find an opportunity when the light could be depended on to remain sufficiently constant.

H. J. CHANNON.

AMERICAN NOTES AND NEWS.

Dr. Goddard's Portrait.—Photographers are indebted to Mr. Julius F. Sachse for providing them with a portrait of Dr. Paul Beck Goddard in the *American Journal of Photography*. It is an enlargement from one of the first Daguerreotypes made with the use of bromine in December, 1839. We have already spoken of Dr. Goddard's researches in these notes, and have now merely to add, on the authority of Mr. Sachse, that the proofs for the assertions formerly made relative to Dr. Goddard's discovery are to be found in the minutes of the American Philosophical Society of the period.

A Palatial Business Establishment.—In its business relations photography appears to be looking up in New York. Mr. G. Genert has just completed a new business structure in the up-town part of the city which has a frontage of fifty feet, a depth of ninety feet, and contains six stories and a basement. It is of handsome and artistic exterior, formed of light buff brick and terra-cotta trimmings, with polished granite pillars up to the first floor. It is said that in solidity of construction and perfection of lighting it surpasses all buildings of its class in New York.

Sympathy with Dr. Ehrmann.—The American papers record the death of the wife of Dr. Charles Ehrmann, teacher of photography at Chatauqua, and one of the editorial staff of the *Photographic Times*. We tender sincere sympathy to our talented *confrère*.

Bogardus on Photographic Possibilities.—There is always to be found a rare mixture of genuine fun and philosophy in the ever-welcome contributions of Abraham Bogardus to the *St. Louis and Canadian Photographer*. He hits foibles and fads with amazing hardness, and yet so manages it as to avoid giving pain to any single individual. Before he retired from the profession, he was probably one of the ablest and best known of professional photographers in the United States, from the Daguerreotype onwards. The amount of money he made in the palmiest days of photography was prodigious. Speaking of the photographs at the World's Exposition being sprinkled all round, Mr. Bogardus is of opinion that, if photography continues to grow as it has done, it will, in a hundred years, be able to hold a World's Exposition for itself, and rule the art matters of the world. In the advance of photography it is wise to receive assistance from all directions. Too much self-reliance has ruined many a man and many an enterprise. Never refuse assistance because the party offering it may look insignificant; he may develop unexpected qualities. You cannot tell how far a toad may jump by looking at his tail. A good hornet, if he feels well, can break up a whole camp meeting. Who is so rash as to limit photography's future?

Still Another Tele-photo Lens.—"All tele-photographic objectives which are brought to America are copies or infringements of Krogman's Patent Lens System, which reference to part fifteen of specifications forming part of Letters Patent No. 409,981, dated August 27, 1889, will prove." This is an extract from a letter in the *St. Louis Photographer*, signed The Cincinnati Photo-optical Company. Having access to Mr. Krogman's patent of the date above given, we have carefully examined it, and find that he has not the right to make any such claim as he does. His invention consists of an

almost plano-convex achromatic lens, the flattest side of which is placed at the back or inner end of the mount; a concavo-convex, or negative meniscus, formed of crown glass alone being placed at the other, or outer end of the tube, the concave surface being to the outside. This is of the same diameter as the achromatised back lens. A second figure in the drawing shows an alternative form. In this, a plano-concave lens of crown glass, and of smaller diameter than the achromatic, forms the front lens, the flat side being to the outside. If any one will be at the trouble to draw on paper the lenses from this description, or examine the patentee's own drawings, he will see that such a combination cannot, in the nature of things, form a tele-photo lens at all. The special claim in Mr. Krogman's patent is summed up in two unequal lenses, the front being a single concave with negative focus, and the back an achromatic, with positive focus. Had he first reversed the position of the achromatic lens, and then reversed the relative positions of the two lenses, so as to have the positive to the outer end of the tube, he might have had an approximation to a tele-photo lens, although one can only guess at this, for the specification, which is very brief, contains no other information than we have here given.

American Estimate of the London Camera Club.—Referring to the falling away of interest in the Camera Club, and to members declining to contribute papers which are withheld from the public, the *Beacon* says: "It should never be forgotten that no photographic society can be healthy, or remain long so, that seeks to confine its benefits to its own members, and it may be taken as a rule that the prosperity of a society will always be in proportion to the publicity given to its proceedings."

Blackening Brass.—Here are some details of the blackening of metal diaphragms, given by H. H. Buckwalter, in the *Pacific Coast Photographer*. He dissolves an ounce of copper nitrate in three or four ounces of water. The diaphragms are then heated in the flame of a spirit lamp, and dipped in the copper solution. Without drying, they are again heated in the alcoholic flame until the metal ets a red colour, which instantly changes to black on withdrawal from the flame. It is sometimes necessary to repeat he dipping. When cool, clean the metal with a damp cloth.

The Ethoxycon.—Mr. T. H. M'Allister, of New York, who occupies a foremost place in the New World in respect of optical lanterns, has, in the World's Fair, a specially fine exhibit of these, many being new in design. Especially interesting and convenient is said to be the ethoxycon, a compact piece of apparatus, which makes the gases necessary for combustion during the working of the lantern. This, we know, has been done some years ago in this country, by Birrell and others. Meantime, no publication has yet been made of the American device.

Restrictions at Chicago.—Loud outcries are being raised against Mr. Arnold, who holds the rights for photographing at the World's Fair, and who seems to be interposing what is alleged to be difficulties in the way of others. Dr. Nicol says (in his *Beacon*) there is now an impression that he is a concessionaire, and one who, in partnership with a son of one of the Executive, got the concession without competition, and with no thought of fitness. "Is it too late to make an Augean clean out of the whole business and start on a new and different footing? The Stereoscopic Concession may be allowed to stand, it is in good hands; but, surely, the most wonderful photographic possibilities that the world has ever seen should not be continued to be sacrificed through the incompetence of an *employé* or concessionaire, even if he has as a partner a son of one of those in power." It is suggested that a staff of competent artistic photographers should be employed so as to make negatives of exteriors and interiors, and supply first-class prints at reasonable prices, which we infer has not hitherto been done.

PHOTOGRAPHIC METASTASIS.

Those of us who are in the habit of taking crepuscular effects, whether at dawn or sunset, have doubtless, at one time or another, encountered on some developed film a black circular dot situated in the midst of a series of concentric halos, alternately light and dark.

When this grotesque pictorial sun presents itself to our notice, we know that the cloud veil was too diaphanous to conceal the shape of his face, and that, though we did not, perhaps, observe it, the disc must have been visible.

Fictitious "suns" behaving in much the same way may be produced by interposing a large sheet of brown paper or cardboard, having a circular hole cut in the centre, between the camera and a pane of ground glass illuminated by daylight, gaslight, lamplight, candlelight, &c.

Again, if a cylindrical aperture over a centimetre in diameter be cut in a body of such opacity that we consider that though light may penetrate it superficially it cannot pass through, and a dry-plate film be exposed directly behind this orifice, and be protected everywhere else, we can readily develop the well-known dark fuzz or halation around the edge of the circle.

If polygonal, bluntly elliptical, or square apertures be substituted for the circular one, but little difference is noticeable in the shape assumed by the halation, and this is also the case where the hole is an equilateral triangle, or, in short, of any form whatsoever provided it be approximately as broad as it is long. Under these last-named conditions there is no series of light and dark halos, but only the dark prototype.

But, if we replace orifices of these forms by those which have some such shape as a very obtuse-angled triangle, a right-angled triangle having one side much shorter than the others, an isosceles triangle, in which the two equal sides, or a scalene triangle, in which the two sides are very much longer than the third, we observe at once that the halation falls away or disappears at the more acute angles, although present everywhere else.

This modification of our former experiments furnishes the clue, hitherto wanting, to the possible reconciliation of our camera and printing-frame experiences, and instantly suggests the means to be adopted in testing the validity of our explanation as to why, in the first instance, a series of concentric rings were produced, which, in the second case, were absent.

If, therefore, we once again revert to our printing-frame circles, ellipses, polygons, squares, or equilateral triangles, but diminish their size till they are only one or millimetres in diameter, we see that exposures which would have produced halation as usually observed, had the apertures been larger, have now no longer this effect, for instead of a dark circle, &c., with a dark halo, whose deepest edge is in complete contact, at least, with the periphery, we have a dark circle with a clear halo immediately beyond the limiting circumference.

Let us, for simplicity's sake, confine our attention to the distribution of the developed deposit in or near a circular area of the film which has been exposed to the action of light through a cylindrical aperture of about a millimetre and a half in diameter, drilled in a screen of ebony. One shade of "half-tone," but one alone, is secured by causing the beam of light to impinge obliquely upon the plate in such a manner as to cast a narrow crescent-shaped shadow on the otherwise unprotected portion of the film. The depth of tint of the shadow as it appears to the eye is not, strictly speaking, an absolute mean between the brightest and darkest parts of the film. Consequently, the number expressing the exposure, which allows the part of the film on which this shadow falls to develop into the densest bit of the film, is not a geometric mean between the numbers expressing respectively the exposures that cause the brightest and darkest parts to develop to the same maximum of density when all three are simultaneously immersed and remain equally long in the same liquid multiplier. It therefore follows that waxing and waning half densities will not be reached at the same moment, and hence, as a matter of course, that, when the two densities are equal, it will be at a period earlier or later than the geometric mean of the exposures which produce the extremes according to the amount by which the brightness of the real shadow is greater or less than half-tone. The actual brightness of the shadow will naturally depend upon the quantity of reflected light which reaches it either from the illuminated side of the cylinder or from some other effectively lustrous body. I mention this in order to show the futility of expecting that such phases or sub-phases should correspond to, or present themselves contemporaneously with, the production of the neutral phase proper (see diagram on page 185 of The British Journal of Photography for March 24, 1893). At another time I will prove, prove beyond all question, that, contrary to Messrs. Hurter & Driffield's

assertion, there are no "periods" of "under-exposure" and "correct representation" obeying separate laws. The law that *the densities are proportional to the logarithms of the exposures* is the natural corollary, the primary inference, to be deduced from, and implied by, my law as given in these pages in 1888; and, generally speaking, this is the closest approximation to the absolute truth which we have as yet been able to formulate. But, as I shall shortly show, the statement which I have put in italics is not quite sufficient, even in its arbitrarily restricted application to a supposed 'period of correct representation,' and to be precisely accurate must be somewhat modified. The amount of silver reduced by the conjoint action of light and a developer is never directly proportional to the exposure. The "inertia," or, as I prefer to term it, the resistance, is an ever-present, constantly shifting influence, essentially diabatic, and to study its transference from point to point in the film is in the highest degree instructive.

But, to realise the facts upon which these affirmations are based, it will be necessary to describe the more striking or salient forms which the image of a small circular aperture can assume, the word "image" being extended so as to embrace the various excrescential halos which under certain circumstances invariably accompany and react upon the more definitely limited disc-image. It will also be advisable, I think, to regard this latter area as a tube—a short tube of force—so as to be able to get an idea of the state in which the film may be supposed to be in *before* the developer is applied. Rightly or wrongly, I insist upon regarding the phenomena which characterise the small image as typical of the manner in which its constituent ultimate particles or molecules are affected.

The following extracts, taken as they stand from one of a host of note-books on the one subject, may now be seen to have some bearing on the question at issue. The exposure values are omitted as tending to distract the attention, and it is to be understood that several of the consecutively described peculiarities may be simultaneously displayed, *e.g.*, the aperture-image reaches greatest density, and the aperture-image begins to reverse.

(*a*) The aperture-image acquires density at first slowly, then with an accelerated rapidity, next with a retarded acceleration, and, finally, with a retardation corresponding to the initial acceleration.

(*b*) The shadow-image only becomes visible under development after the aperture-image has made its appearance and has acquired a density proportionate to the difference in the intensity of the light at the two places. When the exposures have been very short, and the developer is of normal strength, or weaker, prolonged immersion does not appreciably alter the difference between the two densities.

(*c*) When the shadow density is as far beyond the clear film, when fixed, as the shadow itself was brighter than "absolute darkness," the exposure is correct as referred to the developer employed and the duration of the immersion. These factors remaining constants, this is the only instant which produces a true representation of the subject as far as the *relative* proportion of the greatest, intermediate, and least densities may be looked upon as the (inverted) equivalents of most light, less light, and no light in the subject portrayed. Let this be reasoned out. Take, for instance, the case of a star of the first magnitude in the midst of a nebulous unresolved cluster set in a sky "as black as Erebus."

(*d*) A *clear halo* now seems to surround the dark aperture-image, and yet neither the naked eye, nor the eye when furnished with a microscope, can detect the faintest sign of the dark annulus or ring which, in some shape or form, is present at all subsequent stages. The film beyond the clear halo is, or seems to be, uniformly degraded, possibly fogged by the light employed during development.

(*e*) A faint ring, soft although narrow, darker than the marginal portion of the film, now surrounds and emphasises the clear halo, which, probably by an optical illusion, appears still clearer. For some time to come this dark ring will grow more and more opaque, and will widen, fading very gradually externally, somewhat more abruptly internally, encroaching upon, and diminishing the territory occupied by the clear halo.

(*f*) The aperture-image has now reached its greatest density. The shadow image, although very dense also, maintains nearly the same intensity compared to the strength of the aperture-image, but is much too dense *for a shadow* (*vide c*).

(*g*) The aperture-image now begins to clear. This, however, cannot be noticed by the naked eye, and requires for its detection nice photometric testing.

(*h*) The shadow-image vanishes. This is due to the fact that it, ascending, has reached the same density as the aperture-image descending. As this effect, among others, can be materially hastened by the substitution of a developer strong in alkali, or accelerator, for that which we have been employing hitherto, it seems idle, from one point of view, to deny that the ratios are not altered by the developer employed.

(*i*) Halation, as generally understood—that is, a fading fuzz, with its darkest edge in contact with the periphery of the aperture-image—now shows itself. If the screen, ebony or otherwise, is not perfectly flat and smooth, the halation will take the form of dark irregularly radiating brushes.

(*k*) The contrast between the clear halo and dark ring is great. The clear halo now presents the aspect of a vortex motion or smoke ring, owing to the double invasion.

(*l*) The clearing aperture-image is now of the same density as the darkening "clear" halo.

(*m*) The clearing shadow-image is now of the same density as the darkening clear halo.

(*n*) The clearing centre of the aperture-image is contrasted by the darkening "clear" halo. The general aspect of the entire image is that of a weak reversal.

(*o*) A dark line is now observed just within the periphery of the aperture-image. The cause is found in a fact to which I formerly drew attention, namely, that it is the central part of the aperture image which first begins to clear. As this centrifugal action goes on, the inner edge of the circle seems gradually to accumulate all the density at one time spread over the entire disc, and as the centre clears the dark margin becomes narrowed down till it is little more than an outline.

(*p*) Reversal is complete.

HUGH BREBNER.

ON THINGS IN GENERAL.

WANTED, a word! If it were not that our Editor was too great a man, and our JOURNAL too great a journal, what a boom they could create by a new word competition, or tournament it might be called! Wanted, a WORD to describe the particular sort of person who takes a photograph without the slightest intention of bettering any one else with little or no knowledge of art or science—amiably, indifferently or malignantly careless of the labours of past workers who have made latter-day photography possible! A big prize might be offered, as I am afraid the language is not expressive enough, for we see even the painter-artists are not in possession of a word stronger than "sign-painter" when they wish to refer to one not possessed of the divine afflatus spread over the gods of Burlington House. "Amateur" will not suffice. It is the lack of a suitable term that has caused the amateur and professional controversy to be as wanting in conciseness as it is fertile in expletive and declamation. Is there is a single professional of ability who does not honour the memory or the work of those on the long roll of fame who have advanced photography to its present high pitch of technical excellence? Almost every one is, or was, what is ordinarily understood as an amateur, and the present professional owes his means of livelihood to their labours. It is as dishonourable as dishonouring to hold up to photographic scorn these pioneers and apostles of progress in our science. We must look things fairly in the face. The professional photographer is earning a living by doing work which, in a way, can be done by any one who chooses to invest a five-pound note in buying the necessary materials. What is the logical result? He must attain to the utmost skilfulness possible to him, and must then hope to attract clients by the character of his work. I assert that, if he only produces work of a character that a tyro can soon equal, he stands on an inferior level to a so-called working man, *i.e.*, a handicraftsman, and cannot logically expect more pay or as much, unless he can become a master handicraftsman, and make money by employing others and reaping the profit of subdivision of labour. A really good photographer is less readily found than a really clever doctor; the others will, I am afraid, go to the wall. Some of the former also are unfortunately doing so; but, unfortunately also, photography is not alone in that respect. However, it is idle repining to talk of amateurs and the harm they are doing—this is a free-trade country. I should like to contribute my quota to the discussion of the cause of bad trade. From inquiries I have made, there seems scarcely an exception to the cry that enlarged work is falling off everywhere. It has been pointed out to me that a possible explanation may be found in the firms of enlargers supplying the public as well as professions

photographers. Here, again, free trade comes in. They have a perfect right to do so; but also photographers have an equal right to decline to deal with any firm that supplies the public. It would be the height of folly to buy from a man who offers his wares to the next-door neighbour.

The present has been decidedly an optical season; the air is big with lenses, new and old, and discussions on their merits. The tillman-Burton controversy is very amusing, but it is apt to lead to a neglect of the value of the lens in question, which possesses incontestably high merits. I wonder how many photographers there are at this minute who possess a lens that defines with such a stop as is of common use, say *f*-32., equally well in middle and margin of a plate about the same size as (or even larger than) the focus of the lens, as the concentric fairly does. Then we have the double anastigmat controversy, where a lens, evidently of great value, is concerned, as the published diagrammatic photographs prove. Unfortunately for the manufacturer, the sheet of photographs showing the performances of the various lenses loses almost all its scientific value from the fact that the lenses employed were either eccentrically placed as regards the diagrams, or the latter were not properly "squared up," a condition of affairs fatal to the value of the reproductions as scientific evidence. This condition, which instantly struck me when I saw the diagram, is explained by saying that the rails upon which the diagram-holder was placed, "though accurately directed upon the centre of the trial plates, were placed ..... not completely vertical to the plates." This explanation is meaningless as it stands, for the words are self-contradictory.

The editor is again to the fore with some valuable remarks upon the equivalent focus of lenses, and explains in the simplest of manners how, and how easy it is, to find this focus of any lens. But my experience is that few will go to the trouble of doing even such an elementary piece of work as this; they will prefer to guess at it. Now, I am about to propose a still simpler method, which will give the focus quite near enough for practical purposes. Fix the camera at one end of the room, and at the other, and right opposite the lens, place a penny or other tape measure. Focus this measure on the ground glass, and cut a strip of paper, just the same length as the tape appears to be. As it will be small, we will take it in sixteenths of an inch. Then, as the yard tape will contain 576 sixteenths, that number must be divided by the size of the image (expressed in sixteenths of an inch). All that is then needed is to measure the distance that separates yard tape from ground glass, and divide it by the number we shall obtain when we add 2 to the figures resulting from the yard tape as above. The result will be the focus, not mathematically exact, but quite near enough; and any one can perform the operation in a minute. FREE LANCE.

DODGES.*

DISTORTION.

IT may sometimes happen that, notwithstanding the use of a swing back, distortion occurs, through the camera being pointed too much towards the sky. This can be cured as follows:—First make a transparency in the enlarging camera, tilting the negative and plate for transparency until the picture appears as it should do. Develop the transparency, then make a negative from the corrected transparency; or, if the transparency is not quite right, the negative can be further corrected in the same manner, and with care the result should be satisfactory.

A SHIFTING-BACK PRINTING FRAME.

This frame I bring under your notice was some time ago broken and repaired in such a manner as to be useless, owing to the back so easily shifting. For a time it was discarded, but, since, it has been found useful in placing prints on the negatives again in cases of under-printing. Place the negative in the frame and secure it, to prevent it shifting; then place the print to be corrected as nearly as possible in its proper position, fasten up as usual, and it will be found that the back and print will shift about together, so that, by looking at, the front can be accurately adjusted to the negative with very little trouble. I find it useful when letting inexperienced persons do printing, as I can quickly correct a dozen prints, and find it a useful contrivance.

EXPOSURE.

There is often a great discrepancy in the calculation of exposure by different persons, in my experience as much as six to eleven. The pulse-beat in middle-aged persons is nearly correct for seconds. A dodge is also recommended of repeating as rapidly as possible 1, 2, 3, 4; 2, 2, 3, 4; 3, 2, 3, 4; 4, 2, 3, 4, and so on; each four figures will so nearly represent seconds that the difference may be disregarded. It is also recommended to hang from under the tripod-head a small weight on a cord forty inches long—thirty-nine inches I believe to be correct. This will give seconds each sway of the weight. A much shorter cord is undoubtedly more convenient, such as is used on an exposure meter in the market. This, to give half-seconds, should be nine and three-quarters of an inch long. The swing and return will be one second. Considering the inventive genius shown in photographic matters, I am surprised that no one has yet placed in the market a small simple, seconds-ticking instrument, so that by giving a few turns the instrument would tick seconds when required. It seems to me to be a want in the dark room when enlarging.

* Concluded from page 425.

TONING.

When I first tried gelatino-chloride printing-out paper I found great irregularity in toning; the first prints toned all right, but the last of the batch hardly got any gold, owing to the greediness of those first deals with. This difficulty can be overcome in the following manner: Suppose there are eighteen prints to tone; make up the toning bath, pour half of it into the toning dish and place six prints in it, when they are toned take them out and add half of the remaining bath to that already in the dish, and tone six more, take them out and add the remainder of the bath, and tone the remainder; all the prints will by this arrangement be toned in a regular manner. I mention this, as I have heard of this difficulty twice within the last few days.

REGISTERING CLOUDS.

This is a subject which I think deserves some consideration. Clouds too often look very funny in our landscapes, printed without much regard to lighting, and my object in mentioning this matter is to suggest a method of knowing what clouds will fit a landscape. In one of the journals some time ago there was a paper on the subject, and it was recommended to take various particulars—time of day, point of compass, &c., and a diagram—rather a complicated proceeding, and I confess I did not get quite to the bottom of it. My plan is a simpler one, and is this: Paste on the top of camera a small piece of cardboard or paper marked like the face of a watch, with the XII. pointing the same direction as the lens. When a plate is exposed, draw an imaginary line from centre of cardboard to the sun, and mark the plate in your exposure plate the number the line intersects—say it is 8, No. 8 cloud and No. 8 landscape will always fit; No. 8 cloud reversed will fit a No. 2 landscape, and so on. The number need not be very exact—a No. 5 or No. 7 cloud may do for No. 6 landscape. I don't say the cloud will suit, I only say the lighting will be the same. The altitude of the sun should perhaps be taken into consideration, but this can be readily discovered by referring to your note-book for the time of day the negative was taken. This system is easy of adoption; it is not necessary even to have a diagram on your camera, for your watch on the top after each exposure, a note of the number can be obtained.

PRINTING CLOUDS.

I have very little time for cloud-printing, and am obliged to adopt the following rough-and-ready dodge to print clouds quickly. For this method you must have a thin negative. I do not use a frame but paste brown paper to the bottom and top, place the print on the negative, and turn the brown paper at the top and bottom over the print. I then place the back of a printing frame in the usual way, and clamp one side to the negative, holding the other between finger and thumb of left hand. I shade the front portion with brown paper or anything that comes handy, roughly follow the outline with wool, and print in direct sunlight. Should there be a tower or high building with sharp outline print it on a separate piece of sensitised paper, cut it out correctly, and stick it on the print, and proceed to print from the cloud negative. Nearly all my clouds are done in this manner, and only take a very short time each.

One other contrivance I will mention, and that is, a convenient way of drying sensitised plates. You may attempt to develop a plate not exposed, don't throw it away, well wash and dry. There may be other occasions when you may be puzzled for the want of a drying cupboard. For a few plates it is not necessary to have a cupboard, use your old plate boxes. The shape I show you is excellent (a sliding box) when you have a plate to dry. Let it drain, wipe the back, place in the empty box film side up, and close. You will find it quite dry in the morning, presuming the box had previously been kept in a dry place.

C. O. GREGORY.

SEASONABLE NOVELTIES.

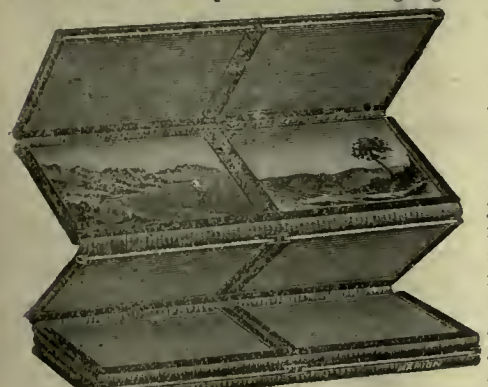
Fallowfield's New Hand Cameras.

Premier Hand Camera.—This neat hand camera is so designed that all the adjustments can be made from the top of the apparatus, all the scales being in full view when in use. While compact, it is light, and strongly made. The drawing conveys an idea of its appearance. It is equally suitable for hand or stand. The one we examined carries twelve plates, or twenty-four films. The lens is Wray's well-known rapid rectilinear hand-camera lens of 5¼ in. focus, fitted with four stops which are changed from outside by the milled head and indicator, and the lens can be instantly taken out for cleaning purposes. The self cap works automatically, so that the lens is always covered except at the actual moment of exposure, and for time exposures can be held open by a turn of the small knob in front. Two finders with metal hoods are provided, giving the identical view on plate, for either landscape or upright picture. The shutter works between the lenses, and being provided with Newman's pneumatic regulation, can be set for exposures of any duration from $\frac{1}{10}$ to one second by the milled head on top of camera. It is set by pulling up the small ebonite knob, and released by pressing the small button below. It is absolutely accurate in working. Focussing is done instantly by central rack and pinion sunk flush below. A scale of accurate distances, 6, 9, 12, 18, 25, 35 feet and infinity, is fitted on top. For use on tripod a light celluloid screen (carried behind changing box) is provided.

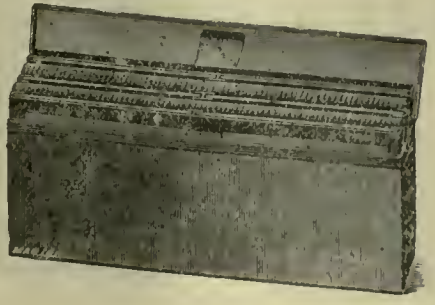
The Focussing Facile.—With the assistance of the cut and the following description, a good idea of this, the latest "Facile," will be had. Focussing is done by adjusting the indicator from six feet to infinity, or at any fixed focus desired. The shutter is fitted with a spring release, giving exposures of any duration, and it is always set. The finders are deeply sunk and thus shielded from the light, and give the identical views as the lens. The plate changing is effected by simply pointing the arm of the indicator to any number of plate on the scale. The finder, focussing scale, and shutter are on the top just under the eye, so that each can be rapidly manipulated. It is finished in dull grain black and has a good although non-pretentious appearance.

Marion's Negative Holders.

This is a safe and simple means of storing negatives for easy inspection and exhibition. Any negative may be inspected and removed without disturbing the others. The negatives are held in independent grooves, and they cannot injure each other. The negative holders, as shown in the cut, are neat metal grooved frames, hinged together with flexible joints, and so arranged that any negative contained therein may be easily inspected and withdrawn. They are folded and enclosed in a japanned metal case, with hinged lid. (See cut.)



They are much more portable and compact than ordinary grooved boxes, and their use obviates the necessity of lifting out of their grooves a number of negatives in looking for those desired. They are destined to become popular, especially as they sell at a very low price.



Our Editorial Table.

The Eastman Company's Publications.

115, Oxford Street, London.

These include pamphlets relating to the Kodak, Solio printing-out paper, the new Nikko paper, with a comprehensive list of the manufactures of goods sold by the Company. From a note we have received concerning the Kodak, we learn that Kodaks and films are very much to the fore in all scientific expeditions and especially in the recent expeditions fitted out to "catch" the North Pole. "Lieut. Peary has taken with him to Greenland, on this last trip of his, no less than five Kodaks and 2500 extra film exposures. You are no doubt aware that he brought back with him about 2000 good negatives, taken on his last trip. Mr. Johnson, another explorer, has also taken to Labrador a No. 2 Kodak and 500 extra exposures. Also Dr. Nansen has taken with him on the *Fram* to the Pole (but whether he will bring them back or not is very doubtful in the opinion of experienced scientific men in this country) a No. 4 Junior Kodak, and a half-plate roll holder, and over 1500 extra exposures." The tractates received include *How to Make Glossy Prints without a Burnisher*, the directions applying both to Solio and Nikko paper; also *The Hypo Toning Bath for Nikko and Bromide Papers.* It is enough to say here that we have followed the directions with great success. Meantime, as we are preparing an article on the hypo-toning bath as applied to these papers, we shall defer special notice of it till then.

Enlarged Convention Group.

This enlargement, by Morgan & Kidd, Richmond, is one of the sharpest and finest of which the art seems capable. The degree of magnification will be ascertained when we say that the Convention group which so recently appeared in these pages has been enlarged to 22 × 16 inches without the slightest blemish or blur.

Fallowfield's P. O. P. Mountant.

Among the various mountants now in the field, this of Fallowfield's will hold a good place. It is white, very adhesive, and contains some antiseptic by which it is prevented from ever going bad. We have proved its good properties.

Mr. C. C. Vevers, Leeds, has issued a price-list of second-hand photographic and lantern apparatus, shop-soiled stock and job lots, from which selections may be advantageously made.

News and Notes.

Messrs. R. W. Thomas & Co. will shortly place the "Sandell" multiple-coated film on the market.

Northern Photographic and Scientific Association.—August 7, Burnham Beeches and Stoke Poges.

Gosport Photographic Society.—August 7, Arundel. Leaves Portsmouth Harbour at fifty minutes past nine.

We are informed that Messrs. Brown, Barnes, & Bell, of Manchester and Liverpool, have reopened their studio at 12, Baker-street, London, W.

Photographic Club.—July 9, Members' Open Night. Bank Holiday Outing to High Wycombe. Leader, Mr. A. Broad. Train from Paddington at eleven o'clock.

Hackney Photographic Society.—August 5, Excursion to Radlet. Leaves Moorgate-street, Midland Railway, by the nineteen minutes past two train for Radlett. 8, *Composition.*

In the Liverpool District Registry of the Chancery Division, High Court of Justice, on the 8th ult., Messrs. Brown, Barnes, & Bell, photographers, of Liverpool, obtained a perpetual injunction restraining Mr. John Ashley, of 87, Bold-street, Liverpool, and Ormskirk, from carrying on the business of a photographer under the style of Brown, Barnes, & Bell, and from representing that the business he is now carrying on at Liverpool and Ormskirk is the business of the plaintiff, or in any other way a part or connected with it.

Bristol International Photographic Exhibition.—The Council of the Bristol and West of England Amateur Photographic Association announces the Triennial International Exhibition of photographs, apparatus, appliances, and processes, to be held in the galleries of the Academy of Arts, Queen's-road, Clifton, Bristol, will be opened on Monday, December 18, 1893, continuing open till Monday, January 22, 1894. Apart from photographs for competition, the Council will esteem it a favour if those who have any interesting examples of the history and progress of photography will kindly lend them for exhibition. All pictures, apparatus, and contributions of any kind will be insured at the expense of the Association. Especial care will be bestowed on the hanging, so that all pictures shall, as far as possible, be done justice to, to facilitate which the whole of the extensive galleries above referred to have been retained. Thirty-six medals, including one gold and twenty-one silver, are to be given. A fee of five and ten shillings, according to space, will be charged each exhibitor.

Photographic Survey of Warwickshire.—On Monday there was opened to the public at the Birmingham Museum and Art Gallery an exceedingly valuable and interesting collection of photographs of Warwickshire landmarks and scenery. The exhibition is the result of the second year's work of the members undertaking the photographic survey now being systematically carried on under the auspices of the Birmingham Photographic Society. Last year, it may be remembered, something like 700 pictures of old and famous buildings —some of them since swept away by the ruthless hand of the present-day "restorer" and speculative builder—were hung in the Art Gallery; and at the close of the exhibition, by a happy idea, they were presented to the Corporation for preservation on behalf of the public. The present exhibition consists of nearly 500 photographs, and, at its close, these also will be presented to the Corporation. The survey, it may be explained, is being carried on voluntarily by the members of the Birmingham Photographic Society, who at their own expense defray all the costs involved in the taking and preparation of the views. The cost of mounting, preparation of catalogue, &c., which is very considerable, is defrayed by the Warwickshire Survey Council (who also provide the oak frames in which the photographs are publicly exhibited) by the help of subscriptions and donations.

Leytonstone Camera Club.—August 5, Open Social Evening at Headquarters, eight o'clock. 7 (Bank Holiday). Burnham-on-the-Crouch. Leader, Mr. A. E. Bailey. The Club will proceed by the train leaving Liverpool-street, G.E.R., twelve minutes past eight, calling at Stratford twenty-eight minutes past eight, arriving at Burnham fifty-six minutes past nine The Club will also attend the Firemen's Fête and Competition on the Essex County Ground, Leyton (open all day).

Ashton-under-Lyne Photographic Society.—Excursion to Liverpool, 29th July, 1893.—Considering a dark and drizzly morning, a goodly number attended, led by Mr. Chas. Lord, who had secured a permit to photograph on the docks, also a permit from the White Star Line to view and photograph the R.M.S. *Majestic* The ship had just been beautified, and those who had cameras soon had them in position, and secured rare and good pictures. After this a number of plates were exposed on ships, &c., amongst them being a good picture of one of H.M. Troopships. Over sixty plates were exposed.

No. 14,604.—"Improvements in Frames for Photographs, Opalines, and other Pictures." P. Campbell.—*Dated July* 29, 1893.

PATENTS COMPLETED.

A New or Improved Process and Combination of Materials for the Treatment of Photographs previous to Colouring.

No. 6906. L. M. Williams, 1, Camden-place, Bath, Somersetshire. *July* 1, 1893.

My invention relates to a new or improved process in the treatment of photographic prints, for imparting thereto a perfectly translucent enamelled or ivory surface, sufficiently brilliant to constitute a finished picture, and which may, if desired, be tinted or coloured in an elaborate and most artistic manner by the application of suitable oil colours upon the back surface thereof, whereby the lighter or more delicate tints, as well as the heavier or more pronounced colours, appear with added brilliancy upon the face of the picture, and I intend that my said process shall be commercially known as "Mrs. L. M. Williams's Enamel Process."

In carrying my invention into effect, I procure a sheet of perfectly clear glass, which I clean with white wax, and edge the same with mucilage, gum, or other, preferably, transparent adhesive substance, the waxed portion of which may then be coated with collodion, and permitted to stand aside until perfectly dry, which, under ordinary conditions of temperature, will generally occupy about six hours, when a well-mixed solution of gelatine and glycerine, in equal parts or thereabouts, may be poured over the plate, and again placed aside until quite dry and hard.

The surface of the glass thus prepared is then well wetted, and upon this is carefully placed (also wetted) the photographic print, with the albumenised side downwards, which, after being treated with the squeegee, is put aside and allowed to stand for about twelve hours, more or less, according to atmospheric conditions, at the expiration of which time, or any reasonable subseqnent period, the whole is then immersed in a bath of hot molten wax, with a photographic print uttermost, and allowed to there remain until the print becomes perfectly transparent, when it may be removed from the bath and placed aside until quite cold. I then remove the picture from the glass by carefully cutting around the gummed edges thereof with a sharp knife, and by the means of the same instrument I remove the glaze from the print, thereby leaving upon the picture a clean, bright ivory surface, of sufficient brilliancy to constitute a finished picture, which may then, if desired, be mounted and framed in the usual way.

If the picture is to be tinted or coloured, I place this face downwards upon a sheet of perfectly clean glass, and retain it smoothly thereon by the application of mucilage, or its equivalent, at each corner, when, by reason of the perfect transparency of the picture (rendered so by the process through which it has passed) every detail of the print will be clearly read upon the back surface, and may then be painted in oil colours to any degree of artistic finish desired, and when quite dry the picture may be removed from the glass, when it will be found that the front of the print has a most beautifully enamelled ivory surface, and showing every detail of colour and tint that has been given upon the back surface, and with a brilliancy not attained by any system hitherto employed. The picture may then be mounted and framed in any manner desired.

The claim is:—The herein-described process, and combination of materials, in the treatment of photographic prints, for imparting thereto a perfectly transparent enamelled ivory surface, which may or may not be afterwards coloured or tinted by the application of suitable oil colours to the back surface of same, substantially as herein described.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

JULY 27,—Mr. A. Cowan in the chair.

Mr. J. COLE said he was making a hand camera with a front which would allow the lens to be used at the extreme edge of the plate. He promised to show the camera at a future meeting.

URANIUM TONING OF PLATINUM PRINTS.

Mr. J. S. TEAPE, in reference to his experiments in the uranium toning of platinum prints, referred to those in which silver, if any present, had been removed, and said it had been suggested that mercury might have remained, which would have accounted for the toning action. In a more recent experiment he had used bichromate of potassium and hydrochloric acid as a means of reducing the silver, if there were any in the paper, to a state of chloride. The print was then washed and put in hypo, as before, for twenty-five minutes. The print was cut in halves, and one half treated in the manner described; then both halves were placed in the uranium toning solution for half an hour, and the two halves toned to precisely the same colour.

Mr. H. HADDON, on chemical grounds, could not understand the reducing action of platinum on potassium ferridcyanide.

LESS CUSTOMARY USES OF ORTHOCHROMATISM.

Mr. W. E. DEBENHAM showed two photographs of a violin. In one the inlaid brown wood was not visible, and neither he nor the possessor of the violin was satisfied with the result. He then prepared a dipped plate, which he used with a deep yellow glass, with the result that a much better result was obtained, the detail being clearly visible. He used an ordinary Britannia plate, dipped in a bath of erythrosine, 1 :10,000, for two minutes, and not washed before being allowed to dry. Ammonia was not necessary. He found that with purchased orthochromatic plates he could not get clearness.

Mr. C. H. COOKE agreed with Mr. Debenham that dipped plates gave superior results. He always used a dipped plate when copying old silver prints.

In reply to a question,

Mr. DEBENHAM said that with the dipped plate the exposure was very much prolonged, though he had forgotten to what extent. He used the coloured glass placed in an extemporised stop in front of the lens. He always used the stop in front of his portrait lenses.

Mr. J. S. TEAPE said he could not get clear results on commercial orthochromatic plates. When using them he found a material sold by Christy & Co. far superior to cherry or golden fabric, to answer well for dark-room illumination. He asked how long dipped plates would keep.

Several members thought they would keep for at least a fortnight. After further discussion on orthochromatic plates, the meeting terminated.

Amateur Photographic Association.—A Council Meeting, to award the prizes, was held July 11, at 58, Pall Mall, the Right Hon. the Lord de Ros in the chair.—The minutes of the last meeting having been read and confirmed, the following members were elected:—R. Darlington, Esq., F.R.G.S., Lady Agnes Dalton Fitzgerald, Newton W. Emmens, Esq., and James Gale, Esq., LL.D. The following resolution was proposed by Mr. Milne, seconded by Mr. Howard, and passed by the Council:—"That, in the event of exhibitors sending in their own prints for competition, members be allowed in future to print clouds into their pictures, it being understood that the clouds added are from negatives taken by themselves, and that a notification to this effect be stated on the exhibit." The SECRETARY (Mr. A. J. Melhuish) stated, in reference to the "British Museum of Portraits," that, in accordance with the wish of the authorities at South Kensington Museum, he proposed in future to send, affixed at the back of each portrait, the place and date of birth, and such other particulars as each person chooses to send, with their autograph at the foot. This was approved by the meeting, and it was considered that it would greatly enhance the value of the collection. The Secretary then laid before the Council the pictures for the current year, which had been arranged and classified by Mr. Glaisher. Class I. consisted of 160 pictures (the largest number of first-class pictures yet contributed). Class II. comprised 130 pictures, and the remainder were contained in Classes III., IV., and V. The pictures in Class I. were contributed as follows:—C. Stephens, 4; Lord de Ros, 1; R. Murray, 6; F. E. Currey, 1; W. S. Hobson, 4; F. S. Schwabe, 4; Major Board, 4; General Sladen, 2; R. O. Milne, 17; R. Leventhorpe, 11; the Earl of Rosse, 2; J. T. Black, 3; M. de Dèchy, 8; Colonel Foster, 3; F. G. Smart, 8; Arthur Dresser, 12; H. Emmons, 6; Mrs. Wrigley, 12; E. F. Scongal, 1; E. Kennard, 5; Viscount Maitland, 6; Jerome Harrison, 31; and Lady Agnes Fitzgerald, 1. Besides these, some very fine bromide enlargements were exhibited by Mr. Milne, which were greatly admired. The following prizes were awarded:—First prize to R. O. Milne, a large silver goblet, for Nos. 49, 51, and 52; second prize, a silver goblet, to R. Leventhorpe, for Nos. 235, 237, and 238; third prize, to Jerome Harrison, a silver goblet, for Nos. 5, 8, 117, and 123; to Arthur Dresser, a silver medal, for Nos. 29 and 89; to H. Emmons, a silver medal, for Nos. 1, 2, and 3; to F. G. Smart, a large landscape album, for Nos. 54, 53, and 57; to M. de Dèchy, a portrait album, for Nos. 1 and 77; to R. Murray, a portrait album, for Nos. 292, 298, and 299; to Mrs. Wrigley, a silver medal, for Nos. 20, 21, and 23; to Major Board, a medal, for Nos. 13 and 14; to Lady Agnes Fitzgerald, a medal, for No. 5; to E. Kennard, a medal, for No. 6; and to Colonel Foster, a medal, for No. 13. It was proposed by Mr. Glaisher that a special medal be given to Mr. Milne for his magnificent enlargements. This was seconded by Mr. Howard and passed. Mr. Dresser's pictures of the *Wild West* were specially noticed as being of exceptional interest. A vote of thanks was proposed by Mr. Milne to Mr. Glaisher for the time and care spent by him in arranging and classifying the pictures. This was seconded by the Earl of Rosse and passed.

North Middlesex Photographic Society.—The first of the new series of Instruction Evenings was successfully brought off on July 19. The subject was *Development Modified to Soften Harsh Contrasts or Under-exposure.* As the lecture and demonstration were for the benefit of tyros, an elementary statement of the generally accepted views as to the action of light upon the sensitive plate was given, and the properties of the reducing agent, the restrainer, and the accelerator explained. The reasons for and against the use of sulphite of soda as a preservative were stated, and beginners were advised either not to use it at all, or in smaller quantities than generally given. Messrs. Hurter & Driffield's views of the impossibility of altering density ratios by development were briefly stated, and Mr. C. H. Bothamley was quoted as showing that, while the density ratios might be unalterable, the printing qualities of the negative and their modification were well within the hands of the worker. For the purposes in view, the developer recommended was:—Pyro, ¼ grain; bromide of potassium, ½ grain; carbonate of soda, up to 12 grains; water, 1 ounce. When the shadow detail was out, this developer must be thrown off and a fresh one substituted, containing pyro, 2 grains; water, 1 ounce; no bromide or soda. Plates exposed at the special outing to Kingsbury, on July 15, were then developed, and appeared to be satisfactory. Prints from them were to be shown at the meeting on July 21. The next Instruction Evening will be on August 23, the subject being *Development Modified to Improve Flat Subjects or Over-exposure.* Visitors are welcome.

JULY 24, Mr. C. C. Gill read a paper, entitled *Notes on Printing.*—He confined himself solely to the practical side, ignoring the historical and theoretical. He dealt with the ordinary silver albumenised print, which, he said, was being ousted by the gelatino-chloride, which gave finer and more permanent results and was equally economical. He advised that Solio paper, notwithstanding the directions of the Company, should not be printed in direct sun; he found the sun shining on to a blind was a capital light to print by, and, where printing was done in the open, to be done in the shade in a north light. He showed a great number of specimens, principally of portraiture, on this paper, which gave splendid results. For portraits he recommended the mauve shade. Dealing with platinum, he demonstrated the development of the cold-bath process, the ease of working which was generally acknowledged. He gave hints as to vignetting, showing masks made of zinc with serrated openings, which, he said, were more useful than those made from any other material, it being very pliable, and thus allowed the opening to be enlarged or otherwise with the greatest facility. An interesting discussion followed. Mr. H. Smith took first place for pictures at the London Colney outing.

Northern Photographic and Scientific Association.—July 20, Mr. Robins (President) in the chair.—Mr. COULTER delivered a lecture on *The Chemistry of the Dry Plate.* A considerable amount of discussion took place after the lecture was over, and eventually a hearty vote of thanks was accorded to Mr. Coulter, to which the latter gentleman made a suitable reply. Mr. COGHILL reported the result of the excursion to South Kensington Museum, and spoke in high terms of the kindness and courtesy extended to the members of the party by Mr. George Murray, one of the Curators of the Botanical Section of the Museum. Mr. GOODHEW reported the result of the excursion to Battersea Park, and handed round some photographs he had taken in the sub-tropical gardens, which were very beautiful. He referred to the courtesy of those in charge of the park, who assisted the party in every possible way. At the excursion to White Webbs Park and Enfield no photographs were taken, as the weather was unpropitious. Dr. Atkinson and Mr. W. V. Haylett were elected auditors for the ensuing year. Five new members were enrolled. A class for beginners is in course of preparation, and those wishing to join are requested to send in their names at once to the Secretary, 32, Park-avenue, Woodgreen, N.

Hackney Photographic Society.—July 18, the President (Mr. Houghton) in the chair.—Various books were added to the library. Mr. POLLARD showed and explained his reduction camera. Mr. HENSLER asked how to intensify a film which had had retouching medium on? Mr. R. BECKETT advised use of turps first to remove retouching medium, and proceeding in the adopted manner. Mr. BARNES asked the best way to develop an old plate? The HON. SECRETARY said, "Use less alkali." Mr. T. H. SMITH asked what proportions of amidol should be used to develop a much over-exposed Cadett plate? Mr. BECKETT said, "Reduce the quantity of sulphite solution to quarter the quantity, four grains bromide, and double the amidol." The HON. SECRETARY (Mr. W. Fenton Jones) then read a paper on *Exposure Tables and Meters.* He advised, before actual practice, overhauling camera, backs, dark room, to see if white light was perfectly excluded, and, when using lens, to cover up diaphragm slot. The sun's position had a great deal to do with time of exposure. Use as large a stop as possible consistent with good defining powers. Rain cleared the air, and many a good picture could be taken when raining. Would not advise judging by amount of light through diaphragm stops. Experience and judgment are best, but a table or meter to start with is advisable. Exposure of bromide plates and papers are best tested by giving varying test exposures, and then according for future use. Plates were not always the speed they purported to be. Mr. PENNY asked, "Was it best to use one table and plate?" Mr. HENSLER had used Watkin's, but not successfully. Mr. MUNN had used Hurter & Driffield's, saving himself a lot of plates. Mr. HAWKINS asked about Cadett's developer being a quickener up of plates. Mr. W. FENTON JONES said he did not study the developer when exposing, and thought it erroneous. Would advise one plate and one table, and that of a simple kind. Mr. AVENT had used nearly every table in the market, and said that, whilst he had found them right around London, in the country they had given him wrong exposures. He was of the opinion, too, that a table should be as much simplified as possible.

JULY 25, Mr. W. Houghton presiding.—Members' work was shown from Messrs. Beckett, Guest, Munn, and Roofe—Question by Mr. Fort: "What is the best varnish for films?" Reply: "Messrs. B. J. Edwards & Co. supply a good one, use cold." Mr. Hensler asked, "Should one aim at softness or contrast in statuary?" Reply: "Softness. Study the lighting. A dark background is generally used because it will permit of more contrast. The range of tone should show relief." Mr. Selfe showed a print in which the sun was solarised, and a second reflection, due to one of the

surfaces of the lens, appeared over the foreground of the print which was weak enough to escape reversal. Mr. Morgan then read a paper on Messrs. Hauff's metol and glycin. He said the class of work which suits amidol will also suit metol. The chief difference is that amidol requires no alkali, metol will tolerate almost any amount—preferably potash carbonate. For bromide papers metol with three parts of their "A" developer to one of "B" will gives as good results as the best ferrous-oxalate ones in half the time and with half the exposure. Experiments were made under same circumstances. Thirty seconds proved correct for ferrous oxalate whilst only fifteen seconds for metol. Afterwards seven half-plate negatives were developed in the same two ounces of metol developer and no difference in density could be detected amongst them. Metol will keep indefinitely. But only half the exposure necessary for pyro is sufficient for metol; this is essential. A plate was developed with metol, in eight seconds the image flashed up strongly at once, but development was continued till dense enough without fear of fog. Over-exposure gives flatness. Negatives and prints were shown, one three seconds with pyro, against one and a half seconds with metol; the pyro one was hard and the metol one soft. The peculiar speciality for glycin is for black and white line subjects, it *must* be used on very dilute form, and its action is nearly automatic, as time will bring varied exposures to full density without its going beyond. For hand-camera work either time or stop can be reduced to half. Generally develop a little deeper than that for pyro, as it prints quicker, because there is no stain and it loses little in fixing. Warm tones can be obtained by development, but it takes too long. Either amidol, metol, or glycin, developed plates can be toned, intensified, or reduced as others. Amidol will stand forcing better than metol.

Brixton and Clapham Camera Club.—July 18, the President (Dr. J. Reynolds, F.R.G.S.) in the chair.—A member of the newly formed Committee of Instruction was present for the purpose of assisting less-experienced members in the more elementary principles of photography and answering questions relating thereto. The attendance of members showed the necessity for forming such a committee, and it is believed that the result of such a step will be to strengthen the number of members of the Club to a considerable extent. This was the first attempt in the history of the Club to form such a committee, and at the meeting two nominations for membership and promises of others were given in. Mr. BALDWIN, of the Eastman Company, gave a very interesting demonstration on *Solio Paper*, and toned several prints by the separate and combined baths with great success. Members were invited to comply with the request of the Photographic Society of Great Britain for a representative set of lantern slides and results of modifications of the several printing processes, and the meeting was then closed. The next meeting will be held on August 1, when Messrs. Fuerst Brothers will demonstrate the working of *Amidol*.

South London Photographic Society.—July 17, the President (Mr. F. W. Edwards) in the chair.—Messrs. Dicker and Tredray were elected members. The evening was devoted to the discussion of methods of combination printing. The following were suggested:—Draw round the outline of the object to be printed with a thick pen filled with Indian ink. When the ink is dry, block out the remainder of the negative with black varnish, and, when dry, print. The printed image can now be covered with gamboge or other non-actinic medium (which can be removed during washing), and the balance or such portion of the picture as is required obtained from a second negative. Care must be taken to print both portions equally. If any white lines appear round any portion of the finished picture, these must be filled in with colour, care being taken to match the tint of the picture. Alternatively the second negative may have blocked out a portion of equal shape and size to that printed by the first negative. To print skies in pictures where there is not a large quantity of fine foliage against the sky, a print is made on silver paper, and the landscape portion is carefully cut off from the sky with a sharp penknife or scissors, and the two portions of the print allowed to discolour, and used as masks, one being used to cover the landscape negative when the sky is being printed from, the sky negative and the sky portion used when the landscape portion is being printed. This must not be printed too deeply, or they will have the appearance of being in advance of the landscape. The PRESIDENT suggested stripping the negatives with cresco-fylma, and cutting out portions of the stripped films, and combining them on an old negative glass. By this method prints are obtainable by one printing, and a considerable saving of time effected where a large number of prints are required.

Liverpool Amateur Photographic Association.—July 27, Mr. William Tomkinson in the chair.—The following gentlemen were elected members of the Association:—Mr. Thomas A. Collinson, Rev. J. F. Anderson, and Mr. Edward R. Dibden. Mr. J. A. Sinclair (Messrs. Adams & Co., Charing Cross-road, London) showed the latest photographic specialities and novelties, including the "1894" Adams camera, with swing back and rising front, the Ideal cameras (ordinary and twin lens), "Lightning" stand, pantoscopes, aluminium view meter, "Adjustable" shutters, club cameras in brass and aluminium, &c.

FORTHCOMING EXHIBITIONS.

1893.

September 5..... *Royal Cornwall Polytechnic Society, Falmouth. W. Brooks, Laurel Villa, Wray-park, Reigate.
,, 20-21..... *Hove Camera Club. Hon. Secretary, H. Emery, 142, Church-road, Hove, Brighton.
,, 25-Nov. 15... *Photographic Society of Great Britain, 5A, Pall Mall East, S.W. Assistant Secretary, R. Child-Bayley, 50, Great Russell-street, W.C.
October 1-31 ..... *Hamburg. Das Ausstellungs Committé des Amateur Photographen Verein, Schwanenwik, 33, Hamburg.
,, 9-Nov. ... *Photographic Salon, Dudley Gallery, Piccadilly, W. Hon. Secretary of Organizing Committee, A. Maskell, 215, Shaftesbury-avenue, W.C.
November 7-11 ..... *South London Photographic Society. Hon. Secretary C. H. Oakden, 53, Melbourne-grove, Dulwich, S.E.
,, 20-25..... *Leytonstone Camera Club. Hon. Secretary, A. E. Bailey, Rose Bank, South-west-road, Leytonstone.
December..... *Madras. The Hon. Secretary Amateur Photographic Society, Madras.

* Signifies that there are open classes.

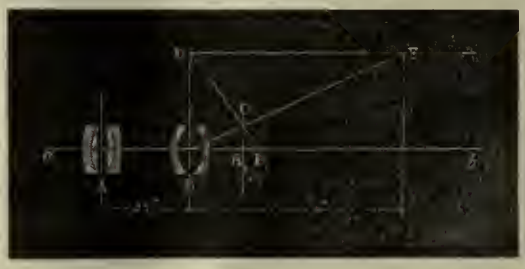
TELE-PHOTOGRAPHIC SYSTEMS FOR MODERATE AMPLIFICATIONS.

To the EDITOR.

SIR,—The appearance of an article on the above interesting subject, from the authority to whom we owe its introduction to the photographic public, leads me to think that you may perhaps find a corner in your JOURNAL for the following items bearing on the matter. The methods here described for ascertaining the positions of lenses and screen, though differing from those in the article referred to, have the merit of being most simple, requiring no complicated calculation, and are likely therefore, to commend themselves to those for whom equations have never had much charm. These methods are the result of studies of my own, and I would not trouble you with them were it not for the fact that nothing similar to them has, to my knowledge, yet appeared in any of the journals.

The first is a diagram, from which the operation of these systems of lenses appears to me to be very clearly shown. In the accompanying



figure, *a b* is the axis of the combination extended away towards the focussing screen. The positive lens at A has its focal plane at A_1 (I have taken for these examples lenses of the same focal length as those referred to in Mr. Dallmeyer's paper, though, naturally, the system is applicable to any others that may be thought of, and set down the drawing to a quarter-inch scale). The negative element, B, of three inches focus, is placed anywhere between A and A_1, so that its focal plane, B_1, may not cross that of A. In this example, the distance of B from A is three and three-quarter inches. In speaking of the distance between the lenses, it is understood that the distance referred to is that between their nodal planes. Perpendiculars are drawn through the nodal point of B and through the focal plane of A at A_1. At any distance from A_1 a part A_1C is taken in this focal plane, representing the size A_1C of an image formed by the positive lens alone. This measurement is purely an arbitrary one, but for convenience sake it should be small. From B_1, through C, draw B_1CD, meeting BD in the point D. The distance BD will now bear that proportion to A_1C which the focal length of the combination bears to that of the positive lens alone—in this case twenty-four to six, or an amplification of four times. The position of the focus screen will be now shown by drawing a line, DE, through D and parallel to *a b*, and a line from B through C to meet it at a point E, which will then mark the distance from B at which the focus of the combination will be found, in this case nine inches. It will be seen that, while the focal plane of A is stationary at A_1, that of B at B_1 follows every alteration of the position of B, and that a line through B_1C will meet BD at a greater distance from the axis of the combination as B moves towards A, and at a nearer point to the axis as B is further removed from A. Therefore, if B be placed at any distance from A, with its focal plane always behind that of A_1, by means of the lines drawn through C, its enlarging effect upon an image produced by A alone, and from this the equivalent focus of the whole (that of A being known), and the distance of the screen from the back lens can always be found. In any case the drawings should be carefully made to as large a scale as possible.

The method above described can be worked out for any combination of lenses, using, of course, the corresponding measurements, and results arrived at in a ridiculously short time, once the simple plan is learnt, and the effects of greater and less separation become so much clearer in a diagram than is possible in the case of a mathematical calculation.

In the second method of calculation I take the focal lengths of the two elements, positive and negative, and multiply them together, placing the result as expressing a fraction, of which the focal length I desire to obtain is the divisor. This result, although apparently of no great value to the process as it represents the distance between the focal planes A_1 and B_1, in the diagram above; but, as Mr. Dallmeyer points out, this factor is by no means an unimportant one, as it affects the results to as great an extent as the very foci of the lenses themselves. Having found this, the distance of separation of the positive and negative lenses is the difference between their foci *plus* this fraction aforesaid. Then follows the last calculation which gives the focus inherent in the elements in their respective positions, and, by subtraction from the focal length required, the back focus or distance from the back lens to the screen. Although apparently complicated, the last calculation is simply this:—The separation of the lenses is multiplied by the focus of the negative lens and divided by the fraction representing the separation of the focal planes, giving as a result the sum which is to be deducted from the equivalent focus decided upon to give the back focus or distance to the screen.

Let us calculate the combination referred to by Mr. Dallmeyer on this basis:—

(1) 6″ Pos. × 3″ Neg. = 18 ÷ 24 equivalent focus required = $\frac{18}{24}$ or $\frac{3}{4}$ separation of focal planes.

(2) 6″ Pos.—3 Neg. = 3 + $\frac{3}{4}$ as above = $3\frac{3}{4}$″ separation nodal planes.

(3) $3\frac{3}{4}$ or $\frac{15}{4}$ + $\frac{3}{4}$ (3 being the focus of negative lens) = $\frac{45}{4}$ ÷ $\frac{3}{4}$ (separation of focal planes) = $\frac{45}{4}$ + $\frac{1}{3}$ = 15 deducted from 24″ equivalent focus required gives 9 inches back focus.

As the degree of enlargement and intensity of aperture can be so easily ascertained when the equivalent focus of the combination and its relation to the focus and aperture of the positive lens are known, these detailed are not referred to.

It occurs to me that with a working intensity of *f*-8 in the positive lens, and four degrees of enlargement or *f*-32 in the combination, no great degree of rapidity can be expected, and that, when circumstances might demand it, a greater separation of the lenses and reduced amplification would be desirable, conducing as they would to enlarging the available aperture, and gaining in rapidity—or are we to take it that definition is likely to be unsatisfactory if a larger aperture than *f*-32 be used.

In the matter of the portability of several negative lenses of various foci to use with a single positive lens or combination, and give various degrees of enlargement, I fancy that, seeing that, in the case of a positive lens of six inches focus, these would require to be all of a power higher than this, and necessarily, if of large diameter, as recommended, of appreciable weight, that the advantage will not be great enough to compensate for these disadvantages, apart from the expense of such a battery of perfectly constructed lenses, and the fact that the beauty of the tele-photographic combination is its power of giving pictures of any size at any distance from an object, subject only to conditions of actinic intensity and available camera extension. Combinations of two negative lenses of dissimilar focus might be made so that they would give three ranges of power, or why not have interchangeable positive lenses with their correspondingly and necessarily modified lengths of tubing, for this latter condition would probably be required in the case of a variety of negative lenses. The same tube length would rarely do for two different lenses. I think that, rather than increase the already necessarily portly size of this useful adjunct to photography, the aim should be to reduce its size as much as possible. As the normal focus of a lens for parallel rays becomes so much increased when used for near objects, I do not recommend a great difference between the power of the positive and negative lenses, as this practically puts it out of the field when used under these circumstances. Where the distance between the nodal planes is small for distant objects, the lens is available for nearer ones without necessarily looking like an astronomical telescope, and every half-inch gained in portability is worth having.—I am, yours, &c.,

Cardiff, July 31, 1893. CHAS. E. HANCOCK.

EXPOSURE, DEVELOPMENT, AND FOG.

To the EDITOR.

SIR,—I have just been reading your leader on the above subject, and, curiously enough, an experience which appears to me to bear directly on the phenomenon in question has just occurred to myself.

Being out with a hand camera and a dozen special rapid plates, I exposed some half-dozen, and, knowing I should not expose any more for a time, I closed the safety shutter of my camera and walked on. After a time another opportunity occurred, and I exposed, as I thought at the time, two more plates, forgetting that the safety shutter was down, so that, in reality, these two plates received no exposure at all.

On reaching home, I proceeded to develop my plates, and all went well, good negatives resulting, until I came to the two unexposed plates, which were treated exactly the same as the others, as I had not then found out the mistake I had made.

The solution, pyro-soda, was poured on, the dish instantly covered and set rocking; but, on looking to see how development was proceeding, I was surprised to find that, instead of the picture being just appearing, the whole plate, rebate and all, was fogged all over, and this in a much less time than the first appearance of the image on a properly exposed plate. The second plate yielded precisely similar results. I was, of course, puzzled at first to account for this, but I soon recollected that I had forgotten to raise the safety shutter.

The question still remained why the plates should have fogged all over when they had never been exposed at all, and the probable solution seems to be as stated in your article, though in my case the plate seems to have broken down in less time than in the case referred to by you.

It may probably be taken for granted that, the more rapid a plate is, the greater tendency it will have towards this particular result, although undoubtedly some makes of plates may be more prone to it than others.

I enclose for your inspection a film taken from one of the plates above referred to, also a print from a plate exposed on the same day and out of the same box, from which you will see that, whatever the true explanation may be, there is no manner of doubt whatever as to the facts.—I am, yours, &c., J. H. BALDOCK, F.C.S.

Croydon.

AMATEURS AND PROFESSIONALS.

To the EDITOR.

SIR,—You have had letters from time to time complaining of the want of unity amongst professional photographers, also hinting at the alleged inactivity of the National Association of Professional Photographers of Great Britain and Ireland in not bringing about the said unity, and, curiously enough, chiefly from writers who have taken no visible part in the work. I am writing to inform your correspondents and the profession generally that a meeting will be held at Anderton's Hotel, Fleet-street, on November 10, and beg that all who are interested in the future of professional photography will attend. The two photographic exhibitions will be open at that date. The time of meeting will be advertised.—I am, yours, &c., THOMAS FALL.

July 19, 1893, 9, *Baker-street, W.*

To the EDITOR.

SIR,—"Pioneer's" reasoning in his latest effusion applies with as much force to the "mob" of amateurs who, according to him, are invading the profession. By the way, the Princess of Wales is a member of the "mob" of amateur photographers; we will, therefore, use his own words to strengthen the said "mob's" position.

Amateurs, "show to your fellow-men that this great art science of photography, of which you are, or ought to be, so justly proud, and which you, as the 'amateur' exponents of, have brought its varied works to such a high state of perfection," shall not be the sole monopoly of a limited number of professionals, but be free to all men, whether for instruction, pleasure, or profit.

As regards his other argument, that the retailing of intoxicating liquors is required to be done under Government licence, it is so appointed to prevent the injurious social results which would spring from its unrestricted sale, and there is not the remotest connexion between that and the art of photography.

We will now further quote from his letter, using it as an amateur weapon ready forged to hand:—

"Another point is almost entirely overlooked in connexion" with the proposed suppression of the amateur, "and that is, the vast army of persons who are employed, directly or indirectly, in the various manufactures and kindred trades" required to supply his wants, &c. . . . . "It behoves us to do all that lies in our power to protect this gigantic industry, and not let its vitality be choked," as it certainly would be, if amateurs were wiped out with "a tax of ten or twelve guineas a year."

I really did not intend to write again to you on this subject, as it looks like seeking notice for myself; but really, as we are on the subject at all, it is as well, if possible, to discuss it thoroughly, and put an end, for a considerable time, to the chronic abuse which the poor amateur receives, and deserves to but a limited extent.

The amateur is here, and he means to stay; professionals must make the best of it, and adapt themselves to the changed conditions of their employment.

If Acts of Parliament were so potent as some think, no trade would suffer from depression, and we would only require a special Act of Parliament for each trade to ensure all-round prosperity. I would recommend certain of your correspondents to study some elementary book on the laws of political economy; also I would recommend to their attention that, if they want due respect to be given to them, they should show it to others, and not look down upon them as members of "a mob," or as a low class of society, for

"The rank is but the guinea's stamp,
The man's the gow'd for a' that."—*Burns.*

—I am, yours, &c., WM. JAS. FARMER.

68, *Blackburn-street, London-road, Blackburn, July* 7, 1893.

To the Editor.

SIR,—In the previous paper under this heading great stress was laid on this fact, that the amateur problem is a very difficult one to deal with, and not the slightest suggestion was intended to be conveyed against the class of amateurs as referred to by one of the correspondents of THE BRITISH JOURNAL OF PHOTOGRAPHY in the issue of the 23rd inst. It is possibly a moot point as to whether a man who makes scientific and experimental photography his hobby and delight is really an amateur at all. True, he may only work for love and not money, but in any way he is not the man who injures the professional photographer, and it was clearly indicated that those who usurped the trade and the benefits appertaining thereto must, for the relief of the professional photographer, be dealt with in some way so as to make the line of demarcation between the two stronger in the future than in the present. If the "miserable work" of some professionals referred to by "Amateur" is the cause of bad trade, then he makes a strong argument for the utter eradication of such men by the examination test as advocated already in "Darkest Photography." If there are too many in the profession, and, as instanced by him, of there being four establishments to a population of 1500 persons in one country town which he knew of, he makes a still further and stronger argument in support of the plan suggested above, and yet he winds up by saying that photography could sustain no greater blow to its development and progress if "Pioneer's" wishes should be realised. The entire pith of the ideas suggested by "Pioneer" is to raise the professional status and weed out the bad from the good, and the substance of "Another Pros.'" letter is strongly in support of the system advocated in "Darkest Photography," more especially in that portion that relates to the examination test. This was originally proposed in the scheme of "A National School of Photography," but when that was first mentioned it was considered too premature (then there was no vast army of amateurs). Now we are told that we are too late. Why? "It is never too late to mend," and, if the aid of the legislature has to be invoked for the benefit of the profession, it only shows to what an amount of importance modern photography has attained. Although we may invent as many new styles of portraits as we may choose, we can never expect any material or lasting benefit till such a time as the whole basis of commercial and professional photography is reconstructed. There are no honours at present to be conferred on the professional photographer, however worthy he may be of them, as is the case in the sister arts of painting, sculpture, architecture, engineering, &c.; but, because they do not exist now, it is no valid reason why they should not be *en évidence* in the near future. With regard to amateurs being received into the ranks of professionalism, any one who follows photography as an additional source of bread-winning can scarcely be designated an amateur, and we only desire to place him on the same level as the professional, and we consider that he should be obliged to satisfy the proper authorities that he intends following it up as a business, and after he passes the test examination he can receive his licence or permit to carry on the business of a professional photographer. Amateurs will then remain within their own sphere, and not clash with the pro. while the latter is earning his means of subsistence, and what the amateurs may elect to do among themselves at their own Society's meetings no one wishes or desires to interfere with, we only want them not to interfere with us. Should, as previously mentioned, any amateur desire to enter the ranks of professionalism, no more obstacles would be placed in his way than any one else's, and therefore they cannot possibly sustain the slightest injury, should the scheme be carried out in its entirety as suggested in "Darkest Photography."—I am yours, &c.,

PIONEER.

To the EDITOR.

SIR,—Mr. A. Levy, of Paris, I notice has contributed a letter on the good old amateur question to the last number of THE BRITISH JOURNAL OF PHOTOGRAPHY. In it he says (speaking of the amateur), "Why, with their knowledge and (superior to all) ingenuity, can they not make up anything portable to change their plates in, &c.?" I should not like to accuse this gentleman of ignorance, but I should certainly say that at the time he wrote it he must have been labouring under a condition of temporary absent-mindedness, or he would most certainly have known what most beginners know, viz., that there are at the present moment plenty of portable changing bags on the market, most of them the inventions of amateurs. So much for the first paragraph of his letter. The next paragraph I have no doubt he considers unanswerable, and he is perfectly correct. Vituperation, however false and acrid, is never worth any one's while to answer, and the chief argument(?), namely, that in former years amateurs used to use tripods for instantaneous work, and now do not, and hence they are unworthy of all consideration, is altogether puerile. There is a certain amount of reason in the next paragraph about amateurs paying for the use of dark rooms (by the way, I have never used one yet that I not been charged for), but even here our friend makes another great mistake. He says that he (the amateur) "will find it as natural to pay for it as he does when he uses a wash room, or asks the advice of a doctor or lawyer." Perhaps it is natural in America to pay the above-mentioned people (and I conclude from his letter that your correspondent is an American), but in England things are different. In England a doctor, even if he has saved your life, is never considered to have an absolute right to any fee, certainly not as much as the grocer, or baker, or chimneysweep. The last paragraph of this effusion does not, as far as I can see, concern the amateur question at all.—I am, yours, &c.,

London, July 25, 1893. ROBERT J. HILLIER.

To the EDITOR.

SIR,—I take it that none of my fellow-workers have any desire to say a word against the painstaking man who carefully works out methods, processes, &c., and freely gives the results of his labours to all and sundry who care to avail themselves of them. This man is only too pleased and gratified to find that his endeavours have proved successful, and looks for no further reward than that his process should prove of service and of practical value. The "Amateur Photographer," as *we* know him, is not related in any degree to this gentleman, whom we are glad to meet, and find many of his ideas happily corresponding with our own, and from whom we can generally learn something of great value relating to our own every-day work, and in clearing away many difficulties we have had no opportunity to ferret out for ourselves. His ideas are always put before us concisely and clearly, and we easily learn what he means. He is in no wise pedantic, and, as we might say, is "clear, plucky, and crisp, or free from fog," &c. We can get along well enough with him, and are happy in his company.

But it is when the very d—— himself, armed with some slides and negatives, comes into your place, and you have to brace on your armour and in every way stand on the defensive, that your gorge rises, and you feel like murder in its most "lingering and boiling oil" form. He *is* a nuisance, and our experience prompts us to inform him that we cannot undertake the work he proposes we shall do on his own terms, &c. This probably loses us the custom of some of his friends, but that we must try to conveniently forget.

I must say this amateur sails under false colours, and actually does injure my business in issuing photographs at a low rate, which he can easily do when he has an income derived from his legitimate business.

Did your correspondent, "F. R. C. S.," take into account the value of the "employer's" services in producing those fifteen hundred negatives—say, three months' proportion of a salary of one or two thousand a year? The professional employed seems to have been a very unbusinesslike person.

"Audacious Operator" comes nearer the source of our trouble when he touches on the idiotic policy of men supplying free sittings, and throwing their work about as though no value whatever should or could possibly be attached to it. As he says, this underselling *is* killing the trade, and compelling men to combine a more lucrative business with their own, which really is one that should be considered as respectable as the professions of medicine, law, &c., instead of which our "social status" ranks somewhere with the local billposter and chimneysweep. Not that their occupations are unworthy ones; honest labour is no degradation. It was only last week one of our boatmen, earning about 18*s.* a week, said, commenting on our work, "Ah, well, there's some funny trades, but anything does for an honest living!"

Who is to blame for this condition of things but ourselves? Why should the average photographer be so abjectly servile that he shall admit his work is unworthy the praise he knows it should attain? Why is he in such a hurry to advertise "One splendid cabinet and three *cartes* for one shilling?" At this rate he must "use up" 2000 sitters before he turns over 100*l.* This at, say, ten sitters a day (which he won't get), and counting Sundays in, would take him 200 days, during which time his rent, wages, &c., would be considerably in excess of his takings. Of course I know he looks for re-orders, but they won't amount to more than ten per cent. on the gross takings, and it doesn't pay, but merely keeps a certain class of sitters out of another man's hands who could get orders amounting to, say, from probably five to twenty shillings from each sitter.

"Silex" says that, because materials are cheaper (he refers to pyro dry plates, &c.), we should drop our prices. How many negatives could we, in those days to which he refers, produce from our Winchester of collodion, our pound of silver, or our glass? And, even with cheapened dry plates, how large do the amounts of our invoices seem for what goes so short a way? The amateur cannot be credited with the lower prices "Silex" mentions; it is merely caused by the law of demand and supply, and where an amateur may use a dozen plates a professional may use hundreds.

Nor do I think "L. C.'s" proposal that we shall adopt, say, the carbon, or any other process, will help us; the amateur would as easily have his prints made by one process as another; he need not print them himself. The carbon is certainly a beautiful and permanent method of printing, but it is not at all difficult to work, and even here the tissue can be procured sensitised ready for printing.

Our only chance seems to be to form a union, or association, which shall insist on no photographer working *below* a certain rate, and I am sure the man getting three shillings for his *cartes* would only be too pleased to be compelled to receive six shillings for the same, for in every way would he be benefited; not only would he be better able to pay

his expenses (for he would lose no custom where prices were raised all round), but he would soon be able to buy better accessories, backgrounds, &c., and have better skilled assistance. The union should be able to grant licences, and determine the ratio of prices in each town, and this each photographer would be compelled to abide by, and it would also license all assistants who could pass a certain standard in *technical* and *practical* proficiency. It is remarkable what a number of untrained young fellows are now in the profession, many even unequal to the task of varnishing a negative; slovenly and dirty in their manipulations generally; and what you, sir, about the time "Silex" writes of, used to call "sloppy photographers." In those days youths were trained to be scrupulously clean in many ways—plate-cleaning, collodionising, sensitising, &c. Of this the modern assistant knows nothing, and seems to believe cleanliness unnecessary.

The National Cyclists' Union has served a very useful purpose for cyclists, and why should not the National Photographers' Union serve the same for photographers? In the case of the Cyclists' Union, the licensing scheme was by many considered impracticable; but, against endless troubles, they have done fairly well, and, to a certain extent, their scheme has done the service expected of it. The method of working, of course, is another story.

The auctioneer keeps his business fairly to himself with his licence, and I think we might manage to do likewise.—I am, yours, &c.,

ANOTHER PROFESSIONAL.

To the EDITOR.

SIR,—Recently a great deal has been said and written as to whether the amateur does, or does not, injure the professional photographer in his business.

Most men are amateurs hanging on to the tail of some profession, which profession they usurp, either in its lower or middle ranks, according to their ability and the light of principle in which they regard what they do.

It is a well-worn saying that "a man who knows nothing is sure to tell it the first chance he gets." The more ignorant they are, the more vain. They *must* have an audience to show all their friends how wonderfully clever they are. Amateur photographers will take you under any conditions, passable or impassable; only, for goodness sake, let them take you. Their portrait work is mostly of a vile character; but their friends will tell you, "So-and-So takes them beautiful." Whether the pictures are so or not, the price is "beautiful," being, in most cases, exactly nothing. Some would object to our claim to being injured in such cases, because we ought to produce better pictures than the amateur, and there can be no question that we *do* take better pictures; but we cannot compete with the price, and when a thing costs nothing—well, people don't look a gift-horse in the mouth.

Nowadays there is scarcely an institution but has its amateur photographer, who does what photographic work he is suffered to do for nothing, or for the good of the cause, he will tell you.

Amateurs are a pestilence upon every profession.

The amateur musician will play your organ for nothing, when some poor professional is down at heels and threadbare for lack of the salary that ought to be paid. He will assure you he does the work for the good of the Church, but that is not true; the fact is, Mr. Editor, he likes to have his sickening vanity tickled. The singer is the same, if not worse. He will scream at you till he nearly drives you mad, if you will only pretend to listen; and you must use all your tact, and sometimes rudeness, to induce him to stop.

All these people only want an audience, and they will perform. They will assure you that they do no harm to the profession, and they do not—to those who are at the "top of the tree"—but they are depriving the more obscure of their livelihood, when time and money have been expended on acquiring the means thereof.—I am, yours, &c.

JOHN RAYNE.

To the EDITOR.

SIR,—Having read with considerable interest the various letters which have been published in your columns relating to the depression in the photographic profession, perhaps I may be allowed to make one or two remarks. Some of your correspondents have not learned to differentiate between photography as a science and photographic work practised for business purposes. Hence, when replying to the remark often heard that amateurs have done professionals harm, they sagely remark that all or nearly all the improvements and inventions in connexion with photography are the result of the labours of amateurs; and Mr. Stillman even goes so far as to ask, speaking of the professionals, "Did one of them discover photography?" Now, I do not think the average intelligent professional photographer who knows anything of photographic history will for one moment refuse to give the amateur his due in this respect. The fact is, and always has been, the professional has to make his living out of the thing, and has not time for the elaborate experiments to which the moneyed amateur devotes his attention. We are most of us glad to use what our scientific investigators give us, and our practice and experience soon enable us to use it successfully. All thanks, then, to the genuine amateur photographer (not the dilettante), who does his work *con amore*, and gives to the world the result of his labours.

But the question as orlginally started is, Has the amateur craze, has the vast army of amateur photographers injured the *business* of photography? Is the present depression attributable to the amateur? To these questions it is impossible to give a definite answer. Undoubtedly the work of the amateur in many cases supplants that of the professional, not necessarily because it is better, though it sometimes may be, but because it is good enough; because, too frequently, the public taste is so bad that a mediocre result for nothing or for cost of materials is preferred to a good photograph at a good price. So far, then, harm has been done, but to what extent? The damage the professional has received in this way is a mere bagatelle to the harm he has done himself and his brethera. The self-inflicted wounds have been oftimes enumerated — price-cutting, indiscriminate gratuitous sittings, turning out of inferior and fugitive work, and lack of enterprise. It was natural that prices should rule somewhat lower as materials and labour became cheaper, but, for some of the starvation prices now asked, photographers have only to thank their own cut-throat policy. No, we may blame the amateur, or the public taste, or anything else we like; but, as Casca says in Shakespeare's *Julius Cæsar*,

"It is not in our stars but in ourselves
That we are underlings."

But this is no consolation to the "poor professional." It does a starving man little good to preach him a sermon on his past follies. We want to alter the present state of affairs as speedily as may be.

The letter of "L. C." in your last week's issue appears to me as practical and to the point as anything I have seen. One of his remarks I take the liberty of quoting, "When your house is on fire do not begin to abuse the man over the way because his building interferes with your ancient lights. On the contrary, take off your coat and look around for a bucket." This is the principle which, acted upon, will lift professional photography out of the mire. Taxation won't do it, boycotting the amateur won't do it, licensing the professional won't do it. Those of us whose hearts are in our work must strive to obtain better technical and artistic results (and, in spite of Mr. Guardia's sneer, many portraits professionally produced now are works of art, although not of the hand camera), we must show more business ability, energy, and enterprise, we must be willing to sacrifice a little for the present in order to educate the public taste so that they may appreciate a higher quality of work and buy it; and we must remember that, as photography as a business has not been depressed in one year or two, we can't raise it again in so short a time.—I am, yours, &c.,

CHARLES HENRY HEWITT.

King's Lynn, July 22, 1893.

To the EDITOR.

SIR,—I have followed with interest the discussion now going on in your JOURNAL, "Depression in Photography." Now, as an assistant who has had fourteen years' experience, I think there is another matter of more vital importance to the profession—that is, how to find a good assistant and how to find a good master. In applying for a situation, I always find the place is described as first class or the best in the town, and the situation will be permanent.

Speaking from my own experience and that of other assistants I have met, in very few cases has that description been justified.

To a man who has been educated in a good house it is, to say the least, just a little depressing to find the best house in the town to be a wooden shanty studio 18 ft. by 12 ft. Now, how are we to know what class of place we are going to? On the other hand, a photographer requires an assistant. He gets lots of applications; three parts are well recommended, and send good references from the best in the town. But how is the master to be better informed than the poor assistant? Generally the man with the most cheek gets the place, and I think I am safe in saying they are the most ignorant, will go for a *moderate* salary, and perhaps have only a couple of years' experience, yet they are able to keep a good man out until he is starving and has to take any poor place he can get.

I think this is demoralising, conducive to bad work, changing of hands, and low salaries. Could we not have a stiff examination that would clear the market of duffers? Let it be like doctors, lawyers, and masters of vessels, liable to have their diploma or certificate taken away; then there would be none but good assistants, and, as a consequence, good photographers.

Hoping that some abler pen will take the matter up,—I am, yours, &c.,

July 2, 1893. ASSISTANT.

[Correspondence on this subject must now close.—ED.]

Exchange Column.

*** *No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance. The full name of the advertiser must in all cases be given for publication, otherwise the Exchanges will not be inserted.*

Will exchange Dallmeyer 2c lens (cost 15*l*. 15*s*.) for good hand camera.—Address, DRURY STOWE, Bedford.

Will exchange Merveilleux half-plate set for hand camera, magic lantern, or quarter plate rectilinear lens.—Address, G. MOORE, Buckfastleigh.

Will exchange ratchet safety bicycle, ball bearings all over, for good hand camera (quarter-plate or 5×4).—Address, G. M. MILLER, 15, Cambridge-terrace, Belgravia, London.

Harrison's head rest, Knox burnisher, ten-inch bar, brass plate lettered "Photographic studio," in exchange for hand camera.—Address, S. E. DAVIES, Broughty Ferry, N.B.

Wanted, good lens for hand camera; will exchange Dallmeyer's whole-plate telescope, new meter, only used a few times, cost 30*s*.—Address, J. ALLEN, 2, Pyrmont, Barber-road, Sheffield.

I will give in exchange a Mawson's cabinet lens, in good condition (but no cap), for a camera and set of Gem lenses in good condition.—Address, J. BARBER, 64, High-street, Loftus, R.S.O.

Will exchange 5×4 camera, with carrier for *carte-de-visit* portrait lens and rapid rectilinear to fit same, for 10×8 or 12×10 camera; difference in cash.—Address, ED. ARTIS, 40, Wesley-avenue, Mutley, Plymouth.

Wanted, 5×4 rapid rectilinear iris diaphragms, in good condition, in exchange for silver Geneva watch, in good condition and working order; approval.—Address, J. K. SMITH, Little London, Rawdon, near Leeds, Yorkshire.

Will exchange Knight's *Pictorial Gallery of Arts*, in two splendid volumes, 4000 woodcuts and steel engravings, in first-class condition, for half-plate camera, without lens or tripod.—Address, C. TAYLOR, 15, Bradford-road, Batley, Yorkshire.

Will exchange new strong oak 12×10 printing frame, Fallowfield's make, for two strong oak whole-plate printing frames, or one whole-plate and one half-plate. Will pay difference.—Address, G. F. JESSETT, 7, Batoum-gardens, West Kensington, W.

Splendid portrait lens, taking up 15×12. Also folding tricycle by Singer & Co., electroplated throughout. Wanted, modern portable outdoor outfit, for groups 12×10 or 15×12; also whole-plate studio universal camera, and 3*c* lens.—Address, LONSDALE & Co., 45, Stroud Green-road, London, N.

Answers to Correspondents.

*** *All matters intended for the text portion of this* JOURNAL, *including queries and Exchanges, must be addressed to* "THE EDITOR, THE BRITISH JOURNAL OF PHOTOGRAPHY," 2, *York-street, Covent Garden, London. Inattention to this ensures delay.*

*** *Correspondents are informed that we cannot undertake to answer communications through the post.*

*** *Communications relating to Advertisements and general business affairs should be addressed to Messrs.* HENRY GREENWOOD & Co., 2 *York-street, Covent Garden, London.*

*** *It would be convenient if friends desiring advice respecting apparatus, failures in practice, or other information, would call at the Editorial Office either on Wednesdays from* 4 *to* 6, *or Thursdays from* 9 *to* 12 *noon, when some one of the Editorial staff will be present.*

PHOTOGRAPHS REGISTERED :—

William Bond, Norwich.—*Photograph of Norwich from the North.*

John Arthur Draycott, Birmingham.—*Six Photographs of Mr. M. P. Manfield.*

Kate Alice King, Notting Hill, W.—*Three Photographs of the Rev. Arthur Williamson, D.D.*

BLACKBURN.—Would "E 25" please send our publishers his name and address.

M. C. K.—The print seems to be over-printed and over-toned, and also appears to have been exposed too much to light during the toning.

WILLIAM BERRY asks: "Do you consider the work done by the electric retouching pencil superior to the ordinary retouching pencil?"—No.

WASP.—As the coloured supplements to the *Graphic* and similar periodicals are constantly framed and sold by picture-frame makers, we take it that you can do the same without "becoming liable to prosecution."

C. TILY.—1. Dr. Miethe's address is Potsdam. 2. We cannot say whether his teleo-objective is patented in the United States, but believe it is. 3. See the JOURNALS from October 30 to December 4, 1891, inclusive.

R. CHURCHWELL.—The action is not due to the tissue acquiring insolubility. That idea was fully discussed twenty or more years ago. If you make the experiments you propose, you will be satisfied on the other points.

ARTHUR CLAYTON.—The copyright is vested in the author of the work—that is, the one who takes the picture. The other question rests upon the terms arranged and the conditions under which the picture was taken.

ALEXANDER MACINTYRE.—When prints have been well toned with gold, we have known ink stains quite removed by treating them with hydrochloric acid. It will be advisable to try it at first on a print that is of no value.

RUBENS.—If the picture is copyright in Germany, there is little doubt, under the International Copyright Act, that it is also copyright here, as that law confers equal copyright in all nations within the Union, and Germany is.

S. BELLOW.—The formula is impracticable. Twenty grains of gallic acid are not soluble in an ounce of cold water. Its solubility can be increased very materially by the addition of glycerine or of alcohol. Neither of these additions would be harmful.

P. DALEY.—A good article may be relied upon from any of the houses mentioned.

S. J. (Berks).—The chalky appearance of the lights and the blackness of the shadows in the photograph of the interior of the building, are due to very much under-exposure. In the next attempt, if another is made, give five or six times as long, actinometer readings notwithstanding.

A. B. Z. (Bristol).—Any elementary work on photography would supply the information. A formula is given on page 792 of the ALMANAC. The bath must be tested from time to time with the argentometer, and its original strength made up either with crystals of nitrate of silver or a stronger solution.

BUCKINGHAMSHIRE.—If you wish to become, as you appear to do, a pot hunter, and acquire a lot of medals, make it a point to show at all the minor exhibitions, such as little local societies that admit outsiders. By following this course, if you send good work, you will soon acquire plenty of medals.

R. A. C.—It is doubtful if you can legally demand, as a right, though a rate-payer, to enter the church at any time to photograph the interior. However, a polite request to the clergyman will, no doubt, secure the necessary permission, and this will, we imagine, prove more agreeable to all parties than asserting rights, real or imaginary.

AUG. WHEELER.—There is little doubt, as you have told your friend, that the spots are due to minute blisters caused by the hot climate. We should recommend alum before fixing, with a pretty thorough washing between the operations. Slower plates would certainly be better for your friend for general work during the hottest weather.

MR. W. C. HEMMONS asks: "Will you inform me, for the purposes of our proposed exhibition, where I can obtain the addresses of the chief English and foreign papers and magazines relating to photography, and the cost of such a hand-book, if there be one?"—We believe that such a list is published at the cost of a few pence.

B. R. A.—The only way by which the spots or markings can be removed from the negatives is by carefully scraping them out with a penknife. If you are not *au fait* with that kind of work, the negatives should be placed in the hands of a skilful retoucher. The emulsion with which the plates were coated seems to have been defective, and the fault is not due to the operator. The sample negative sent has been destroyed as requested.

CORRECTOR.—Although we have had but little experience with the corrector mentioned, it will certainly be quite possible to use it in conjunction with a focal plane shutter. The nearer it is to the plate the better it ought to work, but this will depend upon the curvature of the concave surface and the thickness of the glass. We know of no one who makes such correctors, but we have no doubt that any lens-grinder would undertake the work.

T. BRADLEY.—There are several causes that will account for the ink adhering all over the paper, and refusing to leave the parts protected from light in photo-lithographic transfers. A very prolific cause lies in the bichromated gelatine becoming partially or wholly insoluble, or non-absorptive of water. This may be due to its being kept too long, or from it having been exposed to the light, &c. Another very common cause is the unsuitability of the negative—the dark parts not dense enough, and the lines not transparent. There are other causes, but these are the more general ones with novices.

J. C. T. complains that all the formulæ published for photographic transfer inks seem complicated and troublesome to work, and asks if we can suggest something simpler and more suitable for a beginner. We can, and that is to purchase the ink ready-made from any of the dealers. The beginner can thus ensure having an article suitable for the purpose, and that is more than can be relied upon with a novice's first few attempts at ink making. All who have had any experience in transfer-ink making know quite well that it is not only a troublesome but a very unpleasant operation without special appliances.

D. DAVEY writes: "Wishing to produce some prints on a very rough drawing—or rather tinted crayon—paper of a warm grey tone, I sensitised some, according to several formulæ, and it was a failure in every case. As soon as the paper was dry the original colour was quite changed, and it had become a yellowish brown with innumerable dark brown and nearly black spots. As different formulæ were tried, and all with nearly the same result, I conclude the paper is at fault. As the tint and surface is exactly what I want, is there anything I can treat the paper with to purify it?"—We fear not. Paper of this kind is made specially for artists' use without regard for any other. However, these papers vary considerably in their composition, according to different makers, therefore it is quite possible that a different make will answer the purpose better. If it is possible to obtain the same tint of foreign make, we should recommend a trial of that.

HALATION, AND METHODS OF PREVENTING IT.

A letter which we have received from Mr. C. E. Pettit, and which will be found on another page, reminds us of the fact that of late considerable attention has been bestowed upon the subject of the preparation of plates which shall give freedom from halation.

Very soon after Mr. G. Marlow had directed the notice of the public to the nature of halation—now over thirty years ago—Major Russell tried numerous experiments with a view to cure the evil, and wrote much concerning it. His first suggestion was to employ orange-coloured glass as the support of the sensitive film. After being developed and fixed, the negative pellicle had then to be stripped from off the glass in order to its being printed from. This was found to prove an effectual remedy; but the trouble and risk of removing the film was recognised, and he overcame this by giving to the plate, of ordinary glass, a coating of non-actinic colour; and this, when dried, was found to answer the intended purpose quite well. This was for dry plates; but, when the wet-collodion process was employed, the same end was attained by pressing a sheet of wet red blotting-paper on the back of the plate.

Things remained in this condition for many years (as they do with the majority of workers up to the present time), when a remedy was proposed by Mr. Carey Lea, and others, in the imparting of a yellow stain to the emulsion by which the plate was coated, a stain which should be capable of being removed in course of the subsequent treatment to which the plate had to be subjected. This stain, in the form of an inert substance, was afterwards discontinued on account of the allegation that it impaired the sensitiveness of the bromised film, and both Carey Lea and Col. Stuart Wortley subsequently gave preference to the iodide which, while believed to be not quite inert when used along with bromide, undoubtedly diminished halation by imparting greater density to the film.

Before proceeding further, we pause for a moment to describe, for the benefit of our younger readers, a method by which they can see for themselves the precise effect produced by placing blotting-paper in optical contact with the back of the plate. Hold an ordinary clean plate of glass obliquely so as to reflect the image of a gas flame from its surface. Examine this attentively, and it will be found that, between the eye and the primarily reflected flame, there are several others, each fainter in succession. If a sheet of the red blotting-paper is pressed against the back of the plate, no alteration whatever in the number of reflected images is produced;] but apply a wet sponge to the paper while still in position, so as to wet it thoroughly, and thus establish optical contact between it and the glass, and instantly all these minor reflected images disappear as if by magic, the primary image alone now being visible. This demonstrates in a very simple and effective manner the advantage of backing the plate as a means of preventing halation. This same kind of reflection occurs when the plate is coated with a sensitive film, and it is the stronger in proportion to the translucence or thinness of the coating. If the plate be very thickly coated with any light-absorbing medium, then will there be no halation of the nature now being described. The experiments described should be made at night.

The imparting of opacity to the film whilst at the same time securing maximum sensitiveness was suggested by us seventeen years ago, the means being double films. Writing on the subject two years later (in 1878), a contributor to our pages, Dr. Nicol, suggested a strongly coloured substratum, which, interposed between the glass and the sensitive coating, should act as an anti-halative until the exposure had been made, when, by a subsequent operation, the colour should be discharged. Curcumine, the colouring matter of turmeric, was believed by him to be the best, or amongst the best, substances to employ. Writing concerning this at the time, we spoke of its superiority to methods of staining the sensitive emulsion then known, but which, for reasons given, had received no great amount of recognition. But, whereas Dr. Nicol had spoken of albumen then employed as the popular substratum, we suggested gelatine as a more suitable one, seeing it would so readily part with the colouring matter when its function had been completed.

Just subsequent to this, the Rev. H. J. Palmer wrote to us saying that, at the last meeting of the Liverpool Amateur Photographic Association, he had stated that the freedom from halation which he had experienced had been proved to be due to the slightly yellowish tinge of the glass plates on which he had spread his emulsion. He says he coated his plates with gelatine emulsions of two kinds, viz., one which gave a very slow but dense film, and one made from Kennett's pellicle, which was moderately rapid. He exposed to the inside and east window of a church under conditions of light and atmosphere which are invariably provocative of blurring in its worst form. The sun was shining brightly, but the wind was in the east and the air filled with haze. In every case the test proved entirely satisfactory.

From the few notes here given, Mr. Pettitt will find that he may experience difficulty in maintaining his patent, excellent although the thing is in itself. We have of late received much correspondence relative to the subject generally, and trust that even such a brief recapitulation as we have given may tend to throw some light upon it. Those who wish to inquire more thoroughly into the matter should read the writings relating thereto of the late H. B. Berkeley and others.

FIXING AND WASHING SILVER PRINTS: MESSRS. GRUNDY AND HADDON'S EXPERIMENTS.

The paper *On the Amounts of Silver and Hypo left in Albumenised Paper at Different Stages of Washing*, read by Messrs. F. B. Grundy and A. Haddon before the London and Provincial Photographic Association on Thursday week, and which will be found in another part of the Journal, is a valuable contribution to our knowledge of a subject which, notwithstanding its extreme importance, has never yet been fully investigated, and consequently not understood. The paper, brief as it is, concentrates within its small space the essence of a series of laborious experiments to determine the influence and action of the fixing and washing solutions upon albumeno-chlo o-nitrate of silver, and although undoubtedly of great interest to the chemist and the investigator, will, we do not hesitate to say, have more value for the practical photographer than any paper read before any society in recent times. We endorse the commendatory remarks made in the course of the exceedingly interesting discussion which followed it, and trust that it will stimulate other investigators to take up the study of many vexed or doubtful points met with in practical photography, and strip them of their obscurity.

Messrs. Grundy and Haddon's objects in carrying out their researches were, to quote their own words, "to determine the time the print should be washed," and to "endeavour to determine the cause of the fading of the finished print." The results of their experiments—the methods and accurate applications of which it would be difficult to take exception to—undoubtedly indicate that they have not been unsuccessful in those objects. Summarising the conclusions arrived at, and taking the experimental data as typical of what actually occurs in the fixation and washing of silver prints, it appears that the fixing bath leaves behind a residuum of silver and sulphur compounds, which, although presumably soluble in water, are irremovable by washing within the limits of from five minutes to nineteen hours. This, according to general photographic practice, we may accept as marking the minimum and extreme periods of washing adopted. While there is, of course, nothing new in this, it is possibly the first time that the power of the fixing bath on the sulphur and silver salts left in a "fixed" print have been accurately gauged.

The principal outcome of these experiments, from the point of view of every-day practice, however, lies in the fact of the ascertained limitation of the power of washing prints, as proved by Messrs. Grundy and Haddon. It will be observed that, after ten minutes, the quantities, small though they are, of sulphur and silver compounds left are virtually irremovable by any length of the washing, two hours and nineteen hours respectively being impotent to subtract more than a washing for ten minutes. Hence, accepting Messrs. Grundy and Haddon's figures as correct and confirmable, we have a much-debated point clearly settled, which in itself is a feature so valuable that the experiments might have rested a claim to enduring interest on that fact alone. Before now, we and others have pointed out that long washing was not only unnecessary, but was provocative of danger to the purity and stability of the print, and it is gratifying to find that view substantiated, while to photographers it should be of the highest significance and assistance.

Arising out of Messrs. Grundy and Haddon's paper are a number of problems which we trust they and other experimenters will take up and endeavour to solve. In the first place, such a thing as perfect fixation of silver prints seems as yet unattainable, and the removal of the presumably soluble compounds left is also by no means thorough, so that the hypotheses of the causes of fading are rendered more obvious than hitherto. Starting from this point, a fresh series of investigations, having for their object the providing of a perfect method of fixation and washing, seems desirable. The precise nature of the compounds left behind, and whether they are retained by the paper or the albumen, singly or in collusion, has also yet to be determined. Here are no questions of mere theory to be debated, but matters of the greatest practical import, which we trust will receive attention now that Messrs. Grundy and Haddon have so ably opened up the subject.

In conclusion, we should like to add our tribute of praise to these gentlemen for the great labour and pains involved in the experiments, which, it appears, extended over several months, and the measure of which cannot be taken by the brief record of the results arrived at. We understand that Messrs. Grundy and Haddon intend not only pursuing this subject, but also that of fixing and washing in connexion with the increasingly popular gelatino-chloride paper. Both for what they have done and for what they intend to do the thanks of photographers are due to them.

INTENSIFICATION.

Although more than one of the newer developers must be acknowledged as having obtained an established footing in practice, it can scarcely yet be claimed that their use is as fully and completely understood under all circumstances as is the case with pyro. It is not our intention to argue the question as to whether pyro owes its continued popularity, notwithstanding its faults, to any inherent superiority over its newer rivals, or whether it is not rather due to the more perfect knowledge of its capabilities that long years of use have given us. It is too often assumed that, because a new developer does not at once establish its undoubted superiority over pyro, therefore the latter must retain its supreme position, whereas it seems more than probable that a wider experience with the newer agents may eventually remove certain irregularities and uncertainties that at present surround their use.

That amidol, metol, and other of the recent additions to our list of developers possess certain advantages over pyro is undeniable, but it is equally certain that there are at present counterbalancing features which, to some extent, restrain their general adoption. Chief of these is the uncertainty, and sometimes difficulty, in securing sufficient printing density, as well as the deceptive character of the unfixed image, which very often leads to serious errors of judgment in the matter of density. But, while we recognise this fact, we must also point out another, namely, that many photographers are misled by the extraordinary clearness and delicacy of the images produced by metol and amidol into a false idea of their being too thin for printing purposes, when such is not the case. We

have known several instances in which negatives have been thrown aside as too hopelessly thin to be of any practical use, but which, on trial, have proved to give very beautiful results. In fact, the general character of these negatives is that which is well described by Messrs. Hurter & Driffield as combining "truthful rendering of tone with minimum density."

At any rate, we have heard far more lately about the necessity for intensification than for a number of years past—that is to say, of systematic intensification. In wet-collodion days it was the custom to develop with iron, and then to intensify or "redevelop" with a different solution of iron or of pyro, with the addition of silver, though it was generally recognised that, where it was possible, a better result was obtained where the end was arrived at in a single operation. On the advent of gelatine plates, many operators followed a similar practice, as, owing to a want of familiarity with alkaline development, density and gradation were difficult to combine by its means alone, and intensification after printing had to be resorted to. The necessity for this gradually disappeared with practice, but seems to be temporarily cropping up again in connexion with amidol, metol, and similar agents.

No doubt there are many users of these new agents who will be ready to declare that there is no difficulty whatever in gaining any degree of useful density, and we are quite prepared to agree with them up to a certain point. But that result can only be ensured by using a solution of such strength as to make it rather expensive. What we want to arrive at is a combination of the ingredients of the developer, which while of moderate strength, suffice to give printing density under all ordinary circumstances with tolerable certainty. So far as our own experience goes, the nearest approach to these conditions is secured with carbonate of potash in preference to any other alkali, carbonate of soda, as generally used, being the worst in respect of vigour of image. The omission of bromide from the developer is another prolific source of their images, since the great energy of the unrestrained solution causes it to veil the shadows of the picture before the lights have acquired sufficient strength.

Both amidol and metol exhibit extraordinary power in searching out feeble effects of illumination, and the reflected light in the camera, even with extremely short exposures, suffices, with unrestrained metol, to produce a veil which would not be apparent under other circumstances. That the result is not due to abnormal reduction, or to over-exposure, is proved by the edge of the plate remaining clear where protected by the rebate and by the veil, where the exposure has been barely sufficient to impress the more feeble details. Where such a veil is produced, it, of course, goes on intensifying with the rest of the image, and so limits the duration of development, and, consequently, of intensity; but, where a moderate addition of bromide is made to the developer, the plate remains clear for a long period without to any material extent prolonging either exposure or development.

What we desire to impress upon our readers is, that, where it is at all possible, it is preferable to obtain density in one operation by the judicious modification of the solution; but there are, of course, circumstances—errors in exposure or accidental variations in the character of the films—that may render subsequent intensification necessary, and then the delicacy and clearness already referred to render this class of image more particularly suited to intensification than even the cleanest pyro image. And, moreover, owing to that clearness, the degree of intensification it is necessary to give is so slight for ordinary subjects, that methods which would be of little use under other conditions are quite available here. Among such methods we may mention as an instance chloride of mercury, followed by sodium sulphite, which, as a rule, adds too little to the strength of the image to be of much practical use, although its freedom from tendency to stain recommends it in preference to most of the mercurial methods.

The first necessity before proceeding to intensification is, of course, perfect fixation and thorough washing. The latter is of no avail without the former, indeed it is only when intensification is attempted that we discover how prone we are to be negligent in the matter of fixing. The practice of passing the negative through two separate baths is one that adds little to the trouble of production and adds considerably to the chance of completeness of action as well as to cleanness and clearness of result; for, if the negative be left in the first bath until *apparently* fixed, and then after a slight rinse transferred to the second, the latter will retain its energy and effectiveness for a far longer period than if it were allowed to become decomposed and discoloured by continual additions of minute traces of the developer. A further safeguard against imperfect fixation will be found in the method of treatment with iodide of potassium mentioned in these columns a few weeks back. This only requires the plate to be immersed for a minute or two in a solution of iodide of potassium after fixing and washing when if any silver remain in the film it will be converted into iodide, and thus rendered visible and show the necessity for further immersion in the hypo bath.

For very slight increase of density there is no more convenient intensifier than the one we have just mentioned, namely, chloride of mercury, followed by sodium sulphite. This does not necessitate the careful and prolonged washing after bleaching that is required when other darkening agents, such as ammonia, are used, although the latter gives a much more vigorous result, and perhaps for general purposes is to be preferred. In this case, however, the washing must be very carefully performed, preferably in a running stream of water, for at least an hour; and the final result will be better as regards clearness if the first stage of the washing be performed with soft water, or, at any rate, water as free from carbonate as possible. If these precautions be observed, the intensified image will be as clear and free from veil as before treatment with mercury, and will, moreover, retain that clearness or translucency that adds so much to the delicacy of gradation of a negative. If the washing be inefficiently performed, there is pretty certain to be a certain amount of veil in the shadows of the negative, as well as a want of transparency in the half-tones.

Where a still greater increase of density is desirable, one of the best methods we have tried is chloride of mercury, followed by the usual amidol developer, containing sodium sulphite. This is as clean in its action as the sulphite alone, but gives a much greater increase of strength, and a peculiar non-actinic colour is given to the image by the addition of a few drops of solution of iodide of potassium in place of bromide as a restrainer. By this means, in fact, a very considerable control over the result is obtained.

We have personally always had a preference for silver intensification, which, although it perhaps requires a considerable amount of care, gives, we think, a better result than is to be obtained by any other means. The requisites are, a very careful washing after fixing, as already mentioned; then the application of a solution of pyro or hydroquinone, acidified with citric and nitric acids, and supplemented by the addition

of a few drops of solution of nitrate of silver. Under this treatment the image gains density with great regularity and evenness, and it can be carried to almost any extent, as, unlike the mercury methods, it is a progressive building-up process; or, if only a very slight increase is required, it is equally easily effected. One thing has to be borne in mind, namely, that the density increases on drying.

After intensification, in order to destroy any possible action of the soluble silver salt on the gelatine film, which might ultimately result in the discolouration of the negative, let the latter be immersed for a short time in a dish of water slightly acidified with hydrochloric acid, and afterwards in a strong solution of sulphite of soda, and finish off with a careful washing.

While the present article has been suggested to us by numerous complaints as to the necessity for intensification with the new developers, we may conclude by expressing the opinion that, as these become better known in practice, the difficulties in respect of density will disappear.

A Suggestion.—A lock of hair, particularly of deceased friends is highly treasured by many. A correspondent suggests as a new style of portraiture, which is so often being asked for, that a piece of the sitter's hair should be mounted upon the portrait and arranged as worn at the time of sitting. Such pictures, he says, would be novel, and also greatly prized, especially after the prototype had departed this life, and adds, would, no doubt, take with the public, as they would be entirely new. We give the suggestion for what it is worth. With regard to the novelty, we had an idea on reading the letter that the thing would not be new, as it had been done before. On referring back, we find that a provisional protection was granted for precisely the same thing more than thirty years ago—namely 1859. This is another exemplification of the old adage, "Nothing new under the sun."

The Photographic Trade.—Although we have, for the present at least, closed the controversy on the depression of business, and amateurs *versus* professionals, letters are still being received on the subjects. One writer, adverting to a remark of ours that the introduction of dry plates had not been an "unmixed blessing" to the profession, says that it must have been little less than one to the manufacturers of them and to the sellers of them, also to the makers of cameras and lenses, as well as the manufacturers and dealers in all goods connected, either directly or indirectly, with photographic material and appliances. Of that there is little question. When photography, as a business, was at its zenith, the consumption of material, the demand for lenses and cameras, and other appliances connected with the art, was nothing in comparison with what it has been during the past few years. "It is an ill wind that blows nobody good." Fortunes in connexion with photography have drifted from one direction into that of another. *Long live photography!*

Disfigured Landscapes.—During the past few weeks a considerable number of letters have appeared in a daily contemporary protesting against the disfigurement of many of the most interesting places in the country by hideous advertisements, and not without reason, as every one who admires nature will agree. A Society has been formed for its suppression, and all must wish it success, and we are even promised legislation on the subject. It is exceedingly annoying to be often unable to take a photograph of a charming bit of landscape without including a repulsive advertisement of some quack medicine or other. When travelling on the Great Western, the fields at the sides of which are greatly disfigured by these obnoxious advertisements, with a well-known R.A., he, while bewailing the defacements of nature, remarked that painters could always ignore them in their pictures, while photographers were often helpless in the matter. They must take the landscape as it appears or not take it at all. The latter is the course photographers are compelled to adopt, and, as a consequence, many excellent pictures have to be foregone.

German Prints.—*Apropos* of trade marks, a question of considerable importance was put in the House of Commons, on Friday last, to the President of the Board of Trade. We say the question is important, inasmuch as it has been, and still is, under the consideration of the law officers of the Crown, though many, no doubt, were under the impression there was no question in the matter at all. It was this, "Whether the law officers of the Crown had yet given their opinion as to the legality of the admission into this country of masses of birthday and other anniversary cards, pictures, and religious tokens, printed in Germany, without any notification of such fact, save on the outside band of a large packet?" The reply was, the opinion had not yet been received. From the large number of this class of prints now in the market, bearing the imprint that they were printed abroad, one would have surmised that even the spirit of the law was being fully complied with. We know of instances where collotypes and costly photogravures have been arrested at the Customs, entailing considerable loss both to the producers and the importers, because each individual print did not bear the imprint "printed in Germany." Is there now a doubt as to the legality of this proceeding? The parcels were duly marked as in the cases giving rise to the question.

Trade-marks Prosecutions.—At the Mansion House Police Court last week, two well-known city firms, Messrs. Dollond & Co. and Messrs. Leslie & Co., were summoned for applying a false trade description to clinical thermometers, implying that they were of English manufacture, whereas they were made in Germany. The prosecution was undertaken by the Board of Trade, but was instigated, we believe, by the Master Barometer Tube-blowers' Association. The prosecuting Counsel stated that the words "Made in Germany" would appear on the instruments when they passed the Customs, but they were only in lampblack, and were easily rubbed out. The defence, in each case, was that the thermometers were purchased for English-made goods. In both cases fines of 10*l.* and costs were imposed. Clinical thermometers are not the only scientific instruments sold in this country that bear no indication that they were made abroad. Thousands of photographic lenses, for example, are imported every year that bear no indication that they are of foreign manufacture, and, what is more, they are often afterwards engraved with the names of English vendors. There is no reason why foreign scientific instruments should not be equally as good as those of home manufacture, and many are, if not superior; but the law says they shall bear the name of the country of origin. If they do not, it is clear the law is being infringed, and it often is; of that there is no question.

SUPPLEMENTARY LIGHTING.

I REFER to this matter, having recently had brought to my notice some effects of this method of working. Like most other neglected photographic processes, supplementary lighting is resuscitated from time to time. A quarter of a century ago the matter was threshed out and dropped; whether it was discontinued because it was of *no* advantage, or because the advantages were somewhat uncertain, I am unable to say; but at first some of our leading men, both here and on the Continent, took it up, and, for a time, believed great things of it. Exposure was to be reduced by half, and marvellously short studio exposures for those days could be made to give excellent results, impossible without the extra light. Coloured glass caps were put on the market, by which the exposed plate could be flooded with light of any degree of actinism at the will of the operator. Small windows were cut in cameras, and glazed with coloured glass, for the same purpose.

Most portraitists gave it a trial, for anything that would shorten exposure was a boon and a blessing when about fifteen seconds was considered an instantaneous exposure. However, it dropped through, and in a couple of years I question if anybody used it except for experiment. The theory was excellent. Why didn't it answer?

Surely, if the preliminary effects of light, *up to the time when it began* to make a faint impression on the sensitive surface, could be supplied, in addition to that passing through the lens, so much time would be saved, and the image cast by the lens would begin to make a *useful* impression from its first contact.

I went into the matter at the time, and tried it in a variety of ways, but the results were not encouraging. If a plate was under-exposed, there was *no* more detail impressed, but a slight *veil*, that gave a *better printing negative*, was developed. Printing an under-exposed negative under white paper seemed to have quite as good an effect, and, as *proper* exposures were always aimed at, the advantage of extra light was not very palpable, anyway, whatever the reason the process was dropped.

Supplementary lighting seems to have another effect, which does not show itself by the production of more detail, but density instead. A *very small* modicum of diffused light, such as is reflected from the inside of a camera that has become somewhat shiny from use, or from the lens mount, seems *not* to fog the plate, but to give rather an increase of density to the negative. The line between fog and density is rather difficult to draw: so many conditions may interfere, especially length of exposure, it would be interesting to know for certain how much light can be used with *advantage*. Of course, with wet collodion the mere matter of density was not thought of, as most negatives underwent redevelopment either by adding silver solution to the first lot of developer, or by pyro and silver solution after the development proper had taken place. Sufficient density with the first application of the developer was scarcely expected; so, under these circumstances, if extreme density *was* conferred by supplementary lighting, it was neglected.

Now we work under different conditions, and it might be worth while to go over the process again. I would suggest to any one owning a stereoscopic camera that a little light colour inside the camera or lens mount, for one half the slide, would show if any advantage is to be expected in the matter of *density* by the supplementary light thus introduced. It stands to reason that, with our rapid plates, it must be *very little*, or it will result in fog instead of density. Anyway, I suggest the idea of trying it to those who have more time and opportunity than I have myself.

EDWARD DUNMORE.

ON THE CONSTRUCTION OF INTERCHANGEABLE LENS SCREW FITTINGS.

[Photographic Society of Great Britain.]

THERE is being established among you a system of standard interchangeable fittings for the attachment of lenses to cameras; a system which will presently enable you not merely to covet your neighbour's lens and to screw it without difficulty in your own camera, but will entirely simplify the attachment of your own lenses, so that you may have on each camera one flange to suit the largest lens you use, and every other instrument will either fit this flange direct or be carried in it by a standard adapter. Moreover, the lens will not, as of old, screw and arrive home with utter disregard to your wishes. One will not have its diaphragm index set up where you need a mirror to read it, nor another down where you cannot see it, and all where you have to hunt for them. They will arrive home in one place which may be of your own choosing.

And, in attaching a lens to its flange, you will not have to seek, in patience or in despair, the suggestion of a tendency toward engagement of the screws. You will place them with their zero marks together, knowing that they will immediately engage on being turned, and that you cannot cross the threads. You will know that exactly three turns complete the engagement, and in removing the lens your mental anguish will be neither protracted nor acute, for you will know precisely when to expect the instrument to fall upon the floor.

The old want of system and uniformity in these things is being gradually dispelled, and one by one lens-makers are realising the importance of adopting the Society's Standards for the benefit of their customers.

Such a change, involving so many personal interests, cannot be suddenly accomplished everywhere; but, to those who view the great inconveniences which will be removed by the general adoption of the one standard, there is no doubt that in the course of time, and with constantly accelerating speed, this change will be accomplished.

I speak to-night on the technical side of the subject, of methods of making and measuring such screws as are applied to photographic lenses for this purpose, and in bringing this part of the subject before the Photographic Society, I venture to think it may prove interesting even to those who are not mechanics. Besides its intrinsic interest, however, the subject is of considerable practical importance to photographers at the present time, because, while they are asking and will continue to ask, for standard interchangeable screws, it is a fact, which I have no hesitation in stating, that the methods of screw-making generally employed by opticians are quite inadequate to secure that degree of accuracy on which true interchangeability depends. Before photographers can attain the full advantages of standards for their lens screws, the mechanical practice of opticians must rise to a much higher level of culture than it has reached at present.

My work in connexion with the Opticians' Conference appointed by the Convention Committee, and as a member of the recent Standards Committee of this Society, has enabled me to judge of the regard which opticians generally pay to the technical work of screw-making, and I see there has existed among us in the past a certain disregard, sometimes even bordering on contempt, for over-much mechanical accuracy.

It is quite natural that the optician, whose study and skill are devoted principally toward designing and fashioning beautiful glass work, should regard too slightingly the constructive work and the skill of the mechanic, the worker in metals, and in the past the need of critical accuracy in screw making has not been widely felt as soon it will be, for the need has arisen with the present cry for interchangeability; and, if we are to secure for photographers and for photography the great advantages for which that cry is raised, our neglect of accuracy must be banished and scrupulous care must take its place. We must all learn the use of true standards of length, and of fine measuring appliances, so that the work of the optician may be supplemented by the work of the skilled mechanic.

I am a young man, and I want to see these standard fittings everywhere adopted and properly made before I am old. For several years in the course of my work I have been deeply interested in improving methods of making and measuring such screws as we contemplate, and I have resolved to publish some of the results of my own work, in order, if possible, to make the way easier for others.

INTERCHANGEABILITY.

There is an important difference which I ask you to observe between such interchangeability as we need with photographic lenses and such as is commonly secured among bolts and nuts and among gas fittings: it is this, that bolts, and nuts, and gas fittings may be forced together with wrenches and tongs, while our lenses must never be subjected to such treatment, they must go together freely and without strain; and we may conveniently distinguish this by calling it a condition of *free* interchangeability.

Now, I should like you to realise what this condition means and involves. Let us suppose that we have fifty lenses, each with a standard two-inch male or external screw, and fifty flanges with corresponding two-inch female screws. These are freely interchangeable, when any lens will screw into any flange without difficulty.

There will be 2500 distinct combinations formed in trying all these screws together. Now, if one of the male screws be large, even to the small extent of only one-thousandth of an inch on its diameter, this will effectually prevent its entering every one of the fifty flanges which are of normal size. It is thus evident that every male screw must be at least as small as the normal or standard screw. In the same way it may be shown that every female screw must be at least as large as the normal. These are the conditions of free interchangeability among screws, and I ask you to note them carefully. The small amount of one-thousandth of an inch is sufficient to prevent the screws going together at all. Errors much smaller than this are still sufficient to prevent free interchangeability; and it is thus evident that extreme care and accuracy should be observed in measuring such screws, and in making and measuring the gauges with which they are tested. Particularly is this evident when we remember that it is sought to make the lenses, not merely of one maker but of all makers, freely interchangeable, and that the various makers cannot readily compare their work or their gauges, but must rely upon the accuracy of the standards of length with reference to which their tools are constructed and periodically tested.

THE MEASURING OF SCREWS.

A screw such as you see in the diagram (fig. 1) has three principal elements:—

(*p*) The pitch of a screw, which in general terms we speak of as coarse and fine, is the distance between two successive threads, or turns of the thread, measured in a direction parallel to the axis of the screw. At present we are not concerned with methods of measuring the pitch of a screw.

(*d*) The nominal diameter of a screw is usually the measure of the full outer diameter of the male screw. Thus, the two-inch standard male screw measures two inches over all, and it is a simple

thing to measure this diameter accurately by placing the screw between the plain measuring faces of a micrometer gauge or measuring machine.

In order to fulfil our condition of free interchangeability, it is necessary not merely that this full outer diameter of a male screw be at least as small as the normal; it is also necessary that upon the sloping sides of its threads and at their base or root, the screw should be everywhere sufficiently small. Equally important then with the full outer diameter in securing free interchangeability of screws is the thread form, which determines the size of the screw on the sloping sides and at the bottom or root of the threads. The form of thread is taken as its cross section in a plane containing the axis of the screw. The diagram shows the form adopted in the Society's Standards, and which is known everywhere as the Whitworth thread. It is a form beautifully adapted to the purpose for which it is chosen. It is planned in this way (see fig. 1): A base line is divided into sections, each of a length equal to the pitch of the desired screw. Upon these sections of the base line, isosceles triangles are formed by drawing lines inclined to each other at fifty-five degrees. A line parallel to the base line and touching the apices of the triangles will stand above the base line ·96 of the screw pitch, and will include another series of triangles between the first and similar to them but inverted as at (A). By means of equal circular arcs, one-sixth of the height of every triangle is rounded off its apex, as at (B), leaving the form of thread as at (C). The depth of the Whitworth thread is ·64 of its pitch.

Suppose that we have a screw already made, and we wish to

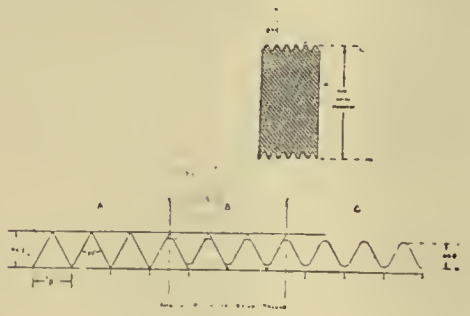

Fig. 1.

measure its thread form. The full outer diameter of the screw is easily measured by placing it between the plain jaws of the measuring machine, as shown at A in fig. 2. This full diameter of the screw is represented by the height of the first thick black line to the right. The depth of thread in any place may be measured by providing the little test piece shown at D, and on a larger scale below in the diagram. This little hardened steel bar of triangular section has its lower edge very slightly rounded, and its measurement, C, accurately determined. When placed along and between the threads

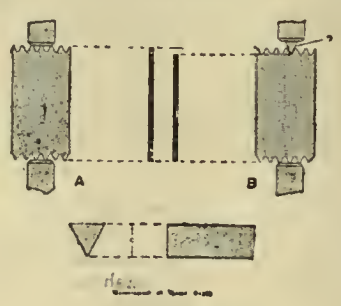

Fig. 2.

of a screw in the direction shown at D, it touches the screw only at the root of the threads, and, by measuring the diameter of the screw, including the test-piece, in the manner shown by the figure, it is easy to determine the depth of thread; for, if we subtract from the measurement so obtained the constant measure, C, of the test-piece, we get a result, indicated by the shorter thick black line, which is less than the full diameter of the screw by exactly the depth of the thread. With due care, and with simple appliances, these measurements may be made correctly within about one five-thousandth part of an inch, which is sufficiently accurate for practical purposes.

The diameter of a screw, as measured on the sloping sides of its threads, may be determined by the aid of a simple application of trigonometry. One easy method, applicable under certain conditions when the angle of thread is known, is to use a small cylindrical gauge placed along and between the screw-threads, so that it bears only against the sides of the threads in the manner shown in fig. 3. The question to be solved by using this little gauge is this—Are the threads of the screw, so to speak, too fat, as at F, or too thin as at T?

You will see that, if the threads are fat, the little gauge will stand too high above their tops. If the threads are thin, the little gauge will sink too low between them. It is a simple matter to discover just where the gauge should stand in relation to the thread-tops, and it is simpler still, and just as useful, to find where it should stand in relation to the base or root of the threads. If the sloping sides of the threads had been continued downwards to form a thread not rounded at its root, but sharp, it would have been of the form shown in fig. 4; and, knowing both the diameter of our little cylindrical gauge and the angle between the sides of the threads, it

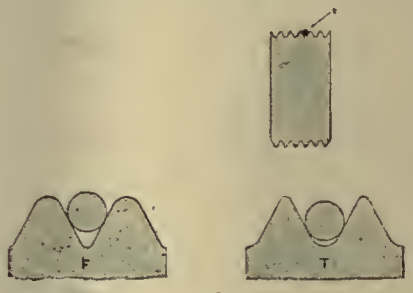

Fig. 3.

needs only a simple application of trigonometry to decide where the gauge should stand in relation to the point P. We know, by the construction of the Whitworth thread, that an amount equal to ·16 of the screw pitch is rounded off the sharp angle to form the rounded

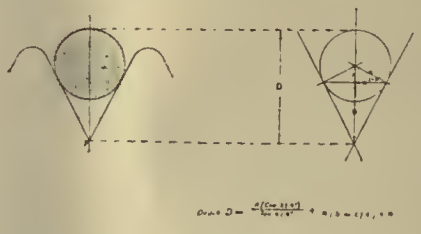

Fig. 4.

root of the thread. Knowing, then, how far the cylindrical gauge should stand above the point P, we can easily find how far it should stand above the base or root of the threads, and how far above their crests.

For practical purposes, the necessary calculations may be made once for all, and I prefer to construct for each pitch of screw to be dealt with a small cylindrical gauge, of such diameter that it shall stand, when in use, one or two-thousandths of an inch, or some such simple recorded distance above the crests of a perfect or normal thread.

The radius of such a gauge for this purpose may be found by the formula:—

$$\frac{1{\cdot}25\,d - p}{3{\cdot}1656},$$

where d is the depth of thread, and p the desired convenient projection of gauge above the crests of the thread. The main features of this problem are shown in the diagram (fig. 4).

If it be necessary to measure the angle between the sloping sides of a screw thread, it may be done by using a second gauge, small enough to lie between the threads close down at their root.*

W. Taylor.

* The use of trigonometry for this purpose is naturally not new. It is employed in a very different way in the measurement of the Sellers form of thread by Messrs. Pratt & Whitney, of Hartford, Conn., in whose works I have had the pleasure of seeing it applied. The use of small cylindrical gauges such as I have described was first suggested to me by Mr. Barber, the superintendent of Messrs. Whitworth & Co.'s gauge department; but, so far as I am aware, the application in the way I have explained is novel.

(*To be continued.*)

DOUBLE TONES IN GELATINO-CHLORIDE PAPERS.

One of the most frequent imperfections which I meet in gelatino-chloride printing-out papers is that there is a marked double tone. This defect is most apparent in the half-tones of the print, and especially noticeable at the edges of vignettes, and, in fact, in all portions of the picture where there is a transition in gradation from half-tone to a lighter tint.

I frequently hear this defect attributed to the use of sulphocyanide of ammonium as a toning adjunct, and I have myself found, at various times, that a sulphocyanide toning bath would give it. As a matter of fact, I am inclined to believe that the use of sulphocyanide does predispose to this defect, and mainly because it is infrequently used with a small enough proportion of the salt to the water, and with an insufficiency of chloride of gold to do the toning work with facility. This is a point which it ought hardly to be necessary to emphasise, as the makers of P.O.P. have frequently drawn attention to the necessity of not overdoing the quantity of sulphocyanide per ounce of water.

It need not be inferred from this that a sulphocyanide bath, properly constituted, will not make good, even, and *single-toned* prints in gelatino-chloride; on the contrary. Nor, on the other hand, are other toning baths free from the trouble. Generally speaking, it may be taken that a double tone in a printing-out paper indicates one of three things:—

1. Insufficient gold.
2. Too large a proportion of the toning adjunct.
3. The use of a partially exhausted bath.

Turning attention for the moment to the first cause, it is tolerably certain that an emulsion paper requires more gold to tone a given number of square inches of surface than does ordinary albumenised paper. This, instead of being a weakness, may well be claimed a strong point for gelatino-chloride, for a strongly substituted gold image is likely to be more stable and permanent than a half-toned one. The question of the cost of production is hardly one which should enter into the question at all, although it is, *cæteris paribus*, a factor. As a basis for estimating, we may assume that, under the best conditions, a sheet of albumenised paper will require one grain of chloride of gold to tone it to a warm colour. I don't think we can expect to tone a sheet of gelatino-chloride paper with less than three grains, but the extra cost spread over the prints is of no importance, compared with the advantages of the emulsion paper, such as the keeping qualities and evenness of coating. This latter is a point of great importance when we remember that every sheet of our old friend albumen had a thick end, and a corresponding thin one, due to the draining of the salted albumen during the drying process.

Not only must there be a sufficiency of gold, and not an excess of sulphocyanide, but the solution must be sufficiently concentrated to change the colour of the prints in a reasonable time. A prolonged toning with gelatino-chloride papers generally means that double colours are obtained.

I have recently seen some very quick toning baths worked with bicarbonate of soda, chloride of gold, and water only. The formula stands about—

Chloride of gold	1 part.
Bicarbonate of soda	20 parts.
Water	480 „

In such a bath the prints, previously well washed, tone in a phenomenally short time—under two minutes. But the tones thus obtained are, to my mind, not very attractive, ranging towards coldness and greyness. There is also the added disadvantage that, with so rapid a change in colour, it is to a large extent impossible to secure other than one tone, viz., the limit to which the bath will go. Moreover, there is an inclination to over-tone, or to eat away the lines of demarcation between the lighter tones, or at the edges of vignettes.

This trouble with the edges of vignettes and of the lighter tones is not by any means restricted to printing-out papers, in which it might be supposed to be caused by a possible mixture of sensitive salts in the emulsion such, as, say, the chlorides and citrates. It might be plausibly argued that the discolouration of the finer edges is due to a slight separation or imperfect admixture of these salts, and not to the toning action at all; in other words, that such an emulsion is but a mechanical mixture and not a chemical compound. It is quite possible and even likely, that an irregularly constructed emulsion would suffer from such a defect; but it must also be borne in mind that all photographic images first show signs of deterioration in this same part, viz., in the lines of demarcation between the finer tones. This is only another way of stating that chemical action commences in these portions of the picture, and the defect has probably come within the observation of many of my readers when reducing a negative with hypo and ferridcyanide of potassium. The action, if too prolonged, or caused by too energetic (strong) solutions, takes effect unduly, and often disastrously, at the junction of the finer tones.

We are therefore justified in concluding that this defect, for I do most certainly view it as a defect both from the technical and artistic point of view, is not inherent in the paper or in any particular toning bath, but only indicates an unsuitable strength of the chemicals used, and this excess is most probably *of the toning accessory*. I mean the sulphocyanide, or acetate, or bicarbonate, or whatever be used.

This conclusion is emphasised by the action of the combined toning and fixing bath. For instance, a combined bath, containing, say,

Water	5 ounces,
Hypo	1½ ounces,
Acetate of lead	120 grains,
Sulphocyanide of ammonium	30 grains,
Gold chloride	2 grains,

will work in a very satisfactory manner for the first time, but afterwards toning will only take place in a perfunctory manner, the half-tones and less tones changing whilst the deep shades remain about their original colour. The gold having been exhausted to a large extent leaves for the second essay an excess of the toning adjuncts, which are, with the remaining gold, only able to attack those portions of the print where chemical action takes place most easily.

Seeing that a combined bath deposits the gold in so facile a manner, I am surprised to hear it maligned now and again. Used only *once*, so as never to permit the possibility of the intricate chemical inter-action between the hyposulphite and the acid products of the double decomposition resulting from the toning, I do not see any greater risk of impermanency than with separate baths.

It has never been shown that the proportion of faded prints was greater, with the old toning and fixing combined, in the days of plain salted paper, than in later days with what is claimed to be the more scientific method. For my part, I should be inclined to expect greater permanency from gold toning deposited upon the fixed image—for that is what a combined toning bath amounts to—than from a gold-toned image afterwards fixed. In neither case can the hyposulphite dissolve away more than a small part of the reduced silver in the image: but, whilst in the separate baths, the fixing solution may take away what may be described as part of the foundation of the image, viz., that upon which the gold has been deposited; in the combined bath, the fixer robs the image of all the reduced silver which it has the power to do, before the gold is deposited in exchange for the remaining metal, viz., that which the hypo has failed to dissolve.

In addition to this, as the prints have to be carried to a further depth in printing for the combined bath, there is an added chance of a greater deposit of metal which may be considered a further guarantee of standing powers. With a combined bath used but once, and not exhausted by excessive work, I have found no tendency to double colours in gelatino-chloride papers. To economise, only sufficient solution need be used to produce the desired effects.

S. Herbert Fry.

ON THE AMOUNTS OF SILVER AND HYPO LEFT IN ALBUMENISED PAPER AT DIFFERENT STAGES OF WASHING.

[London and Provincial Photographic Association.]

Any one studying the literature of photography must be struck with the diversity of opinion expressed by different workers on the important points of fixing and washing prints, some recommending neutral and others alkaline hypo, and the strength of the fixing solution varying from five to thirty per cent., the length of time the print should be washed varying from one to twenty-four hours.

The danger of an acid fixing bath and its tendency to yellow the whites of a print, and in addition its doubtful fixing power, was first pointed out by Mr. J. Spiller in a paper he read before the Photographic Society of Great Britain on January 14, 1865. Mr. Spiller in his paper says that "a hint was thrown out by Messrs. Davanne & Girard to the effect that the so-called 'pure whites' of the albumen prints still retained a small proportion of silver in an insoluble condition, and most probably in the form of sulphide."

Further on, the author says: "My experiments went to prove that the metal was retained in the whites of the albumen print, and indeed

in all parts of the coating, in the form of an argentic organic compound, colourless, unalterable by light, and comparatively insoluble in hyposulphites and other fixing agents. It could not be a simple sulphide, for the test by which I discovered its existence in the paper was the production of a brown stain upon moistening the white surface with sulphide of ammonium." In a paper in the *Photographic News* for October, 1862, Mr. Spiller recommended the addition of carbonate of ammonia to the ordinary hyposulphite fixing solution, for the double purpose of preventing by its alkalinity any chemical change or decomposition of the double hyposulphite; and, secondly, of directly aiding by its special solvent properties in the removal of this organic compound of silver.

In carrying out this research, we had two objects in view: firstly, to determine the time the print should be washed; and, secondly, to endeavour to determine the cause of the fading of the finished print.

Three sheets of albumenised paper from the same quire were sensitised on a fifty-grain neutral solution of nitrate of silver and allowed to dry in the dark. These were then cut into pieces 5½ in. × 8½ in. The pieces from one sheet were marked A, from the next B, and from the third C.

The paper thus cut up and marked was washed for ten minutes in running water till all free silver had been removed.

Two of these pieces, taken from different sheets, which could be easily recognised from the letters on the back, were placed on one side, in order to determine the amount of sulphur originally present in the paper and also the amount of silver that had to be removed by the fixing agent.

The remainder of the paper was placed in a pint and a half of a twenty per cent. hypo bath; and, as this gave a little more than two ounces of hypo per sheet of paper, we consider we were on the safe side, as Captain Abney says that one ounce of hypo will fix three sheets of paper.

The hypo bath was tested before and after use, and was found to be slightly alkaline to litmus. The temperature was 22·4° C.

The prints were kept in the bath with constant changing for fifteen minutes. Two pieces (again from different sheets) were then taken and allowed to drain for five minutes, and the total sulphur and the remaining silver to be removed by washing determined.

The remaining pieces were then placed in a large vessel filled with water and into which water was constantly flowing. The temperature of the water was 13° C. During the first hour the pieces of paper in the water were constantly turned over in order to prevent them sticking.

Two pieces were removed at the end of 5, 10, 15, 25, 40, 60, 90, and 120 minutes, and 19 hours, and the amounts of silver and sulphur remaining in them determined.

The estimation of the sulphur and silver in the papers was carried out as follows:—In each case the two pieces of paper were allowed to drain for five minutes, and then torn up into small pieces and placed in a large beaker, with a mixture of 100 c.c. of nitric acid and 200 c.c. of strong hydrochloric acid (free from sulphur), covered with a dark glass, and heated on a sand bath till the paper was completely destroyed. The solution was then taken down to dryness, and 250 c.c. of pure distilled water and three drops of hydrochloric acid added, and the whole heated to boiling, allowed to cool and filtered, and the filter paper and beaker washed with boiling water. The filtrate was heated to boiling, and chloride of barium added, which precipitated all the sulphate present as barium sulphate. This was then collected on a filter, dried, and weighed in the usual way, and from this the amount of sulphur present in the paper calculated.

The chloride of silver on the filter was then dissolved out with ammonia, and precipitated by means of nitric acid, filtered off and treated in the usual manner.

The figures obtained are as follows:—

1.	Weight of sulphur in original paper	·0050	grammes.
2.	„ in water adhering to paper	·000032	„
3.	„ in paper fixed but not washed	·2243	„
4.	„ after 5 minutes' washing ..	·0063	„
5.	„ 10 „ ..	·0045	„
6.	„ 15 „ ..	·0048	„
7.	„ 25 „ ..	·0044	„
8.	„ 40 „ ..	·0043	„
9.	„ 60 „ ..	·0046	„
10.	„ 90 „ ..	·0047	„
11.	„ 120 „ ..	·0045	„
12.	„ 19 hours „ ..	·0047	„

The amount of sulphur in original paper has been subtracted from results 4 to 12 inclusive.

1	Weight of silver in paper unfixed....	·0734	grammes.
2	„ „ fixed but not washed ..	·0086	„
3	„ „ after 5 mts. washing	·0051	„
4	„ „ „ 10 „	·0035	„
5	„ „ „ 15 „	·0037	„
6	„ „ „ 25 „	·0037	„
7	„ „ „ 40 „	·0033	„
8	„ „ „ 60 „	·0036	„
9	„ „ „ 90 „	·0038	„
10	„ „ „ 120 „	·0040	„
11	„ „ „ 19 hours „	·0039	„

From these figures it will be seen that after five minutes' washing 97·2 per cent. of the sulphur originally present has been removed, after ten minutes 98 per cent., and that, however long-continued the washing, no more of the sulphur can be eliminated. Turning to the silver, we find that as the paper comes from the fixing bath it has lost 88·3 per cent. of its silver; after washing for five minutes, 93·1 per cent.; and, after 10 minutes, 95·3 per cent. After ten minutes' washing the amounts of silver and sulphur remain constant.

It is evident from these figures that the permanency of a print does not depend so much on the washing it receives as on its thorough fixing; and we are strongly of opinion that the best way of removing all the silver is not by using two baths of hypo in succession, but by washing for about five minutes after the first bath, and then soaking in a second fresh bath of hypo.

In what form the silver occurs in the paper, whether as the insoluble $AgNaS_2O_3$, or the soluble $Ag_2Na_4S_2O_3$, held in a sort of "loose combination" with the films of the paper, we are unable to state. However, the fact remains that, after a more thorough washing and fixing than prints generally get, ·246 of a grain of silver remains in each 22 × 17 in. sheet of paper; and this, which is probably in the form of hyposulphite in the presence of light and organic matter, is reduced to silver sulphide, and will easily account for the yellowing of the whites of prints after a time.

We had hoped to determine the silver and sulphur in gelatino-chloride paper, and the silver in paper that has been treated to several baths of different composition; but, owing to the length of time required to carry out these experiments, we have been obliged to defer the investigation of those points for a future occasion.

F. B. Grundy and A. Haddon.

PRACTICAL REMARKS ON PHOTOGRAPHING DIFFICULT INTERIORS.

III.

In previous articles I referred to various classes of interiors, the photographing of which was possible by means of daylight. In numerous cases, however, a worker has to undertake subjects in situations where not a ray of daylight enters, such as dark vaults or underground workings, bonded stores, and many similar places frequently to be met with in all large cities. When such have to be dealt with, some system of artificial lighting has to be resorted to, and, with proper arrangements, made beforehand, and the adoption of a suitable method of illumination, most excellent results are obtained in situations where darkness alone prevails.

Somewhat recently it has fallen to my lot to photograph a good many of these subjects by means of artificial light, and I hit upon a plan or system of working that has yielded most satisfactory results.

What is known as the modern system of flashlight photography or mode of lighting is not so well adapted for photographing large spaces, such as caverns, bonded warehouses, vaults, &c., as for such subjects as small rooms, or objects situated somewhat near the camera; but when interiors, such as those having a great depth, as many of the bonded warehouses and other similar classes of subjects often have (for frequently as much as hundreds of yards in length have to be dealt with), then recourse has to be had to a different method of lighting.

In undertaking dark interiors of any great extent, one of the chief factors towards success is ventilation, or the obtaining of good currents of air. When such exists, a worker is at once master of the situation; without such, considerable difficulty is liable to ensue. The question of ventilation is most important, and whenever such can be improved, or aided even to the slightest extent, a worker should never neglect to do his utmost to assist in getting up a good current of air.

I have known instances, when the atmosphere was dull and heavy outside and no wind blowing, that it was quite impossible to undertake such work in difficult situations, and a postponement had to be made until not only a windy day, but a day when the wind came

from the desired quarter, for not only must the air currents be sufficiently pronounced, but they must be passed in the proper direction. A very useful little instrument, which in my hands has proved of great value in this work, is the anemometer. With its aid the faintest current of air can be detected.

The reason for so much attention to currents being necessary will become at once obvious to those who understand the necessity of guarding against the overlapping of smoke generated by the burning of the illuminating agent or powder. And when it is considered that at times prolonged exposures are required even with artificial light, to get which considerable quantities of powder have to be consumed, very large volumes of smoke are thrown off, and, were such to get wafted forward or in front of the lens, the result would be failure. Hence the importance of carefully studying the air currents, so that all smoke caused by the burning of the illuminating powder be carried backwards, and thereby not interrupt the view.

I have said in some cases prolonged exposures require to be given. By this I mean long exposures when compared with modern ideas of flashlight. In some instances, where deep penetration into dark recesses had to be dealt with, I have burned large quantities of powder in varying situations, the time occupied in the combustion being several minutes. This means large volumes of smoke being given off, but when such was carried outside the field of view no harm resulted.

A worker who undertakes this class of work should provide himself with several well-formed metal saucers, not too high at the sides: they are most useful for burning the illuminating powder in, and prevent all possibility of danger from the ignition of the powder. They are very necessary, for in this kind of photography it is a great comfort to be able to feel that, no matter how much slow-burning powder has to be used, or what extent of flare or blaze takes place, that there is absolutely no cause for anxiety during the time such is blazing merrily away. When all has been carefully arranged beforehand, and an operator knows for certain that there is no danger from fire, the work is done with comfort. On the other hand, if gone about with makeshift arrangements and apparatus, such as burning the powder on a plate or piece of wood, it is just about ten to one, long before the powder has burned itself out, the worker will have seen something to set up a proper fright, not only as far as he is himself concerned, but all others who might happen to be near. With proper metal saucers, securely situated, there is no need for fear.

I have said that the magnesium flashlight is no use for these dark interiors. After a good many trials I am convinced there is no mixture better suited for prolonged exposures than what Messrs. G. Mason & Co., of Sauchiehall-street, Glasgow, specially supply for this purpose. Of what it is composed I am not aware. All I know is, Mr. Carmichael, so long connected with the chemical department of this firm, has the formulæ, and will at any time prepare freshly made up samples for those desirous of photographing by its means. The light yielded is most brilliant, second only to the magnesium; its great fault is the large quantity of smoke thrown off; but, as I have referred to the manner of driving this outside the field of view, this objection can be set aside.

Let me now describe somewhat briefly the *modus operandi* of photographing a dark vault with the aid of the powder referred to.

In the event of the vault being of any great depth, a considerable quantity of powder will be required; possibly one and a half pounds, divided into three portions of half a pound in each saucer, will not be too much to employ. At the outset it is well to understand that a liberal supply of ammunition is always advisable, and, if it seems that the quantity employed is burning too long, the error is on the safe side, and can be easily remedied by capping the lens when the time is judged sufficient. Therefore never stint the supply of powder; it does no harm, and can be allowed to burn itself out.

As a rule, three lights will not be found too much, and, when such are used, the utmost care must be observed that they are placed behind the camera, or, rather, in no way in advance of the lens. Very good results are obtained when two side lights are burned at equal distances apart from each side of the camera a few feet behind the line of the lens, whilst a third is placed on a higher level—say, several feet above the camera, and, of course, somewhat behind it. An ingenious worker will have but little difficulty in rigging up convenient supports to hold the saucers containing the illuminating powder. A very convenient article to use for the rear centre light is a set of house steps, whilst a few old boxes piled one on top of the other serve admirably for the side lights. It sometimes happens that advantage can be taken of certain situations where lights are capable of being burned in advance of the camera at some distance forward. Care, however, must be taken that such are well screened from the lens, and the light from such only projected forward or on to the side; in all cases, however, the smoke must be carefully thought of, guarded against, and currents of air arranged to waft it away from the view of the lens.

All these arrangements should be judiciously gone about with the aid of lamps or other suitable lights, and, when the camera is brought into play, the focussing should be carefully done with the aid of a lamp, the flame of which makes a capital object to focus on. The lamp can then be moved about, and the amount of view included in the picture easily seen on the ground glass when the lamp is placed on both sides of the view. In all interior work wide-angle lenses are most useful, and I have found that, when using such in conjunction with artificial lighting, a more open aperture in the lens is required than would be the case when operating in daylight; even with *f*-16 or *f*-22, it is almost impossible to over-expose a dark interior when using artificial light. In all cases my best results have been got with the lens working with the fullest possible aperture; with such a quantity of powder as I have stated, viz., one and a half pounds divided into three portions, the illumination will be very brilliant, and a most actinic light produced from this excellent mixture; the duration of time which each separate quantity will take to burn varies very little, each portion, if carefully built up in a cone shape in the saucer, will most likely take from forty-five to sixty seconds to burn itself out, and such should yield a fully exposed negative on most dark interiors.

Now as to plates. I have recently made a series of tests on ordinary and isochromatic plates, and was surprised at the difference in results obtained. To get at the best plate to employ I made several exposures with two cameras, under precisely similar conditions as to aperture of lenses; in all cases both kinds of plates were exposed simultaneously to the same light, and the cameras were placed almost side by side. The best results were obtained on fast isochromatic plates, backed with asphaltum. The brand I used was Ilford, although it is quite possible other isochromatics would have shown the same result. The difference, however, in favour of the isochromatic plate over the ordinary bromide was most marked, and really, in some instances, astounding. In all cases, however, the best results were got when nearly the full aperture of the lens was used. This being the case, the focussing requires especial care; but, when drawn well forward and the lamp is used to focus by, excellent results are obtained when using a lens that well covers the plate.

When all is in readiness for the lights to be burned, it is well to call in the assistance of a couple of friends, and, with the lens uncapped and the shutter of the slide drawn, proceed to deliberately instruct the assistants what to do. I know of no better way of setting light to the powder than by the means of the good old fusee; any tobacconist will supply a box for a copper. Hand one each (I mean a box full) to each of the assistants, and proceed to say, "Take fusee." They reply, "Yes." Then give the order, "Light fusee." They reply, "Yes." Then give the order, "Place fusee in powder," and they reply, "Yes," at the same time dropping it neatly on the top of the powder in the centre of the cone. When this is systematically gone about, the three lights will blaze up at the same moment, and second after second gain in intensity, until the vault is lit up in a most wondrous manner, the lights continuing to burn with great brightness for about a minute, according to the quantity of the powder used. And now, at this stage, a worker will appreciate the need of giving some thought beforehand to the ventilation and air currents. Dense volumes of smoke will be thrown off from each light; but, if the currents waft the smoke to the rear, all will go well, and all in front of the camera will be one blaze of brilliant light; but, should by any oversight a door or window be left open whereby the air currents are interfered with and the smoke overlaps forward, all your labour is lost, and the work must be done over again.

Some little thought should be given to the position of the lights so as not to cast too dark shadows, but carefully worked out. Negatives quite equal to daylight exposures will be obtained.

The main points to give heed to are first the air currents. Secondly, a liberal supply of powder burned in suitable positions slightly in the rear of the camera. Thirdly, use a liberal supply, and light the different saucers simultaneously. The cone shape of the powder is easily obtained by pressing on the top of powder a cup or basin.

T. N. Armstrong.

THE PLYMOUTH COVENTION: REPORT OF THE DELEGATES OF THE PHOTOGRAPHIC CLUB.

[Read at the Club, August 2, 1893.]

The Photographic Convention of 1893 has come and gone. To sum up its results in a few words, we may say: Socially it has been a success; from a photographer's point of view, a failure.

Without precise instructions from the Club as to our duties, we have concluded to state our personal opinions for what they are worth, and to give you a brief diary.

The actual programme has, doubtless, come before you, the press having given full publicity to it, as also to the Convention papers. Our part we conceive to be to give you a personal report.

To us the most noticeable feature was a poor attendance. This is a matter for regret. That a gathering which promises and supplies such exceptional opportunities for recreation and intercourse should not be able, out of the thousands of amateur and professional photographers, dealers, &c., to attract more members, is a matter which merits the serious consideration of the Committee of the Convention. We are inclined to attribute much to the date of meeting, and to hold it a cardinal error to have fixed upon one of the busiest weeks of the year, the week of half-yearly accounts, when a majority of business men are intent upon the adjustment of their books. An inconvenient date is not only unfortunate for those unable to go at such a time, but it is even more so for others who, intending to meet old friends, attend, and are disappointed.

There is still another grumble to which, as Englishmen and your delegates, we feel entitled. It is the continued folly of attempting to do too much in one week—too much on each day. The Committee should have experience enough by this time to know that photographers do not want a week of hurry-scurry, but a holiday, and also that most photographers like leisure and opportunity to take pictures when they take their pleasures, even if they take them sadly—the pleasures, not the pictures, which, by the bye, is not characteristic of Conventioners. This year the opportunities were too few, and this was the more tantalising because the pictures were there in abundance, and only leisure was required to work. In fact, an 1893 Conventioner's diary might read as follows:—

Monday.—Journey down. Pleasant day in train. Gloated over a large supply of plates.

Tuesday.—Boat excursion. Rain saved plates.

Wednesday.—Listened to Convention papers. No exposures, but exercised changing box in the bedroom at night.

Thursday.—Excursion through fine country. No stops, so saved plates.

Friday.—Good boat excursion. Reaction too much. Shot plates at everything and anything.

Saturday.—Rail home with, unexposed plates.

Result.—Severe economy in plates.

And now, abandoning this sad hypothetical case, we descend to the Conventional—one week's work.

Monday.—We arrived just in time to dress and rush to the open meeting and reception. This function, honoured by the presence of the Mayor of Plymouth, was held in the Art Gallery, the rooms of which, though small, are suitable and convenient. Here was contained the Exhibition, without which—but for some reason which to your delegates is inscrutable—no Convention is complete. About fifteen firms were represented, and enlargements predominated. There were no noticeable novelties, and it would not have been a matter of any difficulty to select the best exhibit. The Mayor welcomed us in a hearty speech. Then the general President of the Convention, Mr. George Mason, followed with his address—practical, lucid, and Scotch. Afterwards lantern slides were shown upon the screen. Amongst the exhibitors were Major Lysaght, Messrs. York, Cembrano, Hindley, Welford, &c., and many of the slides were exceptionally good. After the formal meeting was closed, an informal adjournment of the male Conventioners was made to one of the local hotels. The fragrant weed and social glass, the merry quip, jovial song, and the tall (and still growing) yarn made all present forget that time was flying, and that the pleasant labours of the morrow called for refreshing sleep.

Tuesday was to have been the day of days, when, as the guests of the local clubs, who treated us most hospitably, we were to have enjoyed the pleasure of a steamer trip in the waters in and about Plymouth. Unfortunately, rain interfered, and somewhat marred the excursion. Still, we adhered to the programme, and it is high testimony to the efforts of Mr. Hansford Worth, the local Secretary—to the beauty of the surroundings and to the jolly dispositions of Conventioners—that, the rain notwithstanding, we enjoyed the trip.

Wednesday was devoted to business meetings, photographing the group of members—always an important function with Conventioners—and the reading of papers. Threatening at first, the weather became finer as the day wore on, and, with its change in mood, Conventioners were drawn away from serious considerations to enjoy the sunshine and the surroundings. The photographing of the group concluded, and lunch discussed, papers at the Art Gallery became the order of the day; but the Gallery was sultry and oppressively hot, and the attendance of members—never large—became smaller by degrees and beautifully less, whilst the temperature rose by tens of degrees.

We think that, if the Convention is to remain anything more than a social and photographic outing, the arrangements for the reading, discussion, and reporting of papers at the Convention will have to be revised. Except so far as the publicity of the press is concerned, the meeting for the reading of the papers was a fiasco. Too many were attempted; consequently it was a rush against time. The discussions were inadequate, and the reports of the discussions, to our mind, very incomplete. Why cannot the Convention issue an official report of its own, after the manner of the Photographic Club?

On the Wednesday evening there was another reception—at Devonport this time—another lantern show, and more papers. The first discussed, *à la* tea and coffee, the papers taken as read, and the lantern show, a lucid interval.

Thursday.—The Royal Wedding-day. The favourite excursion was that to Totnes by rail, thence by steam launch down the Dart to Dartmouth, thence by rail to Plymouth. As a trip to see the country, charming; but, for photographic purposes, the excursion was disappointing. There was no opportunity, save a brief one in Dartmouth after lunch, for taking pictures. Like the restless spirits of which we read in Dante, we were driven at high speed from place to place; no photographic opportunity was ours.

In the evening there was a meeting for papers, but the Wedding festivities on the Hoe and in the Sound prevailed. Like truth, which is also said to prevail, they were great. The view from Plymouth Hoe is a lovely one at all times, but on this special occasion, with the ships illuminated, bonfires on the surrounding hills, search-lights from the men-of-war in the bay, and jollity all round, the sight was most impressive.

Friday.—Three excursions divided the Conventioners. Those who with your delegates decided to visit the Cuttewater Hooe Lake and the Sound had the most pleasant excursion of the whole Convention. The steamer at our disposal was commodious and convenient, and we had ample opportunity of making exposures to our hearts' content; we thoroughly enjoyed ourselves.

In the evening the Convention dinner was successfully carried out. Afterwards music and recitations completed a very pleasant and enjoyable day and practically brought to a close the 1893 Convention.

Saturday.—All excursions were abandoned for this day. This gave us the opportunity to roam about the quaint streets and quays of Plymouth as we liked, and we obtained some of the best pictures on this last day.

In bringing our report to a close, we hope to see the Convention strengthened by certain alterations in the arrangements.

Besides, the points to which we have already alluded as requiring attention, viz., a more convenient date, an official or authorised report, we think there is still too much attempted in the time at the Convention's disposal, too many items of interest crammed into the week. As regards the excursions, the general Committee might make suggestions to the local Committee embodying the general experience of previous meetings and the requirements of the members. A local Convention Committee must always, and of necessity, be inexperienced as far as the requirements of Conventioners is concerned, for we meet but once and then pass on. But in the general Committee wisdom must have accumulated by now! In addition, we believe it would be to the general advantage of the business portion of the Convention—by which we mean the papers and discussions—were taken all together, *de die in diem*, instead of being sandwiched, as now obtains, between distracting entertainments.

And now, in conclusion, let it not be said that we are not grateful for the efforts made to please us. The energetic Local Secretary, Mr. Hansford Worth, and the local societies whom he represented, are to be congratulated on having beaten record for hearty and well-directed hospitality. Towards our Plymouth hosts and friends, if they will permit us the familiarity, we can only have sentiments of gratitude for the successful efforts which they made to entertain us, and their kindness will ever be one of our most pleasant recollections.

We have but one word to add—a member of this Club is the Hon. Secretary of the Convention. Mr. Cembrano is the right man in the right place, and to him the success of the Convention is largely due. We find it a pleasure to be allowed to express what we believe is the universal sentiment amongst Conventioners, hearty thanks for his energetic work in the past, and the hope that he may long stage-manage our photographic holiday.

We trust, gentlemen, that we have carried out our delegation to your satisfaction, and we hope that next year you will be able to dispense with such services by attending the Dublin Convention *en bloc*.

(Signed) J. Guardia,
S. Herbert Fay.

CONFERENCE OF JUDGES OF PHOTOGRAPHIC EXHIBITIONS.

The following is an official report of the late meeting of Judges :—

It having been decided by the Committee of Delegates of Affiliated Societies that it was advisable to hold a conference of Judges of photographic exhibitions to agree upon certain lines of action to be followed in judging, and to offer suggestions for the guidance of societies with regard to exhibitions, a committee was appointed to carry out the necessary steps for calling the same together, and a circular letter was forwarded to thirty-eight gentlemen whose names were well known as Judges, and an invitation to attend the meeting was addressed through the columns of the photographic journals to anyone who had acted in that capacity at least four times at open photographic exhibitions.

Permission having been obtained from the Council of the Photographic Society of Great Britain, the meeting was duly held on Tuesday, June 20, 1893, at the Society's rooms, No. 50, Great Russell-street, W.C. Captain W. de W. Abney, C.B., R.E., D.C.L., F.R.S., P.R.A.S., in the chair.

It was at the outset agreed that the decisions should take two forms: (*a*) Rules which those present should consider as binding upon themselves, and without the observance of which they should refuse to judge; (*b*) suggestions, which should take the form of recommendations to committees or other bodies who may have in their hands the organization of exhibitions.

Both the rules and suggestions were carried in most cases unanimously; in no case did the minority against any rule exceed two.

(*a*) Rules.

1. The Judges' decision shall be final.
2. The Judges shall have full power to withhold any award.
3. The Judges shall have power to exclude all persons from the room while judging.
4. The Judges' expenses shall be paid.
5. It shall be stated in the prospectus that the awards are placed *in the hands of the Judges*, or *at the discretion of the Judges*.
6. The Judges shall not adjudicate upon pictures exhibited as produced with wares of special trading firms.
7. Pictures which have previously taken awards at open exhibitions shall be classed by themselves.
8. Each picture of a set which has been collectively medalled shall be considered for competitive purposes to have received an award.
9. An award shall be made to one picture only except where, from the nature of the subject, the picture bears an obvious relationship to one another.
10. There shall be no distinction between amateur and professional.
11. No production of any kind whatever from the same negative shall receive more than one award, except as defined in Rule 7. This includes lantern slides, enlargements, &c.
12. No award shall be made to a lantern slide until it has been projected on the screen.

(*b*) Recommendations.

13. When Judges have to spend the night away on account of distance, they should not be lodged at the house of a competitor.
14. The Judges should have power to give extra awards where they may think fit.
15. In order to enhance the value of awards their number should be limited.
16. The Exhibition Committee should not accept offers of awards from trading firms.
17. The number of classes should be kept as small as possible.
18. No award should take the form of a money prize.
19. No exhibit at the same exhibition should receive more than one award.

NOTES ON A TOUR IN THE HIMALAYAS AND ON THE NORTH-WEST FRONTIER.

I.

Having just returned from a seven months' tour in the Himalayas and on the Affghan frontier, in which photography was my main object, perhaps a few notes on my experiences may not be uninteresting to others who are thinking of taking their cameras with them to distant countries.

The first consideration must always be the size of the plate to be taken. The more certain a man is in his results, the larger the plate he can take, naturally will give him the finest picture. It is worth while, for instance, for Signor Sella, whose most exquisite Alpine photographs so far surpass all others, to take with him to the Caucasus 120 15 × 12 plates, for he knows he will bring back 120 good negatives, and the extra weight and difficulty of carriage involved in using these large plates is amply repaid by the perfection of the result. I would, then, always advise any one aiming at high results to take with him the largest plates that he can, and the size of his plates will depend then, first upon his confidence in himself to produce good results, and secondly in the equally important question of carriage. In journeys off the beaten track one's means of transport always consists of either mule carriage or coolies, and the loads have often to be made up so that they are capable of being carried either by one or the other as they may offer. A mule in the Himalayas will carry 160 lbs., and a coolie 50 lbs., the former costing 12 annas a day (say 1*s.*), while the latter get 4, 5, or 6 annas a day according to the length of the march. Mules, consequently, are rather cheaper, and, being hired for a fixed period, the use of them avoids the daily bother of engaging coolies. Against these advantages you have the facts that the mule can only go where there is a mule road; secondly, that you carry many more of the precious eggs in one basket; and, thirdly, that on the rough hill paths coolie carriage is much safer than mule carriage. Never once did I see any of the wild hill men ever falter or stumble on the worst of paths, and his load on his back was as carefully carried as himself; whereas the frequent sight of the string of mules staggering down a steep hillside, bumping their loads against overhanging rocks, plunging over the slippery boulders as they forded the stream and scrambling in rushes up the stony opposite bank, was a picture that often made one tremble for the fate of one's plates.

Many will say, Why not avoid all this by carrying celluloid films instead of glass plates? and I must confess that, after my own experience, I find it extremely difficult to give any definite reason, except that I fancy, and it may be only a fancy, that on the whole there is less liability to error in working with glass plates. My experience in this trip was confined to six dozen whole-plate films and eighteen dozen whole-plates. The weight of the former is 4 lbs., the weight of six dozen of the latter 27 lbs. The films require no packing, they are most easily taken out of their envelopes, one by one, as required, exposed, and put back with the same ease, whereas the hours spent by night in one's tent after a long day's march, taking plates out of the slides, numbering, packing away in their paper wrapping and boxes, unpacking the fresh plates (which are always required in broken numbers), and filling the slides, will never be forgotten. It used to take me two hours to get this properly done, and yet, in spite of all this, when it comes to developing the negative in the dark room, I am always hopeful of better results from a plate than from a film. The chief practical difficulty with a film is the want of a really good film-carrier, which, while simple and easy to use, will keep the film absolutely flat. After searching in vain for this in London, I went without any carrier, simply trusting to the dryness of the Indian air to keep the emulsion side of the film concave, while a thin sheet of wood backing (such as used formerly in Eastman paper negative carriers) nipped the edges of the film against the rebates of the slide and pressed it flat. A detail must, however, here be noted, that the single spring, as fitted to most metal dividing flaps of the dark slides, must be removed, as its pressure will bulge out the thin wood backing and the film in the centre, and springs on each edge, to press against the rebate of the slide, must be substituted.

This arrangement will answer in a dry climate, with sizes up to whole-plate, though, in spite of special care being given to putting the films in quite flat, two or three of my film negatives were much spoilt owing to the buckling of the film throwing certain portions of the emulsion out of focus. I used glass plates as a rule for the most difficult and delicate scenes, and the films (which were more rapid) for strong and close subjects; and, though I fancied that the films were less successful in the difficult subjects, yet I must admit that many of them are quite as beautiful in detail and delicacy as those on glass, and, given a good film carrier, there ought to be no reason why a well-coated film should not equal a well-coated glass plate.

The size of the plates that I took was whole-plate; perhaps the most suitable all-round size, though, as I said before, I regret sometimes, in view of the negatives that I brought back, that I did not take a larger one.

(*To be concluded.*) F. St. J. Goad, B.A.

Our Editorial Table.

Adams & Co's. View Meter.

This view meter is so constructed as to show any reasonable width of angle of nature set in a square frame. The lenses (a convex eye-piece and a concave field glass) are so adjusted as to show the scene with sharpness, the amount shown being determined by the drawin

out of the sliding tube containing the lenses. It is adaptable for various lenses. The directions for using it are to unscrew the larger ring, when the sliding tube can be easily withdrawn to distance required. Then focus a view on the focussing screen of camera, noting exactly how much the lens takes in; then look at the same object through the view meter, and slide the tube until it shows the same

amount of view as appears on the camera screen; then scratch a mark on the tube, and make a note of the lens it refers to. Each lens can be registered on the tube in this manner. The sliding tube is fixed by screwing up the larger ring. The above is, of course, only necessary in order to register the user's various lenses; as, when once done, it is merely necessary to use the view meter by setting it at the various marks to see which lens is the most suitable.

This view meter shows at a glance, and without necessitating the setting up of the camera, precisely how much of a scene will be included in the picture to be produced by any given lens, and it forms a handy pocket appliance for seeing pictures in natural scenery, even when one has no camera with him at the time.

The Eastman Company's Mounting Mediums.

There are two classes of this admirable mountant. One of these is in a semi-pasty condition, and when applied to a print secures it to the mount with extreme tenacity. The other is of a more gelatinous character, and the directions for its use are to place the bottle containing it into hot water until the medium is quite liquid, then apply to the back of the prints, which must be quite dry, with a stiff brush. They are put up in wide-mouth bottles with screw-cap metallic covers.

News and Notes.

Manchester Photographic Society.—August 12, Alderley (Ramble)

Northern Photographic and Scientific Association.—August 12, Chigwell.

Photographic Club.—August 16, *Home Portraiture*. 19, Outing to Ongar.

Hackney Photographic Society.—August 15, *My Toning Bath*, by Mr. W. D. Welford.

Gosport Photographic Society.—August 19, Carisbrooke. Leave Portsmouth Harbour at twenty minutes past one.

The London and Provincial Photographic Association has printed and issued a list of members, the number of the latter being about 150.

London and Provincial Photographic Association.—August 17, Delegate's Report of the Photographic Convention of the United Kiogdom.

Messrs. Percy Lund & Co., of Memorial Hall, E.C., have issued a catalogue of apparatus and materials for process work. It is fairly complete, and should prove useful to process workers.

Manchester Amateur Photographic Society.—August 12, Warburton and Ship Canal. Leader, Mr. Drinkwater. Train, Oxford-road Station, five minutes past two. (Book return to Heatley.)

We have received the new edition of the *Traité Elémentaire de Photographie*, by M. G. de Raymond (Paris: Albert Aivas, 39, Rue Vivienne). It is a clearly written and concise guide for the beginner, who should find it extremely useful.

Newcastle-on-Tyne and Northern Counties Photographic Association.—Next Out-door Meeting to Alnwick on Thursday, August 17, under the leadership of Mr. M. Anty. Train leaves Newcastle at twenty-five minutes past nine a.m. for Alnwick.

Leytonstone Camera Club.—August 12, Richmond Park. Leader, Mr. Aubrey Thompson. The Club will proceed by the train leaving Waterloo, L. & S.W.R., at three o'clock, arriving at Richmond twenty-one minutes past three. Open Social Evening at headquarters, eight o'clock.

Mr. Williams R. Kennan has taken larger premises at No. 41, Grafton street, opposite Chatham-street, Dublin.

Mock Suns.—Mr. M. Glover, of 124, Stephen's-green, Dublin, writes to *Knowledge*, enclosing two photographs of a mock sun which he observed at Dublin on the evening of June 30 last. The phenomenon was first noticed about half-past seven p.m., and remained visible for about twenty minutes. The photographs were made with very short exposures, and show the sun's disc seen through cirro-stratus cloud, with a spurious image of the sun also seen through clouds at a distance of about 25° from the sun, and at about the same altitude above the horizon. A similar image was seen by Mr. Glover on the left hand of the sun, but it had faded away before the photographs were taken.

"Photographic English 'as She is wrote.'"—The following circular refers to a new French print-out paper recently put on the market. It is conceivable that some French instructions compiled by English writers may read just as quaintly. "With this sensibilised paper, whose manipulatiou is easy and speedy, you obtain proofs giving vigour, depness, and fineness. Warm hot-pressing, the proofs are more beautiful than those made with albuminized paper. Dry on an ebonite or ferrotype plate, it gives an enamelled surface. Dry on a depolish glass it gives a dead surface as nice as the platina. Every way of virago in use for aristotypique paper can be utilised, nevertheless we recommand the combined virago. You can préserve it several months in taking care to keep it off from ligth and dampness, and carefully put it again in the pocket like we deliver it. Do not care of the slight yellow colour that can get the paper, because that desappear to the fixage."

Messrs. Taylor, Taylor, & Hobson write: "Frequently within the last few months we have received complaints of instruments being sold as of our manufacture when they proved to be otherwise. In some cases the goods were misleading copies of our instruments, and in others they had been represented as ours through misunderstanding and want of care. It is our unvarying practice to engrave upon every lens we issue our name and address and a registered number, and no lens is genuine unless so marked. Upon such small instruments as our circular spirit levels, however, on which it is not convenient to do this, we now impress our newly registered trade mark, of which we enclose an example. This contains the firm's initial, 'T. T. & H.,' upon one heart with a finely engine-turned ground, significant of the precision in mechanical practice which we study to observe. The whole is surrounded by a circle, that which is without beginning or end, a symbol of perfection, which is our aim."

Secretaries of Societies may derive a hint as to subjects for discussion from the following list, which recently constituted the "Question-box" Meeting of the Manchester Amateur Photographic Society:—1. In developing a plate, how is it known when the proper density has been obtained? 2. Why should prints from stereoscopic negatives require to be transposed—*i.e.*, left to right and *vice versâ*? 3. Which is the best backing to prevent halation? 4. How can halation be avoided in interiors and woodland views without backing, and should the plates be over or under-exposed? 5. Does halation ever occur in films? 6. What quantity of water should be added to a saturated solution of hypo for fixing (*a*) plates and (*b*) prints? 7. Can any member show how to mount prints without the mountant appearing either upon the surface of the print or upon the margin of the mount? 8. What is a practical way of binding a lantern slide? It sometimes takes me twenty minutes to bind a single slide. Will one of our lantern-slide makers say a word on the subject, and show how it is done? 9. Has any member used the new "printing-out lantern-plates," and with what result? 10. Why is it recommended to add ammonia to the fixing bath for prints? 11. Wanted a *simple* toning formula. 12. Which is the best snap-shot developer—pyro, eikonogen, amidol, or metol? 13. What is the best developer for bromide enlargements? 14. What is the best method of drying a negative quickly? 15. How are over-exposed prints on P.O.P. to be dealt with before toning? 16. I sometimes perpetrate an alleged "portrait," but find that the "sitter" is disturbed either by the removal of a lens cap or the *click* of a Thornton time shutter. Is there any simple method of working a *cheap* and *noiseless* arrangement behind the lens and *inside the camera*? I should be glad if those of our members who devise "home-made" apparatus from time to time would turn their attention to this, and give the results of their labours?

Improvements in Photography.

No. 11,175. Henry Van der Weyde, 182, Regent-street, Middlesex. *May* 13, 1893.

My invention relates to an improvement in photography, particularly portrait photography, and has for its object to enable the photographer to idealise, to a certain extent, the subject without sacrificing the fidelity of the portrait, and so remove the artistic reproach under which photography has always suffered, that it is incapable of foreshortening without exaggeration (*e.g.*, a hand or foot extended towards the camera) and cannot give that appearance of dignity to a figure which a master in portrait-painting is able to impart by slightly enlarging, reducing, or otherwise modifying, certain portions of the figure.

My improvement, therefore, has for its object not only to enable the proportions of certain parts of the subject to be varied, for instance, to reduce the size of a lady's head, or increase the length of her neck or waist, or of the

skirt of her dress, or to lengthen a gentleman's legs, for the purpose of imparting greater dignity to the figure, but also to correct the distortion due to the effect of foreshortening, or to produce other effects, whether artistic or grotesque—such, for further example, as to cause the apparent rotundity of an obese figure or face to be diminished, instead of being exaggerated, as is usually the case in a photograph, or the size of the hands to be diminished, or the fingers to be lengthened or tapered, or the eyes to be enlarged and the size of the mouth to be reduced, without necessarily altering the shape, size, or expression, or changing the character of the other features, or sacrificing the likeness of the portrait, all these artistic modifications being quickly effected and visible to the manipulator, so that their effect can be readily appreciated, the degree of modification obtainable being almost infinite.

It is preferable to apply my invention in the copying or enlarging of an ordinary transparency, negative, or photograph, with which comparison of effect may be readily made with a view to avoid undue distortion, but the invention is equally applicable while photographing the original subject.

For the purposes of caricature, the image can be so distorted as to produce the most comical effects, such as exaggerating the head, diminishing the lower member or lengthening or broadening the whole figure, or contorting it into eccentric attitudes.

In landscape photography a great variety of artistic effects may be obtained according to the direction in which the distortion is effected; for instance, a picture of ordinary landscape proportions can be photographically distorted or altered in its proportions to fit any frame, even an elongated upright panel, without losing any of the details.

The method whereby these modifications or distortions are effected consists in interposing between the subject (whether it be a person, landscape, picture, photograph, or negative, to be copied or enlarged) and the photographic lens, or between the lens and the sensitive plate, of a transparent medium having lens-like properties, so as to vary the direction of the whole or any portion of the rays of light according to the effect to be produced.

The curvature of the lens-like medium would, of course, depend upon the effect it is desired to produce; for instance, for the purpose of varying the relative proportions of the whole or part of the image, say, the lower half, in one direction only, the curvature of the lens would be in one direction, but for altering the proportions, or changing the shape of the isolated details, lens-like surfaces of spherical, oval, regular, or eccentric curvature would be used, and, to prevent any shadows or lines of demarcation being visible on the picture, the curvatures of the lens-like surfaces would be reversed or otherwise gradually merge with a plane surface, so as to allow the distortion or modification produced by the interposition of the lens-like surface to melt or flow into the surroundings.

For the purpose of varying in a more or less conventional or general way the broader proportions of the subject, I would employ lens-like media formed partly with plane and partly with curved surfaces, such media being formed beforehand and kept in stock for general use.

For this purpose glass plates having curved or partly curved surfaces or lenses cemented to glass plates, or independent lenses supported in any suitable manner, would be used, but for artistically varying the smaller details of the subject it is necessary to prepare a special lens-like medium for each particular subject, and my invention comprises the novel method of artistically preparing such a medium, and the novel application of the material employed for the purpose.

For the purposes of this part of the invention, it is necessary to have a clear transparent crystalline material, whose surface is capable of being easily scraped, engraved, or fashioned by melting at the ordinary, or at a very moderate, temperature, without necessitating recourse to the troublesome operation of polishing.

Amongst other substances available for this purpose, I especially claim the employment of ice in the form, say, of a plane slab of moderate thickness, upon the surface of which I operate by means of tools of suitable curvatures, it being sufficient to apply the tool to the surface of the ice in order to cause the latter to be locally melted by the conduction of heat from the tool itself.

For the purpose of operating on the surface of the ice, the slab would be placed in the same position with regard to the subject and to the eye of the operator as it will occupy in regard to the photographic lens in the operation of photographing, the subject being clearly visible through the slab, so that the necessary modifications of surface may be effected in correct local position to produce the effects desired.

In order to preserve the ice during the operations of working on, and photographing through it, the ice slab would be enclosed in a sort of frame containing a freezing mixture, by which to cool the surrounding atmosphere sufficiently to prevent the melting away of the ice.

My invention further has for its object to impart to a photograph the effect of a line or other engraving, in which the modelled effect is produced by deviations and variations of breadth and spacing of the lines.

For this purpose I prepare, as last-above described, a lens-like surface in correct relation with regard to the outlines and details of the subject of the picture; but, instead of photographing the picture through such lens-like surface, I photograph a surface upon which an engraved line or stipple tint has been printed, the effect being to produce a negative in which the wavy line effects are produced by the local distortion of the lines to correspond to the outlines and contours of the picture, so that, by stripping such negative and superposing it upon the negative of the picture, a compound negative will be formed, in which the engraving effect will be superposed in the form of white lines upon the soft gradations of the photographic modelling, or in black lines by the process of double printing.

Claims:—1. The herein-described process of locally modifying the dimensions of the image in the operation of photographing, copying, or enlarging, by causing the light rays transmitted from a portion or portions of the original subject, negative, or picture, to be refracted through a lens-like medium, interposed in the pencil of rays either before or after transmission through the camera lens, substantially as specified. 2. In the herein-described process, the employment, in combination with a photographic camera, of a refracting plate, having a local lens-like portion, whose curvilinear surface flows or graduates into the plane surface or surfaces of the plate, the plate being interposed in the pencil of rays before or after transmission through the camera lens, whereby to cause certain of the rays to be so deflected as to produce local modification of the image photographed in the camera, substantially as specified. 3. In the herein-described process, the employment, in combination with a plane plate of glass, of plano-convex lenses, whose curvatures are reversed so as to gradually flow into, or merge with, the plane surface of the plate to which they are caused to adhere, as and for the purpose specified. 4. In and for the purposes of the herein-described processes, the method of fashioning a refracting medium so as to produce therein a local plano-concave lens, which consists in superficially and locally melting the plate, substantially as specified.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

AUGUST 3,—Mr. T. Bolas in the chair.

Mr. H. M. Steinmetz was elected a member.

Mr. E. H. Bayston showed an example of outdoor photography taken against a plain background, an umbrella being used to cut off some of the top light.

"AMOUNTS OF SILVER AND HYPO LEFT IN ALBUMENISED PAPER AT DIFFERENT STAGES OF WASHING."

A paper on this subject, by Messrs. F. B. GRUNDY and A. HADDON, was read by Mr. GRUNDY [see page 511].

The CHAIRMAN said that members must feel much indebted to Messrs. Grundy and Haddon for their interesting paper, and, as a chemist, he suggested that one could not measure the work involved in the paper by the length of time taken to read it. It threw light on one of those matters which had been in darkness for the last fifty years, as to whether there was a gain by long washing or not. In fact, there was no point in photographic chemistry which had been so badly treated as this. We found people vaguely stating that long washing was supposed to be unfavourable, others that it was favourable. Now we had some real light thrown on the subject. The outcome, as far as the elimination of silver and sulphur was concerned, was that it made practically no difference whether one washed for ten minutes or nineteen hours. He would like to ask how far the pieces of paper had been agitated and pressed in the washing.

Mr. A. HADDON said the water was kept running from the tap, and the paper changed over. At the end only six pieces of paper were left in. There was no danger of sticking together.

The CHAIRMAN said that seemed satisfactory from an experimental point of view. In some systems of washing, pressure was applied, and it would be interesting to know if that would shorten the washing process.

Mr. HADDON had no doubt that, by the use of lukewarm water, five minutes' washing would suffice.

Mr. W. E. DEBENHAM said that the first thing that struck him was that this was the sort of paper which did credit to the Society it was brought before, and it was one that was really wanted in photography. If investigations of this kind had been made earlier, the complaints of the fading of photographs might have not have been so frequent. Short washing was suggested to him (Mr. Debenham) by the fact that his Monday prints did not look so bright as others because they had been left in over Sunday. The long washing seemed to weaken them, and decomposition presumably set in. He then tried shorter and shorter washing, and finally, though he did not come down to ten minutes, he considered that half an hour with occasional changing and squeegeeing would wash a print as well as it could be washed. Much depended on the number of prints, and the size of the vessel, and the amount of movement given to the prints during the time. In Messrs. Grundy and Haddon's case we understood that the movement was thorough. It would be particularly interesting to hear how ammonium carbonate affected the washing—whether

we had salts of silver and sulphur left in the paper after it. He would also join sulphocyanide to the question as to how far that treatment assisted in removing the residuum which, so far, they always got. Now that gelatino-chloride paper was very much taking the place of albumen, to make sure some fresh experiments would have to be made with that; so far, their similarity was very great, and we could take it that what covered one would go a long way with regard to the other.

Mr. A. COWAN thought that the discrepancies shown in Messrs. Haddon and Grundy's tables might be due to the different thicknesses of albumen on the paper.

Mr. DEBENHAM inquired as to the effect of lime in the water. It was said to have a preservative effect, and yet, judging from what had been said as to the effect of traces of sulphate of lime, he would like to know how that came in. Was it capable of decomposition?

The CHAIRMAN did not think the small quantity of sulphate of lime formed would practically affect a photograph.

Mr. DEBENHAM had found that prints treated with lime did last better.

Mr. HADDON observed that, in the cases of Solio and P.O.P., there was a substratum of sulphate of barytes, and that was a very insoluble salt.

The CHAIRMAN said that sulphate of lime was readily reduced by organic matter to sulphide of calcium, which he did not think held good with barytes sulphate. He had known cases where it had not been reduced when in contact with organic matter. Ordinary water when kept in a closed bottle would soon smell of sulphuretted hydrogen from the reduction of sulphate of lime.

Mr. HADDON said it would be useful to submit a certain portion of the paper to a lime bath before toning and fixing, and observe the effect.

Mr. H. M. SMITH said that he knew of one large firm of portrait photographers who always washed their gelatino-chloride prints in warm water, and their prints had stood for a long time in show cases without showing signs of deterioration.

Mr. A. M. LEVY said Messrs. Haddon and Grundy's paper seemed to be entirely satisfactory and conclusive, and bore out the statement of Stas that a great number of silver salts seemed to arrive at a period when you add a quantity of precipitant to the silver salts and no precipitation took place. The only exception was bromide of potassium. Taking the mean of the figures given in the first table, it was ·0037, and thus we might arrive at the conclusion that we had left ·0037 of silver in a piece of paper after washing it. There was a strong tendency of some kinds of salts to adhere to paper, and it was difficult to remove the last traces of them; some alkalies were impossible to remove, cupric oxide precipitated as hydroxide for instance. Silver and sulphur were left in the paper to react on each other. The "action of mass" was favourable to the removal of silver, but they arrived at Stas' point that a soluble compound was not formed, which was probably due to the interfering action of the paper itself. He thought most salts could be removed by prolonged washing. Hyposulphite of silver was really soluble, and should not have more tendency to adhere to the paper than other salts. He should think that if it were really formed they should be able by washing to remove it.

Mr. F. B. GRUNDY thought the "action of mass" might come into play; but possibly the amount of silver was not appreciable enough for that action.

Mr. LEVY replied that there was a mass of hypo compared with the little silver left. A soluble salt was formed which they did not succeed in removing by washing. Was the silver really present as hyposulphite?

Mr. GRUNDY asked, What else it could be?

Mr. LEVY replied, Why not metalloidic silver, formed in the pores of the paper itself? Hyposulphite of silver in contact with a porous substance and with air having every chance of access to it, would most likely decompose, and possibly metalloidic silver and some insoluble compound of silver be formed.

The CHAIRMAN suggested that it might be possible to ascertain whether the silver could be dissolved out. Bisulphide of carbon would not do for the purpose, as traces of sulphur would be formed by its own decomposition.

Mr. LEVY said there might be silver in an allotropic form, when it would not be dissolved.

Mr. DEBENHAM asked if it would complete the experiment if paper without an inorganic substance were sensitised, and, after fixing with hypo, what was left ascertained?

Mr. GRUNDY said it was not certain whether the albumen held the silver, and he had thought of coating plates of glass with it to ascertain whether it was so or not.

The CHAIRMAN suggested the separation of the paper and albumen and the determination of the quantity of silver left in each and the ratios between the two as a rough method. It would be interesting to repeat the experiments on plain paper.

Mr. HADDON said he and Mr. Grundy had that in view, as well as with glass coated with albumen.

After further discussion, a vote of thanks was passed to Messrs. Haddon and Grundy for their paper, the latter gentleman incidentally remarking that the experiments had extended over six months, and that several Winchesters of nitric and hydrochloric acids had been used in them. The experiments, if continuously worked at, would have taken at least a fortnight.

Northern Photographic and Scientific Association.—August 1, the President (Mr. Robins) in the chair.—Mr. F. W. TEVERSHAM read a paper entitled the *Bacteria found in Water*. The lecturer limited his remarks to the morphological characteristics of non-pathogenic or innocuous germs, as he believed that Professor McFadyean would, at a later date, deliver a lecture on pathogenic or disease-producing germs. In his concluding remarks, Mr. Teversham paid a high tribute to the excellent arrangements made by the London water companies, who did all that was in their power to supply the metropolis with pure and wholesome water. The CHAIRMAN deprecated the practice of passing a vote of thanks to a member of the Association, because, he said, in the first place, it was too formal to be sincere; and, in the second place, it would tend to convert the Association into a mutual complimentary Society. Nevertheless, he felt sure that Mr. Teversham had spoken to a very appreciative audience, who would profit by the lesson they had learnt that evening. Mr. TEVERSHAM said he quite agreed with what the Chairman had said, and went on to say that he hoped, at a later date, he would be able to let the Association have the benefit of any further bacteriological experiments which he had undertaken. An ingenious little instrument, the ellipsograph, was exhibited and explained by the inventor, Mr. J. R. Hicks. A patent catch for tripods, the invention of Messrs. Spratt Brothers, was also exhibited. It was announced that the next ordinary meeting will be on Thursday, August 17, when some views in Devonshire will be shown.

Hackney Photographic Society.—August 1, Mr. W. J. Hensler presiding.—Members' work was shown from Messrs. Barnes, Cross, Fort. Haukins Hensler, Nunn, Puttock, and Roofe. Mr. Barnes showed a negative, a portrait, which was spotted all over the face. A member suggested that it was some incipient skin disease, but it was negatived by having the same spots over the eyes. Mr. Nunn showed a bromide paper print developed with amidol, and asked what caused it to have a yellow tint in places (not stains). No satisfactory reply could be given. Question Box: "What action takes place when an exposed plate is first placed in the alkaline solution only, previous to pyro?" Reply: "A mechanical action only, by which the alkali penetrates deeper into the film, so that when pyro is added more detail is ensured." A case lined with ruby cloth from Messrs. Doublet was shown for storing untoned prints. Mr. Hensler showed a lantern plate, of which he had many similar, which, on developing, was veiled over, and which a clearing bath would not remove. It was a special, bought over twelve months ago. Messrs. Cross, Haukins, and Hudson had had the same experience; no doubt they came from the same batch. A discussion then took place as to in what way our Saturday outings might be improved. Some practical suggestions were made.

Brixton and Clapham Camera Club.—August 1, Dr. J. Reynolds, F.R.G.S. (President), in the chair.—Mr. Morgan attended on behalf of Messrs. Fuerst Bros., and gave a demonstration upon the methods of using the new developers, amidol and metol. He advised amateurs to use the separate developer mixed as stated on the instructions issued by the Company. For bromide work the concentrated solution should be used at nearly its full strength if a black image is required, further dilution giving a cold, grey image. The exposure for plates, &c., should be reduced to half of what would be given were pyro used as developer. Very much over-exposed plates tend to produce fog, but it will be entirely absent if the exposure is not excessive. In using these developers to develop plates, bromide paper, and lantern slides, the members of the Club were pleasantly surprised at the entire absence of veiling and stains. Mr. Morgan stated that the hands will not be stained unless the dry chemical is touched. The solutions may be used over and over again, Mr. S. H. Fry having developed as many as twenty half-plates in two ounces. At the conclusion of the demonstration, a vote of thanks was passed unanimously for Mr. Morgan's thorough explanations of the methods of working these developers, and several members promised to take up amidol and report the result in due course. The next meeting of the Club will be held on August 15, when the Paget Plate Company will give a demonstration before the members of the Club. Photographers residing in the locality are cordially invited. One of the Committee of Instruction, Mr. Edwards, will be present to answer any questions upon photographic subjects which may be put by any members requiring elementary information, and it is hoped that all beginners will fully avail themselves of the opportunity thus afforded.

Rotherham Photographic Society.—August 1, Dr. Baldwin (President) in the chair.—Good attendance of members. The business included the competition arrangements for present year. It was agreed that there should be classes for excursion work, untouched negatives, prints, lantern slides, most artistic photograph, and hand-camera views. It was announced that the room in the Rotherham Public Museum, placed at the disposal of the Society for exhibition purposes, had been opened. The work displayed, although somewhat hurriedly prepared, had been very favourably spoken of.

Sheffield Photographic Society.—August 1, Mr. E. J. Chesterman in the chair.—Mr. B. J. Taylor and Mr. E. Beck were appointed delegates to represent the Society on the Council of the Affiliated Societies of Great Britain, after which the prints of the photographic exchange were submitted to a severe but good-humoured criticism, which will, no doubt, lead to good results, and be for the benefit of the Society generally.

FORTHCOMING EXHIBITIONS.

1893.

September 5..... *Royal Cornwall Polytechnic Society, Falmouth. W. Brooks, Laurel Villa, Wray-park, Reigate.

,, 20-21 ..... *Hove Camera Club. Hon. Secretary, H. Emery, 142, Church-road, Hove, Brighton.

,, 25-Nov. 15... *Photographic Society of Great Britain, 5A, Pall Mall East, S.W. Assistant Secretary, R. Child-Bayley, 50, Great Russell-street, W.C.

October 1-31 ..... *Hamburg. Das Ausstellungs Committé des Amateur Photographen Verein, Schwanenwik, 33, Hamburg.

TELE-PHOTOGRAPHIC SYSTEMS FOR MODERATE AMPLIFICATIONS.

To the EDITOR.

SIR,—It is gratifying to find a communication from another student of tele-photographic systems in your last issue. No one could welcome more cordially than myself suggestions for simplifying technical expressions or interpretations of formulæ into clear language. My thanks are due to Mr. Hancock for this intention.

This gentleman's diagrammatic interpretation of Rule I. given in my paper will serve to impress it upon the minds of all who may interest themselves in the position of nodal points and planes in lens systems. It is needless to say that there are two such points in both positive and negative lenses; but, as we are concerned with only one in each, for purposes of calculation or the construction of the diagram, the second may be ignored, but their positions must be very accurately known and set for practical use.

It has already been shown how very powerfully a *small* difference in the separation of the nodal planes affects the equivalent and back foci. Now, if these positions were very accurately marked upon the mountings, and callipers used to set the separation—after which the calculation or diagram were to be made—I venture to think the labour involved in ordinary practice would be considerably greater than the simple measurement (*i.e.*, back focus) required in Rules III. and IV. already given.

Since writing the paper, I have tried to still further simplify the matter for the average photographic worker who may not have time to devote specially to the study of optics, but who, nevertheless, knows the appearance of an image on the focussing screen, and is familiar with the meaning of "equivalent focus" and "intensity" as applied to a lens.

In the first place, the foci of the positive and negative lenses, or their ratio, only need be known. In the construction recommended the positive is twice the focus of the negative.

Now screw the lens on to the camera, place the screen at a distance from the back (or negative lens) at least the measurement of the diagonal of the plate used (this in order that the plate may be covered), but as much further away as one chooses. The focus for the chosen position of the plate, wherever it be, is then always made by the rack-and-pinion movement on the mounting. In this manner a choice of the amount of subjects included and its size can be made. When this is decided upon, lift aside the focussing screen and measure the distance between its (focussed) position to the cell of the negative lens that projects a short way inside the camera.

Multiply this distance by two (as the ratio between the foci is 2 : 1) and add the focus of the positive lens. This is the measurement of the "equivalent focus."

General Rule to find the Equivalent Focus of any Tele-photographic Lens.—Multiply the back focus (chosen) by the ratio the focus of the positive lens bears to that of the negative lens, and add the focus of the positive.

We have seen that, when the "equivalent focus" is known, the magnification and "intensity" of the system are also forthwith expressed. In the case cited in the illustration, back focus = 9", twice this = 18"; add the focus of positive, 6" = 24" equivalent lens. Thus the magnification is four times, the intensity of the positive lens alone = *f*-8, and hence, for the chosen extension of camera, the intensity of the tele-photographic system = *f*-32.

Mr. Hancock makes a slip in the last paragraph but one of his letter anent the intensity of the system. It is true, as stated, that with a magnification of four times a positive element, whose *initial* intensity is *f*-8 *must become* *f*-32; but Mr. Hancock must certainly *not* "take it that definition is likely to be unsatisfactory if a larger aperture than *f*-32 be used," for any shorter extension of camera or back focus can be used, giving greater intensity but less magnification. Again, there is no reason at all that, in the case cited, the positive lens of six inches focus should not have an initial intensity of *f*-3 or *f*-12 for the combination!

The object of the construction of *moderate* amplification was to make the system applicable to lenses of weaker initial intensity (say, *f*-8) than portrait lenses, but portable at the same time, as Mr. Hancock readily perceives in the last paragraph of his letter. A lens, however, of high intensity and short focus may have great or weak amplifying negative lenses without unduly adding to their bulk or "necessarily looking like an astronomical telescope;" and, for this reason, a "battery" of negatives *might* be useful.

Quite outside the question of bulk, I have already given theoretical and practical reasons for not employing high magnification to positive lenses of a permanently fixed spherical correction. I think, however, that many will prefer, as Mr. Hancock agrees, to employ one negative with different extensions of camera, sacrificing magnification to rapidity when necessary, but making use of a greater degree of magnification when rapidity is not of such great moment.—I am, yours, &c., T. R. DALLMEYER.

25, *Newman-street, Oxford street, W.*

PHOTO-MICROGRAPHY.

To the EDITOR.

SIR,—In the article in the JOURNAL of July 28, commenting on Professor Piffard's paper, it is suggested that the obtaining of sharp negatives of microscopic objects with the objectives in use twenty-five years ago was difficult, in consequence of the want of coincidence of the visual and actinic foci.

It is nearly thirty years since I "took up" photography. My first negative was of a microscopic object, and having produced some hundreds of negatives of very varied subjects, including objects under polarised light, I found no difficulty arising from the above cause.

I worked "in the open," having my lantern at one end of a bench, and the carrier for the plates sliding along it according to the amplification required. The objectives used were cheap French triplets, no eyepiece, but sometimes double concave glasses in front, to increase the size. The light was "oxyhydrogen," and I got fairly sharp definition up to, say, 400 diameters.—I am, yours, &c., JOSEPH H. WOODWORTH.

Booterstown, Dublin.

A NEW PLATE.

To the EDITOR.

SIR,—I venture to hope that a short description of a plate which settles the much-vexed question of halation will be of interest to you and your numerous readers. I briefly describe the method which I have recently patented.

The plate is first coated with a gelatine substratum containing non-actinic colour, and upon this, when dry, is coated the ordinary emulsion. During exposure the colour absolutely prevents the passage of the actinic rays of light to and from the surfaces of the glass, hence there is no reflex action of light and *no halation*. The colouring matter (a harmless compound of carbon) readily disappears during the ordinary manipulations of development, fixation, and washing, so that the printing quality of the negative is as usual.

I think this simple discovery, besides opening a wide field for discussion, really places a new power in the hands of the photographer. Three things can with confidence be stated—first, halation is impossible; second, greater latitude of exposure is obtained; third, the scale of gradation is materially improved.

This, sir, is a short description without an attempt to deal with the scientific aspect of the question. I shall willingly supplement it with any further details you may wish to have. Enclosing for your inspection the first results from the new plate,—I am, yours, &c.,

46 *Fleet-street, Torquay, August* 7. CHARLES E. PETTITT.

PHOTOGRAPHY IN SOUTH AFRICA.

To the EDITOR.

SIR,—I think of going to one of the South African colonies as a professional photographer. As the climate of Cape Colony and Natal is not unbearably hot, it is very likely I shall select one of these as a starting point. Can any of your readers kindly favour me with their professional experience of these colonies, and say what prospects there are of success? Further, what stock of materials it would be advisable to take with me for working in the silver process? Pyro, I understand, is fifty per cent. dearer in the coastal towns than in England, and still dearer in the interior. I have been advised to take a tent as a studio. Some of your correspondents may be able to kindly inform me as to the best method of preserving the tent from the attack of flies, and also the most effective method of preserving the leather of the camera from their attack.—I am, yours &c.,

GEO. F. JESSETT.

7, *Batoum-gardens, West Kensington, W., August* 7.

THE CONVENTION GROUP.

To the EDITOR.

SIR,—Will you allow me to reply to Messrs. Heath & Co.'s letter in your last issue, in reference to the Convention group at Plymouth. I would be specially sorry to take any credit that is due to them for the grouping, &c., and I think, if they read again your commendations, they will find it was more for the promptitude displayed by my firm in getting proofs down to Plymouth with despatch. I will give the plain unvarnished facts as regards the taking of the negative, and leave your readers to judge what credit is due to me, and what is due to Messrs. Heath & Co.

I had prepared myself to take a group of the Convention members, by taking down a 12 × 10 camera with stripping films, with a view to stripping for collotype work, so that they could be done from the original negative. It was suggested by a member of your staff that I should expose on the official group, and I agreed with him that was the proper thing to do. I saw Messrs. Heath, and arranged that they should allow me to fix and focus my camera, and that they would get their assistant to take the cap off the lens (and this accounts for my being in the group). Three plates were exposed, and to my chagrin two out of the three were useless on

account of the camera being shaken in uncapping the lens; otherwise the whole three would have been perfect, and we should have had the advantage of being able to print from two or three negatives in the press at the same time instead of only one.

With regard to the development, this was strictly done under my supervision in Messrs. Heath & Co.'s dark room, their assistant mixing the developer because I could not grasp the formula they were using, no doubt due to my denseness and not to any complication of their formula. I rocked the dish and decided when the plate was developed sufficiently; at my request they dried the negative, packed and dispatched it to my firm at Richmond. I am extremely obliged for Messrs. Heath & Co.'s courteous help, but I do not agree that credit is due to them entirely for the JOURNAL group, but I leave your readers to judge.

Apologising for troubling you over such a stupid matter.

Yours faithfully, R. L. KIDD.

Exchange Column.

Will exchange new whole-plate extra special camera and three slides, whole-plate burnisher and canvas case, for half-plate Acme camera and slides and whole-plate rolling press. Address, S. BARTLETT, Colporteur, Stratford-on-Avon.

Wanted 12×10 and half-plate camera and slides, in exchange for 10×8 camera and three double slides, several wet-plate dipping baths, and cash adjustment.—Address, A. W. DURRELL, Photographer, 44, Birkbeck-place, West Dulwich, S.E.

Answers to Correspondents.

*** *All matters intended for the text portion of this* JOURNAL, *including queries and Exchanges, must be addressed to* "THE EDITOR, THE BRITISH JOURNAL OF PHOTOGRAPHY," 2, *York-street, Covent Garden, London. Inattention to this ensures delay.*

*** *Correspondents are informed that we cannot undertake to answer communications through the post.*

*** *Communications relating to Advertisements and general business affairs should be addressed to Messrs.* HENRY GREENWOOD & CO., 2 *York-street, Covent Garden, London.*

PHOTOGRAPHS REGISTERED:—

J. Whyte, Glasgow.—*Photographs of Sir Michael Corsnal.*

Debenham & Co., York.—*Photographs of His Grace the Archbishop of York.*

IVY.—The address is Messrs. Frith, Reigate, Surrey.

G. P. CARTLAND.—The letter in its original form was possibly libellous.

A. LEVY.—Thanks. Yes; English lawyers can, and do, sue for money owing to them.

R. SIMCOE.—There is no objection to the use of xylonite dishes for the fixing solution for P.O.P., neither is there for the toning bath.

H. L. M.—As the opinions offered are not to your satisfaction, you had better lay the case, with the lease, before a solicitor, get his advice, and act upon that.

W. M.—Sue the husband in the County Court if the wife has not a separate estate. You would not, we think, be justified in adopting the other course you propose to take.

ROBERT J. HILLIER.—As there are two gentlemen of the same name in the photographic world, the alteration was necessary. It in no way destroys the sense of your remarks.

R. H. THOMAS.—1. The firm named bears a high reputation. Possibly you were rather hasty; the delay may have arisen from legitimate causes. 2. The plate would be prepared from the negative.

W. P. WEARNE.—The delay at, possibly, a busy season is scarcely uncommon. We believe the firm named to be respectable. As you have threatened to place the matter in the hands of a solicitor, our advice would be useless.

GUS H.—The photographs of the interiors of the conservatories are very good but for the defects alluded to. They are caused by halation or reflection of light from the back of the plates. Had the plates been backed, it would have been avoided.

H. C. J.—What are termed "ordinary plates" are not, as a rule, sensitive enough for general work with a very rapid shutter and a lens with an aperture of *f*-11. They may, however, answer for some subjects when the light is exceptionally good.

D. LLOYD.—1. Use the largest stop that will secure sharpness all over the plate. 2. All will depend upon the size of the stop used and the quality of the light at the time. No useful information can be given on this point. Better expose a trial plate. 3. Starch paste.

W. T. PINE.—The fading of the print has been greatly accelerated by noxious vapours gaining access to it through the defective backboard of the frame. Such exceedingly common cardboard is very unsuitable for mounting photographs upon. This may as well have conduced to the fading.

GLASS.—Some of the wheel glass-cutters answer very well, but they quickly wear out with constant use. When they were first introduced they were of a much better quality than the majority that are now sold, but they were considerably higher in price. Nothing is so good as a diamond for cutting up dry plates.

B. O.—Send us particulars of your method of albumenising, and we may be able to assist you.

W. BLAKE.—It is so. The price of the specifications of some patents have been raised, while others are lowered. Those which used to be only fourpence are now eightpence, but those which were formerly several shillings, or pounds, are now the same price. The price of specifications is made uniform—eightpence each all round.

A PROFESSIONAL.—This correspondent complains that, when ordering his goods by "parcels post," the firm from whom he buys puts him to extra expense by sending the package by "rail." Such a case would, doubtless, only occur through an oversight. In these times competition is too keen to admit of photographic houses wilfully ignoring their customers' instructions.

J. W. BEATTIE (Hobart).—We have often experienced the same kind of fogging. It arises from the collodion not being sufficiently ripe. This may be cured by either adding an alcoholic solution of iodine, or dissolving in it a crystal of iodine until it assumes a port-wine colour. Try the experiment with only one or two ounces of the collodion at first, and note the results obtained.

Z. A. Y.—You are quite under a misapprehension as to collotype printing by machines being an impossibility. As a matter of fact, the larger proportion of the collotypes now produced, both here and abroad, are printed by power press. Some of the best work is now done by machine printing, but it must be confessed that much of it is inferior to what is possible with hand presses.

J. RINGROSE.—For permission to photograph on open spaces under the control of the Corporation, apply to Sir J. B. Monckton, Town Clerk, Guildhall, E.C.; for the County Council spaces and parks, to H. De la Hooke, Esq., London County Council, Spring-gardens; and for the royal parks, to H. W. Primrose, Esq., Office of Works, Whitehall, S.W., of course in each case enclosing a stamped envelope.

D. MCSKIMMING writes: "I am troubled with a flare spot when using my single achromatic view lens with a small stop. Can I remedy this by altering the position of the diaphragm; if so, must it go nearer or further away from the lens? Am I likely to introduce any other defect?"—This may be cured by altering the position of the diaphragm. Try the effect of withdrawing it about a quarter of an inch. No defect will be introduced.

E. PAINE.—There is no copyright now in many of the fine old engravings, such as those of Hogarth, Bartolozzi, and others; but there would be in all those recently issued, notwithstanding that they were produced by photogravure abroad, and from the works of foreign artists. They would have been made copyright under the new International Copyright Act. It is very unlikely that the owners of the copyright would permit of the copying for lantern slides.

J. J. WILSON asks: "Will you kindly inform me if chemically pure paper pulp is obtainable in small quantities; and, if not, by what means can the ordinary paper pulp be made chemically pure when used for photographic purposes?"—This is certainly not an article of commerce, but it is quite possible that some paper-maker will oblige with a small quantity for experimental purposes, though it would not be chemically pure. The nearest approach to chemical purity would probably be obtained by converting some Swedish filtering paper into pulp.

LONDON, E., says: "When I develop lantern slides with hydroquinone I get a perfectly clear and bright image without any veiling of the lights, but when I use ferrous oxalate, which I very much prefer, the lights are slightly fogged with a kind of white deposit, which seems to be more on the surface than in the film. I have used the developer with different proportions of iron and oxalate, and also more or less diluted with water. I know it must be the fault of the developer because the same plates are all right with the hydroquinone. Can you assist me?" The veiling is caused by a deposit of oxalate of lime from lime in the water. If the pictures be flooded with very dilute hydrochloric acid, it will be removed. One part of acid to twenty or thirty of water will suffice.

E. J. D. writes: "Will you please give me the necessary process to reduce eighteen carat gold in substance to chloride for photographic purposes. Also would the process be different for twenty-two carat gold. I remember reading some time since in one of your notes that photographers have been known to reduce sovereigns for the purpose, but mine is in small particles?"—Dissolve the metal, in a glass flask, in a mixture of one part of nitric acid, five of hydrochloric acid, and three of water with the aid of heat. When dissolved, precipitate the gold with a solution of protosulphate of iron. Wash the precipitate well and then redissolve it with the acid as at first, using no more than is necessary. Then dilute with water, so that one drachm of the solution contains half a grain of gold to the drachm. This will form a stock solution or a strength about equivalent to one grain of chloride to the drachm.

No. 1737. Vol. XL.—AUGUST 18, 1893.

THE KEEPING PROPERTIES OF GELATINO-CHLORIDE POSITIVE PAPER.

How long will gelatino-chloride paper keep good, and what are the influences by which it becomes deteriorated?

It has not yet been sufficiently long before the public to warrant much to be brought to bear upon its keeping properties, but from our own observation, extending to a period considerably over a year, it keeps quite as well as the best ready-sensitised albumen paper, and much better than most of what is procurable. A sample sheet that has been sent to us from the Antipodes, as having gone yellow, has induced us to institute inquiries as to the conditions most likely to promote such discolouration.

First of all, we have opened and examined a packet of this paper which was placed in a flat envelope and sealed with ordinary paste, at the time mentioned. This packet has, since its receipt, been kept in a dry room free, in an average way, from gaseous or other deleterious emanations. When examined, every one of the cut sheets which it contained was found to be without spot or blemish, not the slightest discolouration being apparent. From this it is, we think, a fair inference that gelatino-chloride paper does not necessarily become discoloured for a considerable period when kept with reasonable precautions.

By what we must regard as a singular coincidence, a packet of ready-sensitised albumenised paper, "warranted to keep," was put away at the same time as the other, and with the same precautions as regards preservation. We also opened it, only to find that its contents, six 5×4 sheets, had become hopelessly bad, having passed considerably beyond "the colour of cheese" stage, and hence, quite useless.

Exposing gelatino-chloride paper to a damp atmosphere will, we should think, speedily ensure its discolouring, and this with the more certainty if continued for any length of time in a hot climate, or in such hot weather as prevails at the present time. This has long been known in connexion with albumenised and other paper, and led to the introduction of Marion's preservative case three decades since. This consisted of a cylindrical case with an air-tight cover in which was a small chamber containing dried calcium chloride, which absorbed the last traces of moisture left in the case, and thus ensured the dryness of the paper contained therein. We are aware of the discolouration from damp of at least one sheet of gelatine paper which was received in that state on being opened in New Zealand; but, as other sheets in the same packing-case were good, we conclude that the initial seeds of decay had been sown on the shelves of the merchant by whom it had been packed and shipped.

It may not be generally known that the oft-times offensive effluvium given off by albumenised paper conduces to the deterioration of both gelatine paper and plates. Some dealers, from motives of economy of space, or oven from orderliness, keep printing papers of various kinds stored in close cupboards, gelatine paper being in immediate contact with albumen paper of foul-smelling quality. Can it be wondered at if gelatino-chloride paper, redolent of such an atmosphere and taken out to be closely packed up for a voyage of considerable duration to the other side of the tropics, shows indications of discolouration when received by the consignees? The wonder would be if it were otherwise. We have been made aware of well-certified instances in which this has occurred. Each one can test this for himself by interposing a piece of non-sensitised albumen paper between two sheets of gelatino-chloride and keeping them pressed in a warm moist atmosphere for some time.

Although negative plates are liable to the same action from this cause, it happens that, in virtue of the perfect packing of each dozen, they are but little amenable to injurious consequences arising from vaporous emanations by which they may be surrounded. We know, however, that such plates, when they are removed from the packages in which they are sent out and are transferred to a grooved plate-box, have in a very brief period shown signs of having undergone deterioration, more especially so if the plate-box were a new one. Even the emanations from the flexible leather hinge, which some time ago used to be so commonly applied to the draw shutter of the dark slide, were well recognised as producing an insensitive strip across any plate which had been left standing in the slide for a length of time.

We might expand upon this, but enough has been said to prove that as between sensitive abumen paper and sensitive gelatine paper the latter has immensely the advantage as regards keeping when both are treated alike; and that, when reasonable precautions are taken for its protection from moisture, deleterious atmospheric influences, and injurious vapours, there is no reason why gelatino-chloride or gelatino-bromide paper should not remain quite good for a time infinitely longer than even its makers would care to assign to it.

Gelatino-chloride paper is of only comparatively recent introduction, but we possess valuable pictures on gelatino-bromide paper which were exposed and developed between six and seven years after we had received it from the manufacturer. But it had been well preserved from such destructive influences as those here hinted at.

MIXED DEVELOPERS AGAIN.

As the result of experiments in connexion with the functions of sulphite of soda and alkalies respectively, in conjunction with metol and amidol, some of which were recorded in a leading article a fortnight ago, we have been induced to revert once more to a subject that was treated, though from a somewhat different point of view, a few months back. In our issue of March of the present year (page 161) will be found an article on "Mixed Developers," that is to say, developers in which two or more of the various developing agents are employed in conjunction.

This is a practice which has found some favour both in this country and in America, and has for its object the combination of different characteristics not possessed by any one single substance. For instance, hydroquinone is known to act with great clearness and vigour, and to give images of considerable density under favourable circumstances, but it is extremely slow in action, and, with some plates, has an inclination to produce harsh gradations. Eikonogen, on the other hand, is rapid and searching in its action, and is remarkable for the delicacy and fine gradation of the images it gives, its fault being that this latter tendency is apt to degenerate into excessive thinness or want of printing strength. By using the two agents in combination, however, it has been found that a highly satisfactory compromise is made, and, while the cleanness of working of the two, when used singly, is not interfered with, the density-giving power of hydroquinone is combined with the energy and rapidity of action of eikonogen.

At the time our previous article was written we had not made any very extended trials of metol in any form, and with amidol had scarcely attained any marked success in any combination, but more recently have been led to take up the subject again, and, we may say, with a degree of success that we had never before experienced. There are, in fact, some special features in the character of the newer developers that seem more especially to fit them for use in conjunction with hydroquinone, and our previous failure to derive any apparent benefit from the mixture of that agent with amidol can only be set down to our not having gone the right way about it.

The general peculiarities of hydroquinone, as all who have used it are well aware, are its slowness of action and the extreme vigour of image it gives. These characteristics are greatly modified, if not altogether removed, if a caustic alkali be substituted for the fixed carbonates usually employed, while they are greatly intensified by the use of either sulphite of soda or restraining bromide. The extremely powerful modifying action of these two substances is, in fact, one of the peculiarities of hydroquinone, and, while it is impracticable to altogether dispense with them, hydroquinone has come to be regarded as too slow for ordinary purposes, and more especially useful in cases of over-exposure or for positive work.

Amidol and metol, on the other hand, are extremely rapid in their action, and, especially the former, will work without any alkali at all, the soluble alkaline sulphites, as we showed a fortnight ago, playing the same part in conjunction with them that alkali does with pyro and hydroquinone. Moreover, although it is possible to employ them without bromide, it is found, in practice, that the addition of some sort of restrainer is almost absolutely necessary if images of printing density and free from fog are to be obtained.

Arguing from these facts, it seemed to us more than likely that if properly used greater advantage would accrue from the mixture of metol and amidol with hydroquinone than those we mentioned in connexion with eikonogen, and on putting the matter to a practical test we were not disappointed. The way in which we looked at the question was this :—If, as appeared from our previous experiments, hydroquinone would act as the necessary restrainer, then bromide might be altogether dispensed with; and while the sulphite necessary to confer keeping qualities, as the stock solution, would also supply the necessary developing stimulus to the metol or amidol, as the case may be, any slowing action it might have upon the hydroquinone could be counteracted by the addition of a small proportion of alkali. In fact, it seemed possible to compound a developer without restraining bromide and with a minimumof alkali, which should be rapid in action even with quick exposures, and at the same time give vigorous images.

The merely physical advantages of such a developer, especially in hot weather, are too obvious to need mentioning here; but as we pointed out in our article on "Intensification" last week, it is preferable to get the needful density in one operation; if at all possible there is a palpable gain in that direction. Beyond that, if we consider that users of amidol and metol have hitherto, in order to get density, been using solution containing from sixteen grains of these comparatively expensive salts to each ounce, further heavily loaded down with sulphite, it must be obvious that a great pecuniary saving is effected when the proportions are reduced to about one-fourth, and a cheaper substance partly substituted. Such, however, is the not least important fact of the case.

As a first experiment, plates were submitted to the action of mixtures of amidol and metol with hydroquinone, without sulphite, but in the full anticipation of a negative result, as it turned out, the two former requiring the sulphite, and the latter alkali, before development could be set up. An addition was then made of sodium sulphite, and when dissolved this was again applied to the plates, which had been in the meanwhile covered up in a dish of clean water. After five minutes' action, neither mixture had produced a trace of an image, so we concluded that for practical purposes the alkali is a *sine-quâ-non*, the hydroquinone, as we had expected, acting as a restrainer. The quantity actually necessary to set up development is, however, extremely small, a single *drop* from a glass rod in two ounces of solution sufficing to set matters in motion, though naturally rather slowly. When the quantity was increased, in equivalent to two minims of strong ammonia to the ounce, the image at once began to acquire strength and detail, proceeding almost as rapidly as either metol or amidol alone, but without the slight veil that with most plates would then accompany the non-use of bromide. As the plates had received a full exposure, we accepted this as evidence of the restrainiog power of hydroquinone.

After fixing, the image produced by metol and hydroquinone possessed all the printing density that could be desired, and more might have been obtained by continuing the development further; but amidol left something to be desired in this respect. The plates used were specially chosen as being somewhat difficult to work up to printing density with either metol or amidol. After several trials with different proportions of amidol, hydroquinone, and alkali, it was found that, as in our earlier experiments, no advantage was gained by the addition of hydroquinone until the quantity of that, as well as of amidol, was increased to five or six grains to the ounce. If the former was increased without the latter, density was obtained, but at the expense of gradation, while amidol with a less proportion of the other substance failed to give any increase of vigour.

It has been said that a trace of acid acts with amidol or metol as a better restrainer than bromide, so the effect of an addition of half a grain of citric acid to the amidol solution was tried. The result was a very decided slowing of the action, scarcely, we think, from the slight decrease in the quantity of free alkali present, but evidently the well-known restraining action of the alkaline citrates accompanied by a very remarkable increase of density. With metol, neither the slowing action nor the increase of density was so noticeable, though they were present, not sufficiently, however, to be of any benefit or the reverse.

The question next arose as to the most convenient form in which to employ the mixed developer. Many persons favour the "one-solution" form, in which, however, it is obvious that the only control there is—and it is very limited—is in the greater or less degree of dilution. This may answer, perhaps, with one particular brand of plate, and with tolerably accurate exposure, but not otherwise. If the developing and accelerating solutions are kept separate, so that the proportions may be raised at will, there is, of course, much more scope for modifying the action; but the full power of the mixed developer is only attained when all three solutions are kept separate—that is to say, metol, hydroquinone, and alkali. In that case, it is possible at the moment of use to mix the two former in such proportions as will suit the particular kind of plate, or the class of subject under treatment, and degree of density desired, while the alkali is added to suit the exposure. The power, in fact, gained in thus varying the proportions of the developing agents is one of the most important points in this method.

After a large number of experiments, while we are personally inclined to give preference to the separate solutions, we are quite aware that under circumstances the other methods may be more convenient and equally efficient. For instance, in ordinary studio work, where a known plate is constantly used, the successive exposures are all practically uniform, a one-solution developer is perhaps the best, for at all times there can be kept at hand small quantities of alkali or restrainer for use in emergency. The trouble of constantly mixing up fresh solutions is thus avoided; but, for the run of amateur work, we think the practice of keeping the developer in at any rate two solutions is to be preferred—the developer proper and the alkali—and to use these as circumstances may dictate.

Space does not permit us here to do so, but we hope next week to give briefly formulæ of each kind that seem to answer best with different types of plates, naturally thin plates, of course, necessitating different treatment from those which readily run to density.

DR. EDER ON THE ACTION OF BROMIDE WITH VARIOUS DEVELOPERS.

Dr. Eder has lately been studying the action of bromide of potassium with various developers, and the results of his investigations are decidedly interesting. Bromide, the most commonly employed of the restrainers, he finds varies in the nature of its effects according to the developer with which it is used.

Some developers he points out, are particularly sensitive to the influence of bromide of potassium, iron oxalate, for instance, the bromide used as 1 : 10, and a few drops of that strength being added to every 100 c.c. of solution, having an energetic restraining action on normally exposed plates. For over-exposed plates it is only necessary to slightly exceed the proportion of restrainer mentioned.

Pyro-soda behaves in a similar manner to iron, the bromide acting as a simple retarder; if, however, pyro ammonia be used, the bromide acts as a preventive of fog, to the detriment of its powers as a restrainer of development, and it is necessary, therefore, to increase its proportion. For normally exposed plates, Dr. Eder finds, for each 100 c.c. of pyro-ammonia solution, thirty drops of bromide solution, 1 : 10, desirable, while for over-exposure it should be added in doses of from 5 to 10 c.c. for each 100 c.c. of developing solution.

Hydroquinone-soda (sold in the ready-made form) is less sensitive to the retarding action of bromide than pyro. Development may be restrained therewith by using comparatively large quantities, it is true, but the developer, even with prolonged use, does not yield such good negatives as pyro or iron. Hydroquinone itself, says Dr. Eder, acts as a species of restrainer, for it not only develops slowly, but gives vigorous results, not on account of the bromide that may be used with it, but in consequence of its own decomposition by oxidation, the oxidation retarding the growth of the image without tending to impair the vigour of the resulting negative.

With eikonogen and metol, notably the latter, bromide acts in the double capacity of preventing fog and restraining development, but the retarding effect is less noticeable than with the developers previously named. Very fully exposed plates can be held back by the use of bromide, but over-exposed pictures, says Dr. Eder, when developed with metol or amidol, are not so well controlled, even with large quantities of bromide, which is unable to check the energy of metol. An old solution of metol—one that has been used several times—retards development, but does not yield vigorous negatives.

Dr. Eder concludes his interesting notes by saying that to metol-soda or metol-potash a slight addition of bromide (1·1000) has such little restraining power that the manufacturers themselves often add bromide to the ready-made solutions, without the user noticing any retarding effect of these developers. The only effect produced is that negatives so developed have no fog.

Comet Number Two of 1893.—This comet has been photographed by M. F. Quénisset, and the result communicated to the Paris Academy. It was obtained by means of a Hermagis lens of sixteen cm. (about six and a half inches) aperture and an exposure of forty minutes. The comet shows two tails—one a degree, and the other half a degree long.

Eclipse Photographs.—In the *Observatory* Mr. Turner makes some remarks about the August, 1896, eclipse and reviews the photographic results of the late eclipse. He informs us of one point which appears to us the least satisfactory, namely, that the photographs taken of the corona are in the hands of an astronomer who will make drawings of them. Far better publish the photographs and let them illustrate their own story. Mr. Turner heartily congratulates the observers on their performances. Professor Pickering employed one of Dr. Common's twenty-inch reflectors of forty-five inch focus, and used slow plates, the result being that he has got more detail in the inner corona than is shown in the English photographs. Regarding the 1896 eclipse, Mr. Turner points out the importance of making preparations long beforehand. He says it is not a bit too early to begin at once, for, owing to the position of the central line of totality being so favourable, it is probable that a host of observers, both professional and amateur, will be able to co-operate in the observations.

Ultra-violet Photographs.—With regard to these investigations by Victor Schumann, before referred to by us, he states that he uses gelatine plates of his own manufacture, as commercial plates are less suitable. "When it is important to support as far as possible the optical power of photographic spectral apparatus, where the sharpness of the image is a main condition, also where a strong contrast in the intensity of the lines is needed, the commercial plate is inadequate. It does not work intensely enough to assist spectroscopy to the extent of the modern dry plate. The gelatine plate of my own preparation gives an intense and finely granular image on a ground clear as glass. The emulsion is relatively rich in silver iodide containing, with to 100 parts by weight of silver bromide, four to five parts of silver iodide. Its preparation is effected exclusively on Eder's method, silver-oxide ammonia (J. M. Eder, *Ausf. Hand. d. Photographie*, part iii., pp. 208–211, fourth edition, Halle, 1890), which I have used for more than ten years. For developing the plates I use the soda-pyrogallic developer, and for fixation sodium thiosulphate."

Central Photographic Club.—We gather that the principal reason why the Central Photographic Club has not ere this opened its doors to the several hundreds of members who have joined it is the difficulty which the Committee have experienced in engaging suitable premises. We understand that a considerable number of suites of rooms have been inspected, and in two cases the Committee had come to a decision, only to be disappointed over matters of detail, which rendered it necessary to seek elsewhere. The Committee have now resolved to seek accommodation at a first-class hotel in central London. Negotiations with that object are afoot, and we expect that in a few days the Committee will announce the opening of the Club at some suitable *rendezvous*, where arrangements can be made for use of meeting-room, dark-rooms, smoke-room, library, &c., as well as the supply of refreshments and hotel accommodation, with beds for country members. It appears to us that, with such advantages, the ultimate possibilities in the way of membership are very great indeed.

Extremely Rapid Exposures.—Some little while ago we described the marvellous photographs of flying bullets and other rapidly moving objects taken by Professor Boys; Messrs. E. & L. Mach have been working in the same direction, and have recently communicated a *résumé* of their results to the Vienna Academy. Some 1500 negatives were reviewed, and evidenced marvellous results. Images of the Mannlicher bullets, quite sharp and 3½ cm. (nearly an inch and a half) diameter, were obtained. Instead of electric contacts made by the flying projectiles which were liable to introduce a disturbing element, these experimenters were able to make the bullet itself close the electric circuit mechanically by means of the sound wave it produced. After a number of trials they obtained homogeneous plane parallel glass plates large enough to produce an interference field 8 cm. in diameter for use in Ludwig Mach's refractometer. When one portion of such a field is occupied by a flying bullet, an air jet or a sound wave passing an interfering pencil, the interference bands, usually rectilinear, appear bent in such a manner as to indicate a change of density of air at any point. For the purpose of instantaneous illumination the electric spark was usually employed, but sometimes, especially when longer exposures could be made, sunlight rendered monochromatic blue was used.

Proposed Photographic Astronomical Telescope for Cambridge University—The authorities of this University have made a public appeal for funds to enable them to construct a new telescope for celestial photography. They require about two thousand guineas in addition to what can be advanced from other available funds, the instrument itself and its fittings, dome, &c., being estimated would cost about £3200. They say, "It will be allowed that the Cambridge University ought to be completely equipped for carrying on the most advanced work in modern astronomy. As celestial photography is the branch of astronomy in which the most important advance is now being made, it has been decided that a photographic telescope shall be obtained if the necessary funds be forthcoming. It is the opinion of those most competent to form a judgment that a photographic refractor of about eighteen inches in diameter is necessary to render it possible to obtain results of the highest excellence. The new objective would be corrected for the photographic rays, and the present Northumberland telescope would serve as the guide when attached to the new tube." That such an instrument would be invaluable for the purpose we are quite certain, and the best hopes of all scientific photographers will go with the Senate of the University. For those who would desire to convert their wishes into current coin of the realm, we may note that subscriptions will be received by Sir Robert Ball, or by any of the following members of the observatory syndicate: — Jno. Peile (vice-chancellor), G. G. Stokes, G. D. Liveing, G. H. Darwin, H. M. Taylor, and W. W. Rouse Ball.

ON THE CONSTRUCTION OF INTERCHANGEABLE LENS SCREW FITTINGS.*

Common Method of Gauging Screws.

It is customary, in making screws, for opticians to provide themselves with certain gauges or standards with which to compare their work. Such gauges generally take the form of those shown (not illustrated). Let us suppose that a lens-maker, wishing to do the thing well, seeks the aid of some expert to construct for him a set of standard screw-gauges in pairs, male and female, for each size of screw.

He may keep a duplicate set if he likes, and can afford the luxury. Such gauges may be made of steel; but, as they would warp in hardening, they must be left soft, and are thus specially liable to become worn. They are put into the hands of the workman, who uses them to test his work. When, for example, a male screw has been formed, he screws upon it the ring gauge. If the gauge fit stiffly, he reduces the screw until the gauge passes on freely. In this way he tests one screw after another as he makes them, screwing the gauge upon each, and inevitably wearing it away. It is only a question of time, and generally of a very short time, for such a gauge to be worn large. Suppose it wear only one-thousandth of an inch large on its diameter at the root, or crests, or sides of the threads; it then becomes possible to pass freely through that gauge a male screw which may be one-thousandth of an inch too large. But such a screw does not fulfil our conditions of free interchangeability, and such a gauge, worn even so little, is not capable of ensuring such accuracy as is indispensable. "But," says the workman, "I always make my screws fit the gauge loosely." "How loose?" we ask. "Oh, so that they shake a bit!" he replies.

This is the common method of gauging screws; only it is rarely the gauges are themselves accurately formed at first. But, even if the gauges are correct, a method like this, which depends for its success upon the workman's fancy of the right amount of shake, and which makes things loose to secure their being interchangeable, cannot be considered an exact and satisfactory method, nor should it be tolerated when we know any better way.

Common Methods of Cutting Screws.

The common methods of cutting screws are very simple.

Let us take the case of a male screw. The piece to be screwed is held and made to revolve in a lathe, and its outer surface is turned truly to the form of a cylinder approaching the full outer diameter of the desired screw. Then what is called a comb or chaser is brought into use. This instrument, which may be bought at the shops, is a cutting tool roughly in the form a common chisel, the working end of which is serrated, the series of alternate indentations and projections presenting exact counterparts of the thread form and pitch of screw which it is desired to cut. This chaser is presented to the revolving piece of work, and, sometimes by hand, sometimes by machine, it is moved in a direction parallel to the axis of the lathe, so that it cuts a spiral groove along the cylinder and forms it into a screw. The form of the screw thread is determined by the form of the teeth on the chaser.

We know that it is of great importance in securing free interchangeability that the form of thread be correct, but it is a fact that screws cut by this common method seldom, or perhaps never, are correctly formed in this respect. A famous navy captain, being asked why, on a certain occasion, he had not fired a salute, gave thirty-nine distinct

* Concluded from page 510.

and substantial reasons for his neglect. The first reason was that he had no powder. In the same way, several reasons might be given why opticians fail to cut screws correctly with these common chasers; but the one sufficient reason is that there is not such a tool in the market correctly formed. At least I have never found one, though

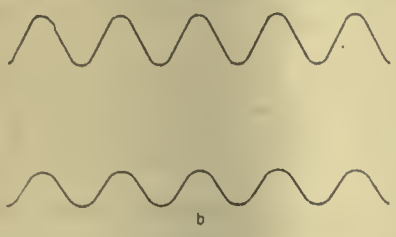

Fig. 5.

I tried hard to do so before giving it up and making my own. All the bought chasers I have seen form threads of wrong angle and insufficiently deep. Since the prominent points of the chaser teeth come into operation first in cutting a screw, and are thus most worn away, and since the chasers are themselves cut and formed by tools

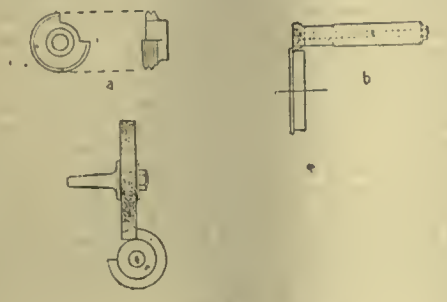

Fig. 6.

liable to similar wear of their prominent edges, we cannot expect very much of the ordinary shop tools, which cost only eighteenpence per pair. And, since everything the workman may do in grinding the tool to sharpen it, in altering the angle of the inclination of its upper face, either by grinding it or by the manner of applying it to its work, tends to alter the form of the screw thread and make it shallow, it comes to pass that the screw threads which are found on scientific instruments generally, and which are nominally of Whitworth form, vary from *a*, in fig. 5, which is correct, to *b*, and even worse than that, which is prepared from measurements of screws furnished to the recent Conference of Opticians by the opticians themselves.

An Improved Form of Chaser for Screw-cutting.

I have shown the two principal weaknesses of the common methods of screw-making—the possibility of error arising from the inevitable wear of the ordinary solid screw gauges, and the certainty of error arising from the use of chasers which in the ordinary way are faulty. It is now several years ago since I designed a chaser, shown in fig. 6, which possesses important advantages over the ordinary form. The chasing tool, *a*, is itself a portion of a screw, with only two turns of the thread, and is produced in a screw-cutting lathe, a quadrant being afterwards removed to form two cutting edges, one for male and the other for female screws. The figure at *b* shows also the chaser attached by a bolt to its holder, and in position for cutting a male screw. This chaser has the following important advantages:—The form of its thread is easily measured by means of the test-pieces which I have described. This is practically impossible with the ordinary form of tool. The circular chaser is easily made, and the tools used in making it are not subject to that incurable deterioration of form which is inevitable with the tools used in forming an ordinary chaser. The circular chaser is easily sharpened by threading it on a fixed pin or stud, S, as shown in the figure at C, so that the chaser may bear on the face of an emery wheel always in the same way to preserve the radial position of its cutting faces. It thus retains its original cutting angle until entirely worn away, and, with ordinary care, it is practically impossible to set it wrongly in relation to its work. It may be removed for sharpening by loosening the bolt, without displacing the holder, and in replacing it the only thing necessary is to set the cutting edge at the level of a fixed line upon the holder. With such a chaser, so easily removed and replaced, there is little temptation for the workman to neglect the sharpening of the tool, while with the ordinary form this temptation is very great.

For want of time I cannot now describe my methods of originating the thread form on these chasers. With suitable appliances the work is quite simple.

When properly constructed and arranged, such a chaser as I have described will form screw threads accurately, and for a considerable length of time before appreciable error arises from the wearing of the tool. For practical purposes it is possible so to rely upon the constancy of the thread form which it produces, that to measure the diameter of a screw on the tops of its threads sufficiently indicates to the workman the gauge of the entire screw.

The Chasing Lathe.

I show you a view of part of a chasing lathe as used for cutting screws with this chaser. The usual slide rest is removed to show the screw-cutting gear without confusion. The spindle which supports the work, and revolves with it, carries at its other end a guide screw of the same pitch as the one we wish to cut. Engaging with this guide screw is a nut attached rigidly to a bar capable of sliding along and behind the lathe bed, which bar serves to support and move the chasing tool. As the spindle revolves, its guide screw, acting on the nut, causes the bar to slide and so to move the chaser along at the necessary rate. For convenience the chaser commences its work at the shoulder of the screw, and moves away from it in performing its work. Then, by raising a handle, the guide nut and the chaser are lifted from their engagements, and the bar is moved back so as to repeat the movement of the chaser from the shoulder and along its work. At each turn, by means of a screw and hand wheel, the chaser is moved a little further into cut, until it has at last produced a full thread on a screw of right diameter, and further advance of the chaser is then prevented by a stop on the hand wheel.

By these means we have accomplished our screw-cutting at Leicester for some time with a remarkable degree of accuracy. We have been able not only to ensure that every male screw shall be at least as small as the normal, in order that it may be freely interchangeable with its fellows, but we limit its error in the other direction also, that it shall not be more than one-thousandth of an inch smaller than the normal—that is, that it shall not be loose nor shake in its fellow more than one-thousandth of an inch on its diameter.

Limit Gauges.

For practical purposes in gauging such male screws, and not for purposes of strict examination, though, indeed, with due care it is a practically complete test, we use a hardened steel gauge such as you see on the screen (not illustrated).

This is the two-inch standard male screw gauge. It is applied to the screw as a calliper to gauge its full outer diameter only. The gauge has two sides, the gap between its jaws on the side marked F being exactly two inches across. On the second side, marked S, the gap measures exactly one-thousandth of an inch less. In using the gauge, the screw is cut so that it passes through the two-inch gap without any jamming, but it is not allowed to pass through the gap, which is only one-thousandth of an inch smaller. Thus the screws are at least as small as the normal, and are freely interchangeable, yet they are not loose and shaky. For gauging female screws we employ a pair of disc gauges, one being of the correct core diameter of the screw, and the other one-thousandth of an inch larger. These are used in a similar way to that I have described for male screws—to limit the error in the size of female screws.

This is not a laboratory experiment. It is a process daily and hourly employed at Leicester, where such screws are made more cheaply than less accurate screws were ever made before. So reliable are the methods, that I could produce from stock at any time a sufficient number of screws of one size to form a million distinct combinations, every one of which would present a sweet, smooth fit without any need of forcing.

It should be understood that our brass work is prepared by special machine tools in order to form it accurately and uniformly as it never can be done by hand. It is in this process of preparing that the accuracy in the cutting of screws is observed. In the subsequent processes of finishing, slight errors are inevitably introduced through the wearing of the parts, but such errors are very small indeed, and do not lead to any sacrifice of free interchangeability, but rather in the other direction.

In order to cover every reasonable risk of our work not being freely interchangeable with that of any other maker who adopts accurate methods for his work of screw-cutting, it is our practice to make every female screw, such as those in flanges and adapters, one-

thousandth of an inch larger than the standard. Flange screws are thus made to fit loosely to this small extent.

It is also our practice, which, to save confusion, I have not previously mentioned, to make the prominent points of the threads upon our screw chasers abnormally prominent, so that the threads which are formed upon the lens fittings are abnormally deep, though they are correctly formed on their crests and on the sloping sides. This has the effect of making the threads bear only upon their sides when they are put together, as shown in Fig. 7, at *a*, an arrangement which has two principal advantages: one, that there is much less risk of the screws sticking fast together, a common defect with ordinary screws, which often fit only in the crests and hollows of their threads and not fully upon their sides. The other advantage is that the prominent edges or crests of the screw thread, which are the parts most liable to damage by bruising or by other accident, may even be bruised to a considerable extent before the damage will extend to the sloping sides of the threads and affect the fit or the free interchangeability of the screw. With the American form of screw, which has a flat and not a rounded crest, as shown at *b* and *c*, any slight bruising of the prominent edge of the thread is certain to affect also the sides, and thus to impair the fit of the screw. For this reason the Whitworth form of thread is better adapted than the Sellers thread for such screws as those on the fittings of our lenses, which we are frequently screwing and unscrewing, and sometimes leaving exposed and liable to damage.

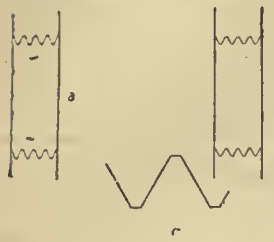

Fig. 7.

Finding the Zero of a Screw.

I should like now to refer to another matter of mechanical practice. Several years ago it occurred to me that it would be possible to provide a system by which all our lenses might be made to arrive home with their diaphragm indexes or other fittings in one position, convenient for use. The principle involved is that we should make the screw threads terminate at the shoulders of all the male screws at a point around the lenses having a fixed relation to the position of their diagram indexes or fittings. For example:—The screw thread of a lens with iris diaphragm might terminate at the shoulder of the screw at a point coinciding with the position around the lens of the iris index zero. If it did this in one lens, it might be made to do so with any number, and in this way all those lenses when screwed in turn into one flange would arrive home with their diaphragm indexes in one position. This system has been adopted as part of the Society's Standards, and it is a matter of considerable importance that opticians should be provided with some easy means of making their lens fittings uniform in this respect. When a male screw with a shoulder is screwed home in a female screw or ring so that the shoulder bears against the face of the ring and stays further advance of the screw, one side of the male screw thread is caused to bear hard against the corresponding side of the female screw thread. One side only of the thread is thus employed, and on the male screw it is the side which faces the shoulder of the screw. The position of rotation at which any lens screws home in its flange is determined by the relation of that active or working side of the thread to the screw shoulder. If we take a number of such male screws and try to discover just where the thread faces lead up to their shoulders, we shall have no easy task if it is to be accurately performed, and, unless we take into account the diameters of the screws as measured on the working sides of their threads, the lenses will not all screw home in the same flange to the positions our calculations would lead us to expect. But there is a simple way of accurately finding that point, which we may call the zero, of any such male screw with a shoulder. It is to have a corresponding female screw ring with the zero marked upon it, and after screwing home the male screw in this ring, to place the zero mark of the male in agreement with that of the female gauge.

The most convenient point to choose as the zero of a screw, is that point around the female screw where the tip of a tool cutting the screw would lie in the plane of the ring face. In other words, it is where the thread becomes complete at the face of the ring; but, if we were to locate the zero by watching where the cutting tool came into this position, or by looking for the commencement of the thread at the face of the ring, we might easily get into considerable error. If, however, we make the thickness of the ring-gauge an exact multiple of the pitch of the screw, and if we put zero marks upon both sides or faces of the gauge, the two zeros will be together at one point on the circumference of the gauge. It is easy to determine the true position of these zeros, for, if any wrong point be chosen for the mark, a male screw would not arrive home in either side of the gauge in the same relation to the zero marks. The true zero is at that point to which a male screw arrives home on both sides alike. This method is very simple and accurate, provided always that the screw of the gauge be of true size and form. Such a gauge should be made of steel, or it will not long withstand the wearing effect of forcing screws home in it.

Facilitating the Engagement of Screws.

This system of providing that all lenses may screw home in their flanges in one position depends, as I have said, upon the principle of making all the male screw threads terminate at the shoulders in one uniform position in relation to the diaphragm indexes or other fittings of the lenses.

This leads me to mention the improvement which I designed a year go for facilitating the engagement of screws.

When a pair of screws accurately formed are merely chamfered at their ends in the usual way, it is astonishing to any one who has not tried it how very difficult it is to get the screws to engage. They work together like a ball and socket joint, and, particularly with screws of large diameter, it is sometimes impossible to find at what part of their revolution the screws first engage. This difficulty is only lessened in common experience because such screws usually fit very loosely. The same kind of difficulty always occurs, if in less degree, with such screws, and we commonly experience the trouble of holding a lens to its flange in the right direction axially, and of finding at what part of their revolution the screws first engage.

The method I devised to overcome these difficulties by removing the usually incomplete portions of both male and female screw thread so that they commence abruptly of full section near the point which I have named the zero of the screw is perhaps familiar to you all.

There is one point only in this to which I wish to call attention in closing. It is that screws so formed cannot be damaged by crossing the threads; and, while this construction renders the engaging of such screws beautifully simple and certain, it removes a source of danger and helps to ensure the permanence of that accuracy of workmanship which is essential to the effective establishing everywhere of standard interchangeable lens fittings.

W. Taylor.

JOTTINGS.

I often met with the double tones in gelatine prints, to which Mr. S. Herbert Fry alludes, some months ago, but latterly I have got rid of them in a very simple way. The bath I used then, and still use, is a combined one, containing sulphocyanide. At first I was inclined to think that the double tone was wholly due to the presence and action of the latter salt, and although possibly it does predispose towards the defect, for defect it assuredly is, I am not persuaded that it is altogether to blame. When I first took up gelatine paper, I printed little, if any, deeper than I wished the finished prints to be, and I invariably met with the tone effect that Mr. Fry speaks of. Latterly, however, I have found that by printing more deeply than hitherto, so as to allow of a very considerable reduction in the combined bath, the tone scale of my prints is remarkably improved; so much so, that I seldom now meet with double tones. All the same, the character of the negative is not without influence on this point, I fancy.

I have an idea for the commercial preparation of thickly coated plates, which, if carried into execution, would entail no extra expense, and very little additional trouble in the method of manufacture. Thickly coated plates are said to reduce the effects of halation and to enable one to obtain richly deposited images, with possibly a better range of gradation than with other plates, so that it is worth the while of the makers to secure such advantages on the terms I am specifying. Good though it is, I shall not patent the idea. No, the only reward I ask is the gratitude of platemakers and plate-users alike; that will satisfy me. But to the formula. Any plate may be converted into a thickly coated one, by the simple expedient of adding to the coated side the quantity of emulsion which is usually to be found *on the backs of the plates*, in which position it takes no part in the formation of the image. During this season I have used gelatine plates of nearly every commercial brand, and I have been

astonished at the quantity of emulsion which is wasted on the backs of the plates. It is matter in the wrong place, but, unlike dirt, it has a right place in which it would be exceedingly welcome.

Once or twice lately the question of individual amateur photographers obtaining from the railway companies concessions in the matter of their fares, such as those enjoyed by anglers, has been mooted. Knowing something of the tricks and manners of railway magnates, I have little expectation that the movement will end in a favourable result. Obviously, the cases of the angler and the photographer are not parallel, and I fear that, if the companies did make a concession to the knights of the camera, the door would be opened pretty wide for the admission of abuses. By the way, amateur photographers on their outings should not forget the fact that to parties of ten and upwards the railway companies, or rather many of them, grant a reduction of fares. Some of the canny Midland and Northern secretaries are alive to the fact, as your pages testify whereas, judging from the silence of London secretaries on the point advantage does not appear to be taken of the fact in the Big Village. Or is it that you Londoners are less enthusiastic in the matter of outings than we dwellers up north?

Reading through a scientific journal the other day, I happened upon a short paragraph in which expression was given to the difficulty of coping with the now voluminous periodical literature of science with the view of collating that which would be worth preservation for future reference and information. It seems to me that the literature of photography must present just about the same difficulty. The number of publications is increasing to such an extent as to quite justify Mr. Mason's remarks, in his presidential address to the Convention, that "the journalism devoted to the profession seems to be out of all proportion to the extent of the trade it caters for." Side by side with this, moreover, has arisen such diffuseness and verbosity among individuals studying photography in its scientific aspects that it is next to impossible for any one person to keep pace with the appalling torrents of talk that are poured out as contributions to our knowledge of photographic science. Camera Club conferences and Photographic Conventions seem to be largely used as pegs upon which to hang long and weary screeds that probably few but their authors ever peruse, and now we have the parent Society cold-bloodedly proposing to inflict a two days' "Congress" of talk upon us. There is too much talkee-talkee in photography. Messrs. Guardia and Fry, the Photographic Club delegates to the Convention, bluntly say: "Except so far as the publicity of the press is concerned, the meeting" (*i.e.*, the Convention) "for the reading of the papers was a fiasco!" But fancy if all those terrible papers *had* been read! Why, they would have driven the Conventioners mad. I don't for a moment suppose that anybody outside a newspaper office has read them in their entirety. To do so would, in my humble opinion, entitle a man to receive the Albert Medal of the First Class from the hands of Her Gracious Majesty.

Talking of the north, it is singular to note that "diffused treatment" does not prevail so largely here as it does down south. Photographers, both amateur and professional, have no sympathy with the extraordinary abortions in the way of focussing that prevail in some quarters. They take their pictures as the human eye sees them, sharply, and as the optical analogue of the human eye, the photographic lens, also sees them, sharply. What's that? The human eye cannot see the different planes of a subject sharply at one and the same time? Granted; but the brain is conscious that when the eye is moved from plane to plane the subject will be seen sharply then; and while this consciousness remains sharp photographs will appeal to the perception of the multitude with greater force than the impressionistic blurs and smudges which are being run by slavish adulators of Whistler and his artistic toadies. With Captain Abney, I say I am a mappist. In my part of the world we are all mappists. And I venture to think mappism will prevail long after the confused dream of fuzzism simply lives in history as food for amused wonder.

The hot weather makes us all uncomfortable, "dem'd moist and unpleasant," as Mr. Mantalini would say, but it brings corresponding advantages in its train. The increased warmth of the solutions certainly hastens development, fixing and washing. The average temperature of the water with which I have been working lately has been nearer 70° than 60°, and, on the score of time saving, I have certainly found that no drawback. Fortunately, we live in days when frilling is comparatively unknown. *Apropos* of warm solutions, there is much wisdom in the remark of Mr. Haddon, made at the meeting of the London and Provincial Photographic Association, and reported on p. 517: He "had no doubt that, by the use of lukewarm water, five minutes' washing (of albumen prints) would suffice." I have long used water slightly warmed for the purpose, and can testify to the excellence of the idea. What a valuable paper that is of Messrs. Grundy and Haddon, by the way. Their experiments, I venture to say, are destined to become classical. Besides that, they will not improbably be instrumental in teaching photographers more than they hitherto knew as to the manipulation of albumen paper, and thus indefinitely stave off the extinction of a printing process the death of which, to say the least of it, has been prematurely prophesied. Than good silver prints nothing are finer, leaving surface effects to individual tastes, of course. As to their permanency, I have some in my possession nearly forty years old, perfect in preservation, and bad to beat from any modern point of view.

How is the Central Photographic Club getting on? I hope it has not fizzled out. Months ago, when the idea of it was mooted, I ventured to doubt the probability of its success, if the promoters in any way reckoned on the support of professional photographers. I fear they have been disappointed. The profession, in the main, is sadly deficient in *esprit-de-corps* and public-spiritedness. The National Society of Professional Photographers is doomed to perpetual impotence, by reason of its paucity of members; the Photographers' Benevolent Association is chiefly supported by amateurs and the trade. The Photographic Convention of the United Kingdom attracts less than a handful of professionals to its gatherings. A nice picture, certainly.

Cosmos.

THE ELECTRICAL ACTION OF LIGHT UPON SILVER.

At the meeting of the Asiatic Society of Bengal in May last, Colonel Waterhouse read a paper describing some observations of the electrical action of light upon silver and its haloid compounds he had lately been making. The subject is of interest in connexion with the formation of the invisible photographic image as well as with electro-actinometry, and an abstract of the paper will, no doubt, be acceptable to our readers.

The paper commences with a short summary of the previous observations of Becquerel, Hunt, Grove, Pacinotti, Hankel, Dewar, Egoroff, Moser, Minchin, and Griveaux on the electrical action of light on silver and its haloids, and on other metals in various solutions. The apparatus used is next described. This consists of two kinds of cells similar to those used by Becquerel—one being vertical, the other horizontal. The former consists of a glass cell in which the plates forming the electrodes can be coupled face to face or back to back, one being screened from light by the other and by one or two interposed screens of ruby or yellow glass, the cell being closed all round except at an opening on one side. This glass cell is enclosed in a wooden box, with a shutter on one side sliding in front of an opening corresponding to the one in the glass cell. In front of this shutter there are grooves in which coloured glasses can be placed in front of the opening. The upper part of the wooden case is open, but can be closed by a lid, through which, if necessary, a funnel may be passed to admit of solution being poured into the cell without letting in light. In this way sensitive plates can be put into the cells in the dark room and the solutions added at the time of observation. The silver plates used with this cell were 4 × 1¼ inches, other plates, such as photographic dry plates or celluloid films, being about the same size or smaller.

The horizontal cell consists of a wooden trough divided into two compartments by a double wooden screen, which allows the free circulation of the electrolytic fluid, while completely shutting off light from the unexposed compartment. This trough is covered with a lid, with two large openings fitted with hinged shutters, to the under sides of which mirrors are attached for the purpose of reflecting light at will on to one or other of the sensitive surfaces in the compartments below. By this arrangement the whole of the sensitive plate can be exposed to light,

while the unexposed plate is more perfectly protected from strong light than it is in the vertical cell. The horizontal trough is constructed to take two plates $3\frac{1}{4} \times 4\frac{1}{4}$ inches, or smaller.

In most cases, even under favourable conditions, the light currents observed are very weak, and, consequently, an exceedingly sensitive galvanometer is necessary. The one used in these experiments is the latest modification of the Rosenthal micro-galvanometer, made by Edelmann, in Munich. It is said to be sensitive to currents of a billionth of an ampère, with a resistance in the coils of only 1000 ohms. It can be set up in any position, is simple in construction, exceedingly sensitive, convenient in use, and easy to observe with fair precision, even in a town on a bad foundation like Calcutta. By using the directing magnet, the normal sensitiveness can be greatly increased; but in most of the experiments this magnet was not used, and when it was used the increase of sensitiveness was limited to about five times. The galvanometer is fitted with a small telescope, by which direct readings are made off the mirror from a millimetre scale placed at one metre from it.

As it was found that work with the spectrum required entirely special arrangements for obtaining a sufficiently large amount of light to make the action of the different rays of the spectrum distinctly visible in the telescope of the galvanometer, and as the weather was also unfavourable, the action of coloured light has only been observed through the ordinary coloured glasses as found in the bazaar. In all cases sunshine was reflected on to the sensitive surfaces by means of a mirror, as it was not convenient to use the direct rays of the sun.

Several difficulties are noticed as occurring in the course of the observations; among them, polarisation, or other currents generated in the cells independently of the action of light, but sometimes brought about by it; apparent reversals of current, due to decreases in the strength of the light. The unusually cloudy and changeable state of the weather during the course of the experiments, and the want of steady, clear sunshine made it difficult to compare the results of observations on different days.

The observations detailed in the paper are confined to pure silver plates in water, dilute acids, dilute alkaline solutions, and on pure silver plates in a dry state, the observations on the haloids being reserved for a future paper. The silver plates used were nearly pure, being about ·993 touch (not ·974, as stated in the paper). They were $4 \times 1\frac{1}{4}$ inches, and immersed in the various solutions from 2 to $2\frac{1}{2}$ inches, and about half an inch apart.

I.—Silver Plates in Water.

Distilled Water.—The current observed in distilled water between the exposed and unexposed silver plates was exceedingly small, and could only be clearly seen with strong sunshine. In nearly all cases the exposed plate was positive to the unexposed, as zinc to copper, and formed the anode or dissolving plate of the couple.

Tap Water.—The ordinary water from the town supply was used; and at the time of observation there would be a fair proportion of chlorine in it amounting to 1 to 1·2 parts per 100,000. In most of the cases observed the exposed plate was distinctly positive to the unexposed, as with distilled water. The plates were rather more sensitive than in distilled water, and were easily affected by changes in the strength of the light. In some cases, when fresh plates were exposed to daylight, the exposed plates were negative to the unexposed; but on subsequent expose to sunshine they were positive, and remained so on further exposures. Hankel found that, of two silver plates immersed in water, the plate exposed to white clouds, or to the setting sun, was negative.

II.—Silver Plates in Dilute Acids.

Becquerel found that with plates of gold or platinum, immersed in acid solutions, the plate exposed to the light was always positive. The same rule seems to apply to silver plates in most cases, but not in all.

Dilute Sulphuric Acid.—The action of dilute sulphuric acid upon silver plates under the influence of light seemed to be rather irregular, the exposed plate being sometimes negative on first exposure and positive in subsequent exposures, or *vice versâ*, but the general tendency seemed to be for the exposed plate to be positive.

In distilled water acidified with one drop of ordinary sulphuric acid in sixty c.c. of water, the exposed plate was generally positive when exposed to bright sunshine, but on two occasions it was observed to be negative.

In tap water similarly acidified, the plates appeared to be negative on first exposure, under white or coloured glasses, and on being exposed again later were also negative, but became positive and more sensitive both to white and coloured light. The plates were very sensitive to changes in the strength of the light.

With plates immersed in distilled water containing one per cent. of acid, it was found that, if the plates were exposed to sunshine a very short time after being immersed in the dilute acid, they were at first negative and fairly sensitive to light; but, in a case when the plates had been kept in the cell for twenty-four hours to reduce polarisation, they were positive and much less sensitive than the plates which were negative. After being exposed a few times they lost all sensitiveness.

In tap water containing the same proportion of acid, the exposed plates were generally positive on first exposure, but the current quickly decreased on subsequent exposures, and in some cases the exposed plate became negative.

With plates immersed in distilled water containing two per cent. of acid the deflections were usually positive, and the plates became less sensitive by repeated exposure and by keeping.

With plates immersed in freshly mixed dilute acid at five per cent., the exposed plates were positive on first and subsequent exposures, but with plates kept in the acid for twenty-four hours the first plate of the pair was negative when exposed; but, when the unexposed plate was also exposed, it remained positive. The increase of acid lowered the sensitiveness of the plates.

Dilute Nitric Acid.—With nitric acid the exposed plates are nearly always positive, and the action is more uniform than with sulphuric acid, especially when dilute solutions containing one per cent. or more of acid were used. Becquerel also found the exposed silver plate positive in dilute nitric acid.

Dilute Phosphoric Acid.—With dilute phosphoric acid the exposed plates were almost always positive. On first exposure they showed fair sensitiveness, but it rapidly decreased on further exposure.

Dilute Hydrochloric Acid.—With one per cent. of hydrochloric acid, s.g. 1·150, in distilled water, the exposed plates were uniformly positive, and, owing to the formation of a deposit of chloride, they were much more sensitive to light than plates immersed in acids which do not form a sensitive compound with the silver. The sensitiveness was greater according to the time the plates had been kept, but was reduced by increase in the strength of the acid. Coloured glasses all gave positive deflections, the red being the smallest, and then the green.

Dilute Hydrobromic Acid.—With dilute hydrobromic acid the exposed plates were uniformly *negative* and very sensitive to light. Coloured glasses gave fairly large negative deflections, the red being the smallest, and then the yellow. The plates were coated with a grey greenish-yellow deposit of bromide, which turned dark on exposure.

Dilute Hydriodic Acid.—A dilute solution of the acid was roughly made up by precipitating a solution of barium iodide with sulphuric acid. There was, however, a quantity of free iodine present, the solution being of a light sherry colour. The exposed plate was strongly negative in sunshine, but comparatively very insensitive to weak daylight. Coloured glasses gave negative deflections, the red and green being the weakest. The plates became less sensitive by keeping. They were covered with a strong loose deposit of iodide, under which the silver surface was darkened. A faint image of the exposed part of the plate was visible.

Dilute Glacial Acetic Acid.—In dilute glacial acetic acid at one per cent. the exposed plates were positive, but became less sensitive by keeping. In a five per cent. solution the exposed plate was also positive, but less sensitive than in the weaker acid.

Dilute Formic Acid.—In dilute formic acid at one per cent. the exposed plate was positive, but after being kept in the cell for twenty-four hours became much less sensitive.

III.—Silver Plates in Alkaline Solutions.

Becquerel found that, when platinum or gold plates were immersed in alkaline solutions, the plate exposed to light was negative. This rule does not appear to hold good with silver, the exposed plate being almost always positive.

Solution of Caustic Potash.—In a solution of caustic potash at one per cent. the exposed plate was positive and fairly sensitive. Coloured glasses gave position deflections, the red and yellow being the smallest.

Solution of Potassium Carbonate.—In a solution of anhydrous potassium carbonate at one per cent. the exposed plate was positive and fairly sensitive to diffused daylight as well as to sunshine, more so than in the solution of caustic potash.

In tap water with a few drops of 10 per cent. solution added to 60 c.c of water, the exposed plates were also positive and very sensitive on first exposure, but the sensitiveness decreased with the further action of light, and also by keeping the plates in the cell.

Solutions of Sodium Carbonate.—In a one per cent. solution of anhydrous sodium carbonate in distilled water the exposed plates were positive, but much less sensitive than with the potash salt, and further lost sensitiveness by subsequent exposures. With a stronger solution at five per cent. the results were similar, but the plate appeared somewhat more sensitive.

Solutions of Lithium Carbonate.—With plates exposed shortly after immersion in a one per cent. solution of lithium carbonate in distilled water, the plate exposed to sunshine was positive. The plates lost sensitiveness after the first exposure, as well as by keeping, but remained positive.

Dilute Solutions of Ammonia.—With a solution of four c.c. of strong liquid ammonia in 100 c.c. distilled water, the cell having been left standing fourteen or fifteen hours, the exposed plate was found to be positive, but exceedingly insensitive.

In a freshly mixed solution of half the above strength, the exposed plate was rather more sensitive, but the sensitiveness decreased on further exposure, and after a short time the plate became quite insensitive.

Potassium Cyanide.—With solutions of potassium cyanide at one per cent. there is a strong polarisation current which takes several hours to subside. When freshly immersed, the exposed plate was negative, but not very sensitive. On subsequent exposures the plates were first nega-

tive and then positive, and gradually lost sensitiveness. Some peculiar reversals and polarisation currents were observed, which require further examination. The plates were coated with a dark grey deposit, thicker at the upper part of the plate than at the lower. About the immersion line there was a yellowish white deposit, and the plates were deeply corroded, but no sign of an image of the exposed part was visible.

Plain Silver Plates Dry.—When a silver plate about 5×4 inches, not immersed in any solution, but with its ends connected by silver bands to the terminals of the galvanometer, the directing magnet being placed so as to increase the sensitiveness of the galvanometer about thirteen times, was exposed to light, so that one-half remained unexposed, it was found possible to detect a slight current between the exposed and unexposed halves of the plate, the exposed half being positive to the unexposed. With a plate that had been lying by for some time, and was not cleaned before exposure, the deflection in bright clear sunshine was fairly large, amounting to about ten divisions or rather more than the deflection caused by the contact of dry zinc and copper. When the plate had been cleaned with cyanide of potassium, followed by rubbing with emery cloth, the deflection on exposure was still positive, but much smaller, and became less by subsequent exposures.

Some other very pure silver plates, about 999·5 touch, also gave positive deflections on first exposure, but very small, but sometimes the deflections were negative, or became so by prolonged exposure. With silver deposited on glass the deflections were sometimes negative and sometimes positive, but always very small. These effects did not seem to be due to heat, because with the plate first observed, and with the purest silver plates, the action of heat applied at the exposed end of the plate was to cause a positive deflection, but with other silver plates not quite so pure, and with some largely alloyed with copper, the heated end of the plate was always negative to the cool end. The deflection invariably increased with the continuance of the heating and was always in the same direction on repetition of it. The light currents, on the other hand, showed a decrease of deflection from repeated exposures, and sometimes a change of sign contrary to the heat currents shown by the same plates. The observation is a very difficult one, and requires further repetition, under more favourable conditions of light and weather, in order to obtain definite results.

From the above experiments it would appear that, as a general rule, sunlight has an oxidising or dissolving effect on silver, whether in acid or alkaline solutions, the exposed plates being nearly always positive and consequently forming the anode of the voltaic couple. With solutions decomposed by silver and forming sensitive compounds with it the action is variable.

STEREOSCOPY.

[Fairfield Camera Club.]

One would think it hardly possible in these days to meet with anybody who does not know what a stereoscopic slide is, but I assure you it is not an infrequent occurrence to find good photographers who have not the slightest idea why a stereoscopic slide consists of two pictures, or in what way these two pictures differ; and, indeed, I might even go a step further.

Not very long ago a member of this Society called upon me, and, in the course of conversation, he said that he had never seen any use in stereoscopic slides; he had a stereoscope and some slides at home, but he could see the pictures best without the stereoscope. I gave him some of my slides to examine, and he very soon altered his ideas, and became deeply interested, and wanted to know more about them. In the course of a very agreeable chat, I asked him if it had ever occurred to him why he had two eyes? "Oh, every fool knows that!" he said; "it's so that, if I get one knocked out, I have another to fall back upon." But I think our friend would be able to give a better reason now for his having two eyes, for he has since become a most enthusiastic stereoscopist.

Binocular Vision.

Now, as the whole principles of the stereoscope are involved in binocular vision, we had best begin by a little consideration of the sense of sight.

The sense of sight has been called distant touch; it enables us to perceive light, and to distinguish bodies, not only as to their colour, form, and distance, but also as to their motion or repose.

The organ of vision is composed of a *receptive apparatus* and an *apparatus for transmission*. As a receptive apparatus we may compare it to a photographic camera and lens. We have a nearly globular chamber, composed of a thick, strong, white substance—the *sclerotic coat*—part of which is seen as the white of the eye. The inside of this chamber is interlaced with minute blood vessels, covered again by a thick black pigment, called the retina, and the whole is filled with a transparent jelly; in front is a transparent convex membrane (the *cornea*), fixed, like a watch glass, into the sclerotic coat, and behind this is the *crystalline lens*, covered in front by a curtain, which is perforated by a round hole in the centre, and is called the *iris*.

It is by means of the crystalline lens, which is bi-convex in form, that images are formed on the retina, and, as in the case of any other bi-convex lens, the image formed is inverted, just as the image formed by a photographic lens is inverted on the ground-glass screen of the camera; but, as we all know, the photographic lens, as it is generally used, has no fixed focus; the nearer an object be brought to such a lens, the further from the lens, on the other side, the sensitive plate must be placed, and *vice versâ*. For this reason we have a rack-and-pinion movement to our camera for focussing; but in the eye we have no rack-and-pinion movement, but we have an elastic lens which automatically flattens or bulges, to become longer or shorter in focus as we observe distant or near objects; thus the crystalline lens has the *power of accommodation*, as it is called.

The iris, too, is automatic in the adjustment necessary for more or less light admitted to the eye.

The receiving surface for the inverted image is, as has been said, the *retina*, which is an expansion of the optic nerve by which light impressions are transmitted to the brain. The eye thus receives impressions for the inspection of the mind.

But the *retina* is not equally sensitive over its entire surface; indeed, there is but one spot near the centre where distinct vision is possible. This is a yellowish depressed spot, sometimes called the "pit" (or *forea centralis*), so that, when observing natural objects, we only see distinctly a very small area at a time, all other parts are indistinct, or what a photographer would understand as out of focus, or very inferior definition; but the rapidity of the movement of the eye enables us to combine the successive images, and we know, from experience and the sense of touch, what they mean. To make this part of our subject still more clear, let us look at a landscape in nature. We concentrate our attention upon a tree. Now we see only the tree or a portion of it distinctly for the moment, all other parts of the landscape are more or less out of focus; but, as we desire to see other parts of the landscape, the movement of the eye and the accommodation of the crystalline lens instantly adjust themselves to produce sharp or distinct impressions of whatever part we turn our attention to; thus, "whatever we want to see we look at, and we see it distinctly; what we do not look at we do not as a rule care for at the moment, and so do not notice how imperfectly we see it.

Here I would suggest that a little study of the theory of vision might assist the followers of the school of out-of-focus photography—misnamed naturalistic photography—to a modification of their ideas.

Inversion of the Retinal Image.

Well, up to now we have only very briefly considered vision with one eye, and before we leave this part of the subject I must remind you again that the retinal picture is inverted both as regards top and bottom, and right and left, of the actual objects just as the image is inverted on the camera ground glass. Then the question follows, How do we get the impression of their true position? The theory of vision cannot be explained by anatomical facts, so that many hypotheses have been invented to explain it. The most reasonable of these is that of the late Professor Fick, by assuming that, as all retinal impressions are conveyed to the brain for the inspection of the mind, the nerves of sight and those of feeling are co-operative, or in correspondence.

If some of us forget our own first difficulties in composing a picture on the camera ground glass, we can care to mend the difficulties of photographic tyros. It is only by constant practice that we can adjust our instrument, and, when this is attained, there is no difficulty in arranging the composition of our picture; we may cut off the foreground, balance the sides of our picture with perfect ease—in fact, so accustomed are we to the inverted image on the ground glass, we do not even notice that it is so; but, when the negative is developed and printed, we can no longer tolerate its inversion, and to judge of its composition, or even to examine its detail, we turn it right side up.

As I stand now, I see the President in his chair, and, although the image of him on my own retina is inverted, I know that his head is up and his feet are down; and if I now turn my back upon the President, and assume the ungraceful position by bending my body with my head down between my legs, the retinal image of the President will be *reversed*, but I have still the impression that his head is up and his feet down.

Another instance of the correspondence in the sense of sight and that of touch is demonstrated by a man who shaves before a looking-glass. Those who are not accustomed to shave are in fear of cutting themselves, for the razor seems to go the wrong way. The same thing is experienced by young microscopists in attempting dissections under a microscope.

But it is time we began to consider vision with two eyes, or

binocular vision as it is called. When we look at an object with two eyes we receive two retinal images, one in each eye, and yet, under normal conditions, only one impression is produced in the mind. We direct the optic axis of both eyes to the one object, therefore they converge, and the images, falling upon corresponding parts, are transmitted by corresponding nerves, which may be described as bundles of fine fibres, the inside set of which cross like the reins of a pair of horses, and are brought together before entering the brain.

Convergence of the Optic Axis.

The power of convergence of the optic axis to one point is attained in infancy, and I have no doubt many present can call to mind a very young baby before it begins to "take notice" has a very vacant look about the eyes; it disregards the fond father as he approaches or recedes. The nurse draws her hand over the organs of vision as she notices the baby's eyes sometimes diverge, and this, she says, is to prevent it from having a permanent squint; soon the baby acquires the power of convergence, and then the nurse says baby is beginning to "take notice." But everything is to the baby upside down as yet; very often the bottle gets knocked over, and sundry other things go wrong, the baby begins to turn and twist its little hands about and examine them very carefully. Now is the time the direction of motion is beginning to be learned. Then toys are given, a soft ball, say, which baby throws away and cries for it to be brought back; no sooner is it restored than away it goes again, and father says it is getting tiresome. Then it hits its little nose, and cries again. Now, the facts are, the baby did not intend to throw away the ball or to hit its nose—things went the wrong way, like the razor to the man who is not accustomed to shave. Later on, other toys are given to the child, which are turned over and over; then the sense of touch and of sight are becoming associated, and soon we gain experience.

It is by this convergence of the optic axis that we are enabled to estimate the third dimension, distance; but it will be seen that when we view an object in nature with two eyes the retinal images are not alike, because they occupy different stations, just as if we take a photograph, then move the camera the distance our eyes are apart, viz., 2½ inches, and expose again, the two pictures will be dissimilar; and it is by the association in the mind of these two dissimilar retinal pictures that we know from experience we are looking at a solid object or a landscape in nature. If we place two similar objects, say, two billiard balls, in the centre of a billiard-table, and look at them with two eyes, we shall see two balls of a certain size and at a certain distance; but, if we direct the axis of the right eye to the right-hand ball, and the axis of the left eye to the left-hand ball—which may be done by two tubes—there will be the retinal image of only one ball in each eye, and the mind will unite these as one, and we see them as only one ball; but, in consequence of the optic axis having little or no convergence, the 'one ball' looks very much further away, and therefore very much smaller.

It is also quite easy to concentrate the attention on an image formed in one eye, and to disregard a different image formed in the other eye, as is the case when a microscopist applies one eye to his monocular instrument, at the same time keeping the other eye wide open; he sees only that which he concentrates his attention upon (through his microscope); this is called the *rivalry of the retina*.

Now, it will be understood that a man with a permanent squint, that is to say, having no power to converge the optic axis to one point, would most certainly see double, if it were not from the fact that he disregards the retinal image of one eye, and consequently he sees no better than a man with only one eye. This experiment may be tried by rolling two pieces of note paper into tubes, and applying one end of each to the two eyes, at the other end diverging objects may be observed through either tube, and seen distinctly, but it is impossible to see distinctly through both tubes at one time.

Now we are able to perceive that, although with two eyes we converge to the same spot and see that spot distinctly, the indistinct image or out-of-focus parts of the object or of surrounding objects are not alike in each eye, and by falling upon portions of the retina which are not in correspondence these images are doubled, but by being indistinct and our attention not upon them for the moment we do not notice that they are double. Here is an illustration: If I hold my finger, say, 8 inches in front of my nose, and now look at the wall opposite, first with one eye and then the other, there will be certain parts of the wall obliterated in each case because my finger blocks the way, but when I open both eyes there is no portion of the wall I cannot see, notwithstanding that the finger still remains, and the indistinct image of the finger gives me the impression that two fingers are there; indeed, I really see indistinctly *two* fingers, but, my attention being upon the wall, in the ordinary course of things I should not notice the finger at all.

If, now, we look at a box on the table with one eye, we get an impression such as a single photograph would produce; with the other eye we get another view of the box; when we open both eyes these different images are by experience from infancy associated with what we know to be a solid box of a certain size and depth and at a certain distance.

If the box be removed to a more remote position, we see it with less convergence, and we estimate its distance by the amount of convergence more or less; then, if we move two photographs of the box, such as would be seen by the right eye and the left eye separately, and present these to their respective eyes separately, the mind combines the retinal images, and we get the same impression of size, shape, and distance as in nature, colour, of course, being absent.

To do this is the science of stereoscopy. Stereoscopic photographs are, for various reasons, generally taken on one plate by a camera provided with twin lenses and a division inside the camera, so that we have practically two photographic apparatuses combined in one body. Now, the picture taken by the right-hand lens must be presented to the right eye, and the picture taken by the left-hand lens must be seen by the left eye. And now let us see how this is to be accomplished in practice.

Stereoscopy in Practice.

We hold a stereoscopic negative in the same position that the plate occupied at the time of exposure, viz., inverted, with the film side away from us the picture taken by the right-hand lens is on our right; if we turn the negative to get the image right side up, as we say, we find the right-hand picture is now on our left, and a print from the negative would have the same fault. This is caused by the fact that each photographic lens inverted its image independently of the other, and what we have just done with the negative is to reinvert the two together; and the only way to correct the inversion caused by the lenses is to reinvert the two separately, or, what amounts to the same thing, transpose the pictures. Sometimes this is done by cutting the negative, and then a single print may be taken from the transposed negative and mounted in the ordinary way as for a single print; but as there are some delicate points to observe, and as amateur photographers are not usually expert glass cutters, the transposing and trimming is oftener done in the prints.

In making transparencies on glass from uncut negatives a special printing frame is generally employed by which the right-hand side of the negative is printed on the left end of the transparency plate, then a second exposure is made on the other end of the plate from the left side of the negative, or the same camera and lens used to take the original negative may be employed as a copying camera, in which case the lenses reverse the negative image independently, and thus transpose at a single operation, or with one exposure.

Size of the Pictures.

The next thing to consider is the size of a stereoscopic picture, and to arrive at this we must not forget many things that have been said; we know that the pictures must be observed with no more and no less convergence than would be employed in viewing the natural object or we shall get wrong impressions of distance, and therefore of size, and, as our eyes are only 2½ inches, or 2⅝ inches, apart, it would seem that to be able to see corresponding points in pictures mounted at wider centres a divergence of the optic axis would be necessary; but by employing slightly prismatic glasses in the stereoscope it is quite possible to combine pictures up to 3 inches centres, but any increase on 3 inches is apt to produce a strain upon the eyes and become so painful as to condemn the stereoscope.

If 3 inches be considered the limit, it is clear that the pictures cannot be larger than 3 inches wide. The depth is not controlled by the same conditions, and may be anything up to 4 inches or more, consistent with the composition of the view or the taste of the photographer. Now, objection has been taken to the smallness of stereoscopic slides, but the objection has no foundation in fact, for it has been clearly demonstrated on many occasions that when a photograph is viewed at the angle at which it was taken, that is to say, at a distance from the eye of the observer equal to the length of focus of the lens employed to tone the negative, we get the apparent natural size of the object; thus a 3-inch square picture taken by a 5-inch focus lens, and viewed at 5 inches distance, would convey the same idea of size as another picture 6 inches square taken by a 10-inch focus lens, and viewed at 10 inches distance: it follows, then, that if a stereoscopic negative be taken by 5-inch focus lenses, the stereoscope should have lenses of the same focus, for in that case we have the apparent natural size, and therefore larger pictures would have no advantage. Of course, when a picture or a photograph is framed, or even mounted in an album, there are surrounding objects that are taken notice of, and these may interfere with the retina impressions;

but by a stereoscope all surrounding objects are excluded, we should see nothing but the picture, and for this reason the card mounts for paper slides should be black or very dark in colour (not to be seen), and when transparences on glass are printed they should be bound up with black paper marks showing nothing but the actual picture.

W. I. CHADWICK.

(To be continued.)

NOTES ON A MONTH'S TRIP TO CHICAGO.

In these days of ocean travel there is little of interest to record in the short journey across the "herring-pond." We embark in one of the floating palaces, and in a short week find ourselves on *terra firma* in the New World. If it were not for the general *bonhomie* of the passengers, short as is the passage across the Atlantic, the voyage would indeed be monotonous. Very few vessels are sighted, and, as one gazes around, nothing meets the eye but sea and sky, and sky and sea. There may be a remote possibility of sighting an iceberg, or, as the banks of Newfoundland are neared, where the warm Gulf Stream encounters the cold current from the Arctic regions, an impenetrable mist may envelop the vessel in its clammy shroud. Then the fog-horn intermittently belches forth its deep, harsh, guttural sound, to the annoyance of all on board, as the steamer ploughs on its way.

The excitement of the passengers grows intense as the land discovered by Columbus hoves into view. Even the yellow-faced occupants of various deck-chairs throw off their lethargy and pick up fresh courage at the prospect of ridding themselves of the nausea demon. Soon the vessel crosses the bar and enters the Bay, passing some massive battlements at the entrance. As it steams through the Narrows, between the villa-crowned shores of Staten and Long Islands, those who possess cameras are busy depicting each point of interest as they are unfolded to the view.

Bartholdi's colossal statue of Liberty is soon passed, and the city of New York lies before us, with that marvellous specimen of engineering skill, Brooklyn Bridge, in full view. The ship is soon berthed in one of the docks, which, by the bye, do no credit to an enterprising country like the United States, nor to a city of such pretensions as New York.

After the usual customs declarations have been made, we land, and, having collected our baggage, proceed to the Customs Office, where, on presenting our ticket, an officer is deputed to overhaul our trunks. (Note.—Don't wait until they come, but get your ticket without loss of time, for it is first come first served here.) The camera is duly investigated, but after due explanation it is admitted free of duty. Having consigned our baggage to an express agent, we proceed on foot to the hotel.

Two days are spent in visiting the lions of the city. An elaborate system of elevated railways and tramways facilitates locomotion. The paving of the roadways, however, leaves very much to be desired, and the elevated rails, although a convenience, are by no means elegant structures. Besides being obnoxious to the inhabitants of the houses in the streets which they traverse, they are a source of annoyance to the unwary foot passenger, who is liable to be bespattered with hot, rancid grease from the engines of passing trains. Central Park, of which the New Yorkers are justly proud, possesses many attractive features, engineering skill having remedied most of the defects of nature.

From New York the train is taken to Philadelphia, and a day spent there. The City Hall of Philadelphia is an immense solid and substantially constructed building, reputed to be the largest in the world used as business premises. From the top a splendid panorama of the city and the adjacent country can be obtained. Independence Hall, of historic interest, stands in the heart of the city, and there are some pretty spots worth photographing in Fairmount Park, the largest park in the world. An evening train lands us in the course of three hours at Washington, a city well worthy of its title, the "Queen of Lilies."

The site of Washington has been admirably chosen, and nothing could improve the positions of the many fine public buildings it possesses. The Capitol, a magnificent structure in white marble, one of the finest architectural designs in the world, is imposingly situated on a hill overlooking the city, and lends itself agreeably to the art of the photographer. A trip down the Potomac River to Mount Vernon, the home and burial place of George Washington, results in many pretty views being obtained. From the top of Washington's Monument, the highest in America, a splendid panorama of the city, the Potomac River and the distant hills is spread out before us. Two days spent in Washington are hardly sufficient to see and photograph everything of interest.

Leaving Washington in the evening, we take the train to Chicago, the objective point of our expedition. The railway traverses the renowned Alleghany Mountains, passing through beautiful mountainous scenery. As it travels on its upward course, valley after valley unfolds itself to view, with distant ranges of blue hills; now it crosses a mountain stream, then taking a sinuous course at high speed, on the brink of a wooded precipice, until it reaches the highest point 3000 feet above sea-level.

Then it gradually descends again, and morning finds us steaming along the banks of the Ohio. Another 300 miles or so over flat uninteresting prairie land, and we arrive at Chicago.

Everything in Chicago is on a colossal scale, hotels forming cities in themselves, theatres to seat thousands, public buildings and business premises towering many stories high that it becomes painful to look at their summits.

The main feature of Chicago is its magnificent boulevards, and the citizens may well be proud of them. They traverse miles and miles of the city, and are lined on either side with private dwellings of quite a particular style of architecture which has received the name of Chicagoesque. A bit of Norman, a bit of Grecian, a bit of the seventeenth century, and then some addition to suit the personal taste of the occupant, and we have it.

The Exposition fully indicates the desire of the Chicagoans to do things on a colossal scale. The immensity and grandeur of the various building are certainly marvellous. For the modest sum (?) of two dollars per diem, a camera may be taken within the precincts of the Exposition and the photographer will find much to interest and much to amuse him. The varied styles of architecture, the crowds of people of all nationalities, the villages and inhabitants of different countries, the gaily dressed Turk with a strong Hibernian accent, Greeks, Muscovites, Javanese, Esquimaux, and many others, are all seen under native conditions.

It is truly said that the Americans can build an Exhibition, but their management leaves much to be desired. Apart from the catalogue being misleading, the guides who are stationed to direct visitors seem ignorant of the position of the exhibits.

I was very desirous of seeing all that was new in the optical world and what improvements in lenses, cameras, and optical lanterns were being exhibited. A diligent search and numerous inquiries resulted in my arrival at length in the section devoted to same, which is sixty feet above the ground floor and in such an out-of-the-way place that no one would see it casually.

To say I was disappointed with the number of exhibits is only repeating what others interested in optical matters have said; and, although the majority of those who were showing photographic instruments are well-known firms whose apparatus enjoys a good reputation, the absence of anything decidedly novel was marked. Perhaps the annual exhibitions of the Photographic Society of Great Britain and the off-recurring exhibitions at the Crystal Palace and elsewhere has made as familiar with recent inventions, and so there was little left in the way of a surprise for visitors and our American cousins.

On leaving Chicago we take a night train to Niagara, as a visit to America would not be complete without seeing the Falls.

The first sight of the Falls is disappointing, but their immensity and grandeur gradually impresses one. Here there is plenty of field for the camera, as so many different views can be obtained of the Falls and the Rapids on all sides.

A night train conveys us to Albany, the capital of New York County, from whence we go aboard one of the magnificent river steamers that ply on the Hudson.

The Hudson is a grand river, in some places three miles wide, and the scenery on its banks is very grand. With a long-focus lens many fine views can be obtained, but the vibration of the steamer is not conducive to perfect negatives. New York is reached in the evening and the following morning we board the mail boat on our homeward journey.

No difficulty was found in changing plates, the photographers very obligingly allowing use to be made of their dark rooms without any charge whatever.

J. J. STEWARD.

WALTHAM CROSS.

WITH an intention of catching the 10.25 from Liverpool-street and arriving full early, brought a wee bit of good fortune by getting the one earlier at 10.5, a quicker and better train, reaching the destination with only about two stoppages. This train seems much patronized by the followers of the gentle craft. The Great Eastern Railway carry many to the banks of the Lea. Our compartment is very crowded with bundles of rods and fair-sized wood boxes, holding enough to outfit a family in clothing. Each have more or less length of rope as handles, and generally fitted through with every care to drawers and partitions, all to carry artful devices to deceive the bright, lively members of the finny species. While many are gentle in hobby, some are noisy in voice, and far from decent in language. When one reaches manhood's function it is to be regretted he wastes so much breath to so bad a purpose. In his own estimation he may feel taller much, but those not so closely and nearly related may consider him lower, if not very low indeed.

At first reaching Waltham Cross, nothing pretty is noticeable only for its noticeable absence. Taking a turn to the right from the station, innumerable narrow streams suddenly dart out in all directions, from under house windows, beside and under the road, and between rows of houses, all clear as crystal, and alive with small fry. The abbey now soon makes its appearance in the near distance—a noble, strong, firm-built-looking structure, standing as it does at the top of the main street. To this hangs a pile of age and history. It made its *début* about 1100, and suffered itself to be knocked and cut about from its original cross shape to its present with seeming indifference, to suffer so much as one would suppose. History of this and the brave Harold will a tale unfold to those who care to make its reference—and an interesting one, too. Hard by still stand the stocks, full of ancient carving and memories.

We were assured there is yet a man living near who remembers them in full active use. Beside the abbey stands an inn, and a very old one too. The present host is a genial man, a good assistant and pilot to the tramping amateur. Half a glance tells him to be a military man and a man of the world. If you play cricket, and cricket your hobby horse, with him you are at once at home and at your ease. If there is one thing he more glories in than the antiquity of his home and its surroundings, it's cricket. Feeling our knowledge to be dull on this particular spot, we spoke of photography and our requirements. You have only to leave the old-fashioned room, take three steps, and find the yard all that can be desired. It's been standing so 400 years. It's the old-fashioned coaching yard one sees often engraved, but not in reality; here you have the reality without the engraving. This old house is called the "Cock Inn."

You may get one or two views of the yard. Mr. Ward will willingly and pleasantly, if you wish, take you under his wing, and, within a distance of a couple of hundred yards, show you some fine bits and their best points. We saw the effective corners, and felt far from happy. To do them was next to making money for comparison of difficulties. The wind saw our desires and groaned and went on much, and that dreadful. When the camera became a standing figure, it raged and became perfectly wild with delight at such presumption. He snatched the focussing cloth and vibrated the camera. We waited, to wait him out. This could not be done; the more we tried the greater he laughed and became tearful, just remaining quiet long enough to consider removing the cap, when he would quickly and carefully place a dense cloud before the shining sun, then allow it to peep through in all its beautiful glory, and in the next turn start the trees waving their arms in wild pleasure. For one hour we waited, and ate sandwiches, and still he went along as only the wind can, till we confessed our defeat and accepted his least noisy turn and uncapped the lens, recording a little bit of English landscape showing the quaint Harold's Bridge (the oldest in England). The *Sporting and Dramatic Paper*, dated June 30, 1888, gives it as the second oldest, and at the same time a chatty, interesting article, made especially so with eleven sketches of spots round about. Anyway, whether the oldest or its next junior makes but little difference. It's an "old-un" anyway, built of stones, and jolly old stones they seem—ever watching and keeping guard over a tiny stream of clear, baby innocence, gliding on its ever-moving course, quite careless and regardless of the stern, time and weather-beaten, stone-hearted father bridge above it.

The old gateway is in good preservation considering its age, and good for a picture with ruined abbey viewed in the distance. Such bricks! many measuring 15 inches in length. Our forefathers did with the secret of brick-making, and carried it with them. So bright are they in colour and tough in texture, a lazy Socialist would rather do one class of strike than break such walls as these. By now you may receive slight notice the inner man would prefer some consideration. You once again hie for the "Cock" Inn and its master, where, and by whom, you may be suited to your wishes either in lunch, dinner, or tea.

After a comfortable meal and pleasant chat, you away to another direction, working on pictures of another character, consisting of a ruined wooden shanty standing on the edge of the narrow stream, with distant view of small ruined-looking bridges. Many are the different bits of this kind here obtained, that one's half-dozen plates are soon gone, to the sorrow of the photographer. Finding you have pleasantly and quickly passed a few hours, you, with a feeling of strong reluctance, put away your last slide, determined soon to return, possibly with another chum, who may have full play with a roller slide of unlimited exposures; in fact enough—time, tide, and weather permitting—to swallow up all Waltham Cross.

TOM COAN.

A DEVICE TO TAKE THE PLACE OF THE CAMERA LUCIDA IN MICROGRAPHY.

THE art of micrography, or the reproduction on paper of images of minute objects seen through the microscope, says Dr. H. G. Piffard in the *New York Medical Journal*, may be practised in various ways, of which the three following are the principal:—

1.—The observer studies the object on the slide, and when he thinks he has the outlines and details, or a portion of them sufficiently impressed on his mind, withdraws his eyes from the tube, and commits the mental picture to paper, using, of course, both eyes in direction of movements of his pencil. Success with this presupposes a retentive memory and considerable skill as a draughtsman.

2.—The observer, looking down the tube in the usual way with one eye—for convenience, the left—is, after a little practice, enabled, by a sort of auto-projection, to see an image of the object on a sheet of paper by the side of the microscope. The outlines of this image he traces with the pencil, using the right eye to direct its movements, the observation and the reproduction being simultaneous.

3.—By the aid of a camera lucida, of which there are many different sorts, a reflected or projected image is visible on the paper with the eye that is at the same time occupied in directly observing the magnified image of the object on the stage. In one of the latest forms of camera lucida—the Abbe—this use of half the eye for observing, and the other half for recording, is a reasonably convenient method, if the observer's eye is approximately normal; marked myopia or hypermetropia, and still more pronounced astigmatism, necessitating the use of spectacles, render the use of the camera lucida inconvenient, if not well-nigh impossible.

Some time since it occurred to the writer that the practice of micrography could be greatly simplified by adopting the principles employed in ordinary projection, as used in connexion with the optical lantern, the projection microscope, photography, &c. It was only a question of reflecting the projected image on to a piece of drawing-paper fixed in some convenient position. To this end I requested Messrs. Bausch & Lomb to mount a right-angled, reflecting prism with a short tube extending from one of its square faces, this tube to be of such calibre that it could be inserted into the microscope in the place of the eyepiece. From the other square face a similar short tube extends, capable of receiving the ocular and holding it firmly.

When preparing to use this device, the object is placed on the stage and focussed in the usual manner. The microscope is then brought to a horizontal position, the eyepiece is removed, and the prism case put in its place, the ocular being inserted in the short tube provided for its reception. The ocular should point downward. The lamp, or other source of light, should then be disposed in such a way that it properly illuminates the object to be examined, it being expressly understood that no light shall escape toward the observer except that which first reaches the object. A Beck lamp is conveniently adapted to this purpose. If a piece of drawing-paper is placed beneath the ocular, and the room darkened, a brilliant image will be projected on the paper, and its reproduction can be easily accomplished with a maximum of rapidity and a minimum of discomfort. In guiding the pencil the draughtsman uses both eyes, and his spectacles, if needed, and sits in whatever position he finds most comfortable.

With a proper lamp, and careful utilisation of its light, this device gives excellent results with amplifications up to four and five hundred diameters.

If a sensitive photographic plate be substituted for the drawing paper, an exposure of a few seconds will impress an image that may be developed in the usual way.

Our Editorial Table.

FALLOWFIELD'S PHOTOGRAPHIC ANNUAL, 1893-4.

THE *Annual* of Mr. Jonathan Fallowfield is, as our readers are probably aware, an illustrated catalogue of the goods manufactured or sold by the firm. When one looks over the 700 pages contained in this *Annual*, he is tempted to exclaim, 'Prodigious!' and wonder at the fertility of invention by which photographers could be enabled to usher into the world such a variety of articles in furtherance of their calling. When we say that there are twenty-four columns of index, it will be seen how unnecessary it is for us to even indicate the contents of such a compendium, which appears to include everything. The "Hints," which formed a useful feature in the previous *Annual*, are reproduced, with some additions, and form useful reading matter. In addition to the woodcuts, it contains six pages of snap-shot illustration (two on a page) taken by the "Facile" hand camera. Post free, 1*s*.

ADAMS & CO.'S PHOTOGRAPHIC ANNUAL, 1893-4.

WE are glad to see that Messrs. Adams & Co. have reprinted in this *Annual* the leading articles by various authors which enriched the previous edition. There are certain topics which, when well treated, are useful for all time. In other respects the *Annual* forms a well-arranged *répertoire* of the specialities of the firm, numerous pages being devoted to cameras for both studio and field work, while of those belonging to the hand-camera family there is a very large assortment, among which the well-known "Ideal" occupies a central position. The variety of apparatus described, illustrated, and priced in this *Annual* of 400 pages is very great. It is nicely printed on toned paper. Price 6*d*., post free 1*s*.

PHOTOGRAPHS FROM MR. F. A. JOYNER, ADELAIDE, AUSTRALIA.

WE are always glad to see specimens of the work of brethren at a distance. Mr. Joyner has sent us some charming examples, showing two children at play with a garden roller. The expression, posing, and execution are admirable.

From Archer & Sons, Liverpool, we have received their supplemental list of new cameras and apparatus, together with their list of second-hand and soiled apparatus in stock.

Wratten's "London" Plates.

Messrs. Wratten & Wainwright, of 38 Great Queen-street, W.C., have now been making their justly appreciated plates for something like sixteen years, and their good qualities seem to have assured them a perennial popularity. As an example of their remarkable keeping properties, as well as an indication of the length of time sensitive preparations can remain unimpaired in quality, we may mention that some few months back we had an opportunity of trying some plates of the "Instantaneous" brand that had been made ten years ago. These, with normal exposure and pyro-soda development, yielded clean, vigorous, harmonious negatives. The plates did not appear to have undergone the slightest deterioration, either in rapidity or good qualities. Samples of the "London" plates (Instantaneous), made recently, were also subjected to trial, demonstrating by their ease of development, and charming richness of image that Messrs. Wratten fully maintain their high reputation in the plate making art.

News and Notes.

Photographic Club.—August 23, *Printing on Rough Paper.*

Northern Photographic and Scientific Association.—August 19 St. Albans.

Hackney Photographic Society.—August 22, *Photographic Mirrors*, by Mr. J. Miller.

Gosport Photographic Society.—August 19, Carisbrooke. Leave Portsmouth Harbour at twenty minutes past one.

London and Provincial Photographic Association.—August 24, *Glycin and other New Developers*, by Mr. L. E. Morgan.

Manchester Amateur Photographic Society.—August 19, Bollin Valley. Leader, Mr. J. Ferguson. Train, Central, thirty-five minutes past one.

Croydon Camera Club.—August 23, Whole-day Excursion to Forest Row, conducted by Mr. H. Maclean. Train leaves East Croydon at thirteen minutes to ten.

Photographic Society of Great Britain.—Technical Meeting, Tuesday, August 22, at 50, Great Russell-street; subject, *Aluminium Flashlight*, a demonstration by Mr. Bolas.

Leytonstone Camera Club.—August 19, Along the Roding. Leader, Mr. E. A. Golledge. The Club will assemble at Ilford Station, G.E.R., at thirty minutes past three. Open Social Evening at Headquarters, eight o'clock. 23, Special General Meeting to receive and pass new set of rules, and elect Assistant Secretary and Curator in place of Mr. Montague Atkinson, resigned. Chair taken at eight o'clock.

The Queen has accepted a copy of the Rev. C. Cæsar Caine's *Martial Annals of the City of York*, which was forwarded to Her Majesty by permission. The last section of the work embraces a review of the life of H.R.H. the late Duke of Clarence and Avondale during his four years' residence in York Garrison. This book was noticed, with an illustration, in a recent issue of The British Journal of Photography.

Messrs. Morgan and Kidd's Employés.—For many years the *employés* of Messrs. Morgan & Kidd have enjoyed an annual holiday together, and on Saturday, August 5, their extensive premises in Kew Foot-road were closed for this year's outing. The members of the party assembled at Teddington Lock, and, embarking on the *Windsor Castle*, the largest steam launch on the river, they had a pleasant run up to Hampton. They were received at Hampton by Mr. and Mrs. Kidd, at their charming house, Castlemaln, where dinner was served in a large marquee erected in the grounds. The tables were beautifully decorated with flowers and palms, furnished from the gardens and conservatories of the house, and were filled with an extensive and varied array of appetising dishes. About 100 sat down to a very enjoyable and well-served dinner. The usual toasts followed, and Mr. Kidd, replying to the toast of "Success to the Firm," said that the present year was a very notable one in the history of Messrs. Morgan & Kidd. For some years past he had been solely responsible for the direction of the firm, but at the beginning of this year Mr. Ernest Morgan and Mr. H. M. Dennes had been admitted as partners. He hoped that the success of the firm would be fully maintained, and that with new blood it would receive a still further impetus. Mr. Dennes gave a hearty welcome to and proposed "The Health of the Visitors," and and Mr. Ernest Morgan "The Health of Mr. and Mrs. Kidd," a toast always very popular. Year after year the company find themselves deeply indebted to Mrs. Kidd for the active and invaluable share she invariably takes in the organization of the outing, and her spirited speech in reply to her part of the toast was received with great enthusiasm. After dinner a photograph was taken of the whole party, and the launch was again boarded, and continued its run up the river until Penton Hook was reached. Tea was served on the return journey, and the run back was enlived by the diversified musical talent of the members of the party. Most of the songs were rendered in considerably better style than the average of amateur ability, and were very heartily received. Teddington was reached about half-past nine, and a thoroughly enjoyable holiday brought to a close, the whole of the company pronouncing it one of the most successful outings ever given by the firm.

,, 26	Hull	71, Prospect-street, Hull.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

August 10,—Mr. Thomas Bedding in the chair.

Mr. A. M. Levy was elected a member and Mr. J. J. Briginshaw an honorary member of the Association.

Mr. J. Cole showed a hand camera, constructed according to his own design, the principal features of which were that it could take lenses of from four to nine inches foci, the front of the camera being used as a sky shade, and the rising front being either raised or lowered by means of screw adjustment. The finder is placed beside the lens, and the camera was fitted with reversing back. Mr. Cole said he was in the habit of attaching the camera to his waistcoat by means of a small chain. This freed one hand and steadied the camera.

Exhibitions of Members' Work.

A question was asked as to whether it would not be desirable to occasionally have a Salon Evening, at which members would put their best pictures on the walls? and, further, might not such evenings alternate with the Lantern Evenings?

After some discussion, Mr. H. M. Smith proposed and Mr. W. E. Debenham seconded, "That it is desirable to occasionally have a Salon Evening, at which members might put their pictures on view."

An amendment, substituting the words "an Exhibition" for the words "a Salon," having been carried, the resolution, as amended, was also carried.

Nikko Paper.

Mr. H. M. Smith showed an untoned print on Nikko paper. He said the prints were toned with a hot solution of alum and hypo, which was a very curious toning compound. Such prints had been exposed for two or three months to strong sunlight, and have shown no traces of fading whatever. He asked whether members thought there was anything likely to be hurtful to the keeping qualities of the pictures in the toning solution?

Mr. H. Mackie asked: "What was the object of toning the prints?"

Mr. Smith replied: "To get a warm or sepia colour."

Mr. W. E. DEBENHAM had experimented with the action of silver on cotton, using silver tartrate, reducing by heat. This, on washing, left a reddish colour, which exposure to the vapour of sulphuretted hydrogen changed to a rich black. In a few months sulphur-toned deposits became faded and yellow, whereas those reduced by heat stood very much better.

Mr. SMITH pointed out that a developed image had stood when a printed-out image had faded immediately. Toning built up the developed image, and enabled it to stand exposure to sunlight.

Mr. P. EVENITT said that Captain Abney had characterised sulphide of silver as the most permanent of silver salts.

MYSTERIOUS MARKINGS ON A NEGATIVE.

Mr. Everitt exhibited a negative having diagonal wave-like markings of less intensity than the rest of the image. The plate was developed with pyro, to which sulphurous acid had been added. Three plates showed the markings, but a fourth, from the same box, developed with pyro, with the addition of sulphite of soda, was free from them.

Mr. A. HADDON did not think the markings could be due to the sulphurous acid, which never came into contact with the plate, it being converted by the alkali into soda sulphite. Therefore the same markings should have come when sulphite of soda was used.

After other discussion the meeting terminated.

North Middlesex Photographic Society.—August 14.—This was a technical night, and the attendance was affected by the holiday season and also the tropical weather. An interesting talk was held as to the use of amidol as a developer for bromide and Alpha papers. Mr. GREGORY had tried it, and got good black tones with much shorter exposure than when using ferrous oxalate. He used the formula mentioned in *Photographic Scraps* for July. Mr. BEEDLE had tried it, too, and had succeeded also in getting good blacks with very little trouble, but could not get greys, which he rather wanted. Several other members related their experience, but the general opinion seemed to be that, to keep amidol under control, fairly large quantities of bromide were necessary, and this so slowed the action that it became no faster in use than ferrous oxalate, and that, after all, the latter had not yet been ousted from premier position with regard to paper. One member had tried it with Alpha, but found he could on development only get a green-brown tone, which was no good for after-toning, a warm brown being necessary, but this he had not succeeded in getting. Mr. BEADLE showed a series of prints showing the result of partial reduction of his negatives, thus removing the effects of halation in interiors or through trees, bringing out distance which which was over-dense and did not print through, &c. The difference of before and after treatment was most marked. He described his method as follows:—A solution of hypo of ordinary strength had an addition to it of a little strong solution of ferridcyanide of potassium—just enough to give it a yellow colour; a small piece of sponge is dipped into this, and then squeezed fairly dry, and the part of the *dry* negative to be reduced gently touched or rubbed with the sponge until sufficiently reduced. The next meeting is on the 28th inst., when the Sandell plate will be dealt with by Mr. Herbert Fry. Visitors are welcome.

Hackney Photographic Society.—August 8, Mr. R. Beckett presiding. Report read of August 5 excursion to Radlett. Members' work was shown from Messrs. Guest, Hensler, Pollard, and Selfe. Question: "What is the best method of reduction of a negative overintensified with bichloride of mercury and ammonia." Reply: "After ammonia or soda sulphite, refix the plate with hypo, and it will come out little denser than it was before intensification. After cyanide of silver, reduce with ferricyanide of potash and hypo. Hypo alone makes little difference." Mr. Hensler succeeded in removing veil from lantern slides with Farmer's reducer. Mr. BECKETT said, if a single unexposed plate is left for any considerable time in its own box, on exposing and developing, often the paper mark becomes clearly visible. Mr. Blake showed negatives of a Lilium auratum on isochromatic plates, one with a light yellow screen and the other without; although two and a half times' exposure was given to the former, yet it had green fog. Three to four and a half times was recommended. Mr. PENNY showed a negative veiled over, and asked whether it were chemical or light fog? It was restrained with two or three drops of ten per cent. solution of bromide of potassium. Reply: "Quarter grain to four ounces is the correct quantity. Too much soda sulphite was probably used. It is safer to start development with half quantity and increase as necessary." Question: "Can Alpha paper be developed with amidol and be toned afterwards?" Reply: "Yes."

South London Photographic Society.—August 9, the President (Mr. F. W. Edwards) in the chair.—The Secretary announced the postponement of the President's lecture, *Reminiscences of a Few Eminent Men*, which was to take place on September 4, and stated a demonstration of the new developers, *Amidol*, *Metol*, *and Glycin*, would be substituted on that occasion. The names of two new members were proposed. Mr. MAURICE HOWELL (one of the Vice-Presidents of the Society) then gave a short lecture on *The Chemical Action of Intensification*. He stated that intensification was resorted to when the negative was not what it should be through errors of exposure, insufficient development, or several other causes. They, no doubt, all knew how to mercurially bleach the negative, but he proposed to enumerate several ways of turning the white preparation into a black one, and giving density to the picture. Ammonium sulphite was almost always used in the old days to intensify collodion pictures, but this process had the bad effect of darkening also the half-tones and entirely blocking up the shadows. A solution of ammonia or sulphite of soda might be used, but the best of all was ferrous oxalate, because it reduced both the silver and the mercury to a metallic state, and it possessed the best keeping qualities. Ferrous oxalate restored the image, and it had another advantage, as the negative might be bleached and intensified over and over again, so as to increase the opacity of the negative, and without apparently injuring it in any way. The mercury chloride could be used again and again until a very heavy deposit was obtained. He also referred to potassio-silver cyanide, ferridcyanide of uranium, and bromide of copper, the latter appearing to act as an admirable intensifier for lantern slides, but it did not act so well for negatives. They had their choice of all these processes, but he himself was in favour of ferrous oxalate, as he was of opinion that the deposit left on the surface was less likely to decompose when printing, especially when using albumenised paper. He used the ordinary formula for ferrous oxalate, taking one part each of Nos. 1 and 2, and adding one part water.

Leicester and Leicestershire Photographic Society.—The third excursion of the above Society took place on the 12th inst., under the guidance of Mr. J. Porritt (President), the rendezvous being the far famed Castle of Belvoir, the seat of the Duke of Rutland. The members and friends mustered in good numbers, and included several ladies, whose presence added greatly to the enjoyment of the party. The castle, built of freestone, chiefly in the Gothic style, is a magnificent building, standing on the wolds above the Vale of Belvoir, and occupies the site of an old fortress said to have been built soon after the Norman Conquest. After inspecting the exterior, the ladies and some of their friends paid a visit to the noble apartments, the picture gallery, containing an extensive collection of works by some of the most celebrated masters, and the Gobelin tapestry, while others rambled about the beautiful grounds and shady glades, taking views which it is hoped will prove happy reminders of a pleasant time and beautiful day. The light was about perfect for photography, but unfortunately the district is not a photographer's paradise.

FORTHCOMING EXHIBITIONS.

1893.	
September 5.....	*Royal Cornwall Polytechnic Society, Falmouth. W. Brooks, Laurel Villa, Wray-park, Reigate.
,, 20-21	*Hove Camera Club. Hon. Secretary, H. Emery, 142, Church-road, Hove, Brighton.
,, 25-Nov. 15...	*Photographic Society of Great Britain, 5A, Pall Mall East, S.W. Assistant Secretary, R. Child-Bayley, 50, Great Russell-street, W.C.
October 1-31	*Hamburg. Das Ausstellungs Committé des Amateur Photographen Verein, Schwanenwik, 33, Hamburg.
,, 9-Nov. ...	*Photographic Salon, Dudley Gallery, Piccadilly, W. Hon. Secretary of Organizing Committee, A. Maskell, 215, Shaftesbury-avenue, W.C.
November 7-11	*South London Photographic Society. Hon. Secretary C. H. Oakden, 53, Melbourne-grove, Dulwich, S.E.
,, 20-25.....	*Leytonstone Camera Club. Hon. Secretary, A. E. Bailey, Rose Bank, South-west-road, Leytonstone.
December	*Madras. The Hon. Secretary Amateur Photographic Society, Madras.

* Signifies that there are open classes.

Correspondence.

PHOTO-MICROGRAPHY.

To the EDITOR

SIR,—I am afraid that the value of the evidence produced by Mr. H. Woodworth as to the possibility of producing sharp negatives by ordinary micro-objectives, is somewhat discounted by the fact of his using cheap French triplets only, my experience of such objectives being that it is impossible they can give a sharp picture of anything, and consequently, when the image in itself is worthless, a little more in or out of focus does not count. I happen to have been experimenting lately with a variety of the best object-glasses turned out at different periods, and am certain that with the far greater number—not apochromatic—there is difference enough between the visual and actinic foci to utterly spoil the picture photographically when ordinary plates are used.

I read with great interest your article on this subject in the number for July 28, and have nothing to say against the value of the methods there described for correcting the divergence of focus; but, having myself been teaching for some time past how the same thing can be produced without any addition to the objective whatever, will you allow me to give the readers of your valuable JOURNAL my experiences on the subject?

My method is a very simple one indeed, and consists in nothing but substituting isochromatic plates for those not colour correct, and as yet I have not found a lens which will not produce photographically as sharp a picture as can be produced visually, and that without any readjustment of the image thrown on the screen. I may say that I have worked at this subject somewhat exhaustively, Mr. E. M. Nelson having kindly placed at my disposal a selection from his unrivalled collection of object-glasses, and ranging in period from 1836 to 1887. In addition to this, I have experimented on several objectives made since the production of the Jena new optical glass and partly made with it, but without fluorite, and send you a selection of prints showing the difference of focus when isochromatic plates are used and when Ilford ordinary. In all the cases

the picture was perfectly true to focus when the former plate was used, but more or less out when the latter.

I do not profess to have been the first to discover the advantage of using isochromatic plates, but with others the question was always mixed up with the use of a coloured screen in conjunction with them, and, as they did not take the trouble to find out what the effect would be without the screen, confused cause and effect, and put down to the latter what was due to the former.

In conclusion, allow me to say that all my experiments were conducted without any screen whatever.—I am, yours, &c., T. F. SMITH.

185, *Brecknock-road, N.W.*

MESSRS. GRUNDY AND HADDON'S PAPER.

To the EDITOR.

SIR,—In your report of the discussion which took place on Messrs. Haddon and Grundy's very valuable paper (*vide* THE BRITISH JOURNAL OF PHOTOGRAPHY, August 11, page 518), the remarks I made have been so altered in transcription as to become quite meaningless. I will, with your permission, rectify the text so as to render the report accurate.

In the first paragraph is said:—

"Some alkalies were impossible to remove; *caustic potash* from cupric oxide, precipitated *by that agent* as hydroxide, for example." (Underlined words have been omitted.)

Second paragraph standing under my name:—

"Was the sulphur" (not silver, as printed) "really present as hyposulphite?"

Third paragraph under my name:—

"Why not metalloidic *sulphur*, formed in the pores of the paper itself? Hyposulphite of *soda*, in contact with a porous substance, and with air having every chance of access to it, would most likely decompose *in a very dilute solution*, and possibly metalloidic *sulphur* and some insoluble compound of silver be formed."

Fourth paragraph under my name:—

"Mr. Levy said there might be *sulphur*" (not silver, as printed) "in *that* allotropic form, when it would not be dissolved by *carbon disulphide*."

These corrections will restore to the passages quoted their real meaning.

With reference to the insoluble silver compound formed in the pores of the paper, M. Delafontoine (*Würtz, Dict. de Chimie*, vol. i. page 371) states that both the double hyposulphites of silver and sodium decompose "with the greatest ease" under the influence of heat *or water*, and yield silver sulphate, silver sulphide, and a sodium salt.

With reference to the decomposition of hyposulphite of sodium above alluded to, aqueous solutions of this salt decompose slowly in contact with air, and deposit sulphur. Even when air is excluded, sulphur precipitates in time, and the solution, under the conditions, contains a quantity of neutral sulphite (*op. cit.*, vol. ii., page 1535).

The above facts seem to point out that the theory I proposed at the London and Provincial Association, as to the nature of the compounds retaining both the silver and the sodium, and unremovable by washing, has, at least, some probability.—I am, yours, &c.,

ADOLPHE M. LEVY.

37, *Basset-road, Ladbroke-grove-road, London, W., August* 12, 1893.

TELE-PHOTOGRAPHIC SYSTEMS FOR MODERATE AMPLIFICATIONS.

To the EDITOR.

SIR,—Mr. Dallmeyer has been good enough to approve of the spirit of my letter, and to explain the question of rapidity in a manner that should satisfy every one. I did not, however, venture to suggest that definition would be unsatisfactory if a larger aperture than *f*-32 were used, but only asked for information on this point. My reasons for being a little doubtful about it were these—that, seeing that the operation of the instrument consists essentially of the formation of an image by a positive lens a certain distance behind a negative lens, but within the focal length of the latter, which image is then enlarged and projected on to a screen by the negative lens, and brought to a focus at a distance corresponding to the greater conjugate focus of the back lens as related to the lesser one, or distance from the lens to the primary image of which the enlargement is made, if the image produced by the front lens is unsatisfactory, the enlarged one must necessarily be so as well. I was thinking at the time of the appearance of images formed with a large aperture, say in bright light—the general brightness of the whole, but an indistinctness of detail, due to the superabundance of light transmitted. Enlargements of pictures such as these could not be satisfactory. Such pictures would be flat, weak, in fact, generally without sparkle. I cannot deny that a large aperture would be useful to some extent in dull weather, but I am afraid the evidence of which I speak would become very apparent if *f*-3 or *f*-2 were used, or, say, *f*-12 or *f*-8 with four times enlargement.

My idea is that most photographers would be satisfied with a more moderate equivalent focus, and gain the rapidity by this means. Seeing that the ability to regulate the amount of view included would be preserved, I do not think it would be necessary to do more than construct a lens that would give such a minimum equivalent focus as would ensure a picture of satisfactory minimum size, with powers to increase these to an extent that would not overtax the powers of the instrument by reducing to any important extent the available aperture. It was with this idea in view that I suggested the use of a negative lens of lower power than that referred to by Mr. Dallmeyer. Such a lens, say, of five inches instead of three inches focus, would require 7·33 back focus to give an equivalent focus of, say, fourteen inches, whereas the three-inch lens would give the same equivalent focus with only four inches back focus—insufficient to cover anything but a small plate. I do not offer my figures except as illustrations of the idea. There are perhaps obstacles which I have not yet encountered that would interfere with the practical solution of such a plan, but I must confess that I do not conceive what form they would take.

I should like to refer to the power of pictorial composition possessed by these lenses in connexion and comparison with their use for photographing objects at great distances. I would myself sacrifice the latter for the former. We have seen the print from a plate of imposing dimensions cut down for the sake of pictorial arrangement of subject, until the pity of working large apparatus for such reduced results has struck us forcibly. Now, the tele-photographic lens will do our print-trimming in the camera, and we can compose our picture in the field instead of with a pair of scissors. This is such a boon to those who would rather take one or two pictures that had demanded and received proper study than a dozen that depended upon more or less ungovernable conditions of apparatus, that comment is needless.

I must point out that I did not submit my diagram as a method to be followed in the field, its impracticability under these circumstances being evident, but rather to show quickly the actual working of my combination, and facilitate the choice of one that might answer special requirements.

For a method of ascertaining the back focus only, the following is a very simple plan: Multiply the focus of the negative lens by the number of times of enlargement minus one—thus, by three for four times enlargement, as in Mr. Dallmeyer's original illustration. A division of the result by the actual number of times of enlargement will, by the bye, give the distance of the primary image from the back lens. These calculations are only those common to the old style of enlargement-making, only that an alteration of minus for plus takes place as necessary to the use of the negative lens.

This is, however, only a reversal of the calculation in Mr. Dallmeyer's Rule III., for finding the extent of magnification, but it appears to me to be simpler than the process which is given in his Rule II.—I am, yours, &c., CHARLES E. HANCOCK.

15, *Oakfield-street, Cardiff.*

HALATION.

To the EDITOR.

SIR,—If Mr. Pettitt's new plate possesses all the qualities he claims for it, it is undoubtedly the plate of the future. For what is halation, but over-exposure and diffusion, caused by a semi-transparent film upon a perfectly transparent basis? By substituting a non-actinic medium all degradation of the high lights would be prevented, and the beautiful gradations of light and shade seen upon the surfaces in a well-lit studio would be retained; whereas they are now too generally lost, buried fathoms deep by a multitude of conflicting reflections.—Yours truly,

Nyassa, Bournemouth, Hants. HERBERT GLYN.

CELLULOID FILMS.

To the EDITOR.

SIR,—I have just been making some comparative trials with films and plates, and would like to know if any amateur who has gone over the same ground has arrived at the same results. I have tried a plate by Schleussner, of Frankfort, against films of four of the most renowned English and American makers, and they all failed, while the plate, with an exposure the minimum of the Thornton-Pickard focal plane shutter, supposed to be less than the $\frac{1}{1000}$ of a second, with *f*-12 of the Zeiss 111 screw, gave a fair negative, and what is more curious is that a Schleussner film was far worse than any of the others. May it not be that the celluloid has a deteriorating influence on the emulsion, or is it due to the pressure of the sensitive surfaces one against the other in the packing, causing rapid deterioration? These films all fogged with the same exposure and developer which was used on the plate.—Yours truly,

Venice, August 12. W. J. STILLMAN.

Exchange Column.

Answers to Correspondents.

*** *All matters intended for the text portion of this* JOURNAL, *including queries and Exchanges, must be addressed to* "THE EDITOR, THE BRITISH JOURNAL OF PHOTOGRAPHY," 2, *York-street, Covent Garden, London. Inattention to this ensures delay.*

*** *Correspondents are informed that we cannot undertake to answer communications through the post.*

*** *Communications relating to Advertisements and general business affairs should be addressed to Messrs.* HENRY GREENWOOD & CO., 2 *York-street, Covent Garden, London.*

*** *It would be convenient if friends desiring advice respecting apparatus, failures in practice, or other information, would call at the Editorial Office either on Wednesdays from* 4 *to* 6, *or Thursdays from* 9 *to* 12 *noon, when some one of the Editorial staff will be present.*

G. W. T.—Lead toning is not to be recommended if permanence is a consideration.

JAMES CRAIG.—The address, "Holborn-viaduct, London, E.C.," will prove sufficient.

L. NIEVSKY.—We can hardly publish your letter; the opinions are expressed too forcibly to be enshrined in print. Thanks all the same.

ANXIOUS.—Fallowfield keeps collodion paper under the name of "Celloidin silver emulsion paper."—You had better not trouble to prepare it yourself.

T. BENWOOD.—Very thin guttapercha—guttapercha tissue—may be obtained at most of the indiarubber shops. We are unable to say its present price.

CARL NORMAN & CO. — So far as we are aware, there is no agency at present for the double anastigmat lens of Goerz in this country.

A. LASCELLES (New Zealand).—Thanks for enclosed print. The discoloration of the paper is believed to arise from damp. See also leading article in the present number.

T. MCPHERSON.—Be not disheartened by a few failures; they must be expected at first. The formulæ are all right. You must bear in mind that collotype, like most other processes, is not learnt in a day.

W. T. M. DAVIDSON.—Messrs. Hughes & Kimber, West Harding-street, or Messrs. Winstone & Sons, Shoe-lane, or, indeed, any other dealer in printers' materials, will supply all that is necessary in any of the photo-mechanical processes.

R. W.—If the indentures are not properly attested and duly stamped, they are not binding on either party—the master or the apprentice, or, as put, "articled pupil." With regard to the premium paid, better obtain the advice of a solicitor.

W. G.—1. The formula mentioned at the page you quote would probably answer as well as any. See also pages 780-81 of THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC for 1893. 2. Should recommend fresh solution for each batch of plates.

NEMO.—The greater portion of the official photography is done by the Royal Engineers. If you desire to do that class of work, you had better enlist in that regiment. You can get full particulars of your prospects before joining by writing to the commander.

F. E. G.—The spots may be reduced or removed by very carefully painting them with a solution of ferridcyanide of potash, and immersion of the plates in hypo. On the few data given we cannot suggest the cause of them. Send us one of the plates for examination.

LAMP.—1. Have the sides and top of the lamps of metal, and try the effect of one, two, or three thicknesses of canary medium, and have the means of introducing a sheet of ruby medium. A little experiment with the effect of various thicknesses of the media on sensitive plates will indicate the safety or otherwise of the illumination.

M. BARRY.—There are no patents in connexion with orthochromatising collodiobromide plates with eosine or anything else, whether added to the emulsion or by bath. As a matter of fact, eosine was first used as an orthochromatising agent, and its properties in this direction fully established, with this process, long before gelatine plates were an article of commerce.

H. T. LAWSON.—Bearing in mind that all chemical action is assisted by heat, it follows that you will have to reduce the strength of your developer and, at the same time, increase the proportion of pyro and bromide, so as to ensure density before the whole of the details flash out. With this precaution there will not be need for cooling the developer with ice.

A. Z. B.—From what you describe, we imagine you are suffering from astigmatism somewhat badly in one eye. Our recommendation is, Go to a properly qualified oculist without delay; if you are, as you intimate, unable to pay a specialist's fee, go to one or other of the ophthalmic hospitals. Advice there is gratuitons, and eyesight is not a thing that should be tampered with.

YE PRINTER.—There are several causes for spots such as these, but it is obvious that, from simply looking at the prints, even if they were not stuck together as a conglomerate mass, as these were when received, and no other data, it is impossible to indicate from which they proceed. However, from the stains and dirt on the backs of one or two pieces we were able to detach, we should suspect that careless manipulation was the root of the trouble.

ROSE & CO.—If the articles cannot be obtained through the firms named, we cannot say where they can be had. We do not know them ourselves from your description. If you send the firms a sample, they can possibly supply them. Have you tried Marion & Co.?

T. HARVEY puts the following: "I put all my print washings (washing before toning, of course) into an old paraffin-oil cask, and add a little muriatic acid from time to time. The cask has no cover, and therefore is, part of the day, exposed to full sunshine, and a good deal of the chloride is dark instead of being white. Do I lose any silver by this? I have an idea I may."—No harm whatever is done. The light rather aids in the deposition of the silver than otherwise.

ATTENTION.—You appear to have under-exposed the negative, and to have used large quantities of sulphite as a remedy. You should have first increased your pyro to obtain density, and then increased the alkali. The spots on the intensified image may be due to the insufficient removal of the hypo. Try the effect of reducing the negative to a thin image by means of ferridcyanide of potassium and hypo, and then reintensify by means of mercuric chloride, and redevelopment with ferrous oxalate.

M. STEPHENS writes as follows: "Would you please inform me of a paste, for mounting photographs in an album, that does not cockle? I am under the impression I saw a recipe in the JOURNAL some time ago for same, but am not quite sure."—The best mountant for the purpose, which has been frequently described, is a solution of gelatine in which alcohol is made to take the place of a large proportion of the water. Make a fairly thick solution of the gelatine in water, and then thin it with the spirit, taking care not to add sufficient to precipitate the gelatine.

T. J. W., writing on his first attempts at working the Stannotype process, and proceeding exactly as directed in the articles on the subject in our columns a few years ago, says that the tissue cannot be developed even after it has soaked in water, as hot as the hand can bear, for more than an hour, and none of the gelatine will dissolve. His actual query is: "Did the long time it took to dry, nearly a week, have anything to do with the difficulty?"—It certainly did. Indeed the trouble, in all probability, is due entirely to that and nothing else, supposing the gelatine mentioned was employed and the details, as described, followed. With tissue, however good it may be, that takes so long to dry insolubility must be expected.

R. STEWART writes: "I am building a studio 36 feet long by 18 feet broad by 18 feet high at ridge, and a dark room at one end, and dressing and waiting rooms at other end—in all about 70 feet long. Can you tell me of a cheap, good, strong, effective, economical pipe-heating system? I think there was an Edinburgh photographer's described about the time of Convention there last year. Any information will be much appreciated."—On the whole, the best, and in the end the most economical, system we know of is hot-water pipes such as used in horticultural buildings, running through the length of the rooms, with a good-size "saddle boiler" and a well controllable furnace as the source of heat. Possibly some correspondent can suggest a better system for such a size structure.

PERPLEXED says: "I shall be very glad if you can inform me what is the cause of the spots on the enclosed photographs. I have had some dozens spoilt in this manner and cannot trace the cause of same. The spots do not show until prints are mounted and nearly dry, and mounts are therefore wasted too. I have tried fresh hypo, new dishes, and everything I can think of, but all to no purpose, and if you can tell me how to prevent same in future I shall be very grateful, as it is a great hindrance to business."—As all the spots have a pronounced nucleus, like a particle of metal or other reducing agent, and only show after the prints are mounted, we conclude that some pernicious matter comes in contact with them in the later stages of the operations. Floating particles of an injurious matter in the air settling on the prints while moist, will cause similar spots. So will particles of iron in the water. It will be well to test the mounts, as they do not appear to be of an extra good quality.

R. C. GARSIDE says: "Will you inform me what proceedings to take in case stated below? I was ordered to photograph the enclosed, for two dozen order, whole-plate price quoted, 2*s*. each first dozen, 1*s*. each after. Proofs were submitted (4); but, during the interval another contractor got a travelling photographer to take his works, and the charge was 5*s*. a dozen cabinet, 10*s*. a dozen whole-plate; therefore my customer sends back to say enclosed is not satisfactory, but will find no fault, but gets the other photographer (cheaper) to do the work. An assistant and myself were there from one o'clock till seven o'clock, had train fare to pay, and a two miles tramp to the works; so, on those conditions, can I claim damages?"—We should think our correspondent would have no difficulty in recovering by County Court summons. A solicitor should, however, be consulted in the matter, as it is a purely legal one.

THE BRITISH
JOURNAL OF PHOTOGRAPHY.

No. 1738. Vol. XL.—AUGUST 25, 1893.

COUNTERACTING THE HEAT IN THE STUDIO AND OPERATING ROOM.

The unusually great heat experienced during the past fortnight has caused us to receive several letters expressive of the difficulties in photographic practice which have arisen in consequence of the increase of temperature.

In countries nearer to the equator photographers calculate upon being subjected to heat during the summer, and take precautionary measures to obviate the inconvenience arising therefrom; but in Great Britain the normal temperature is usually so mild and equable that when, as of late, it is high, beyond average, they are found unprepared to cope with such difficulties as are thereby engendered.

These difficulties find development in two directions. First, the heat in the studio or gallery, and the unpleasantness to the sitters arising therefrom; and, secondly, the increased temperature of the solutions employed in the production of the picture. The first of these may be mitigated by erecting, where the configuration of the roof permits it, a shade of any opaque material outside of the roof, so as to prevent, as far as possible, the sun from striking the glass. In a studio in one of the Southern States of America, we once saw a shade of the nature mentioned supported on strong uprights projecting above the roof, the management and unfurling of this being done from the inside. In another we have seen a water pipe running along and outside of the ridge of the roof perforated with small holes to permit a gentle stream of water to flow down the sloping sides of the glass roof, and thus keep it cool. This it does, on the principle that evaporation produces cold; the hotter the sun the more rapidly does evaporation proceed.

We have known it recommended to cool the interior of a studio by the suspension of sheets kept wet by being frequently sprinkled with water. This is not judicious, because, while such proceeding will ensure the cooling of the sheet itself, it has the undesirable effect of surcharging the surrounding atmosphere with moisture, and causing perspiration and a feeling of oppression to those present. To aid in keeping the studio cool, the sun's rays should be debarred all admission by blinds running along the roof, a feeling of greater coolness being induced by having them of a blue colour. It is almost unnecessary to recommend that the fullest ventilation should be had recourse to.

In hot countries ice is a necessity, and in all cities is usually delivered every morning at residences. A lump of this placed in a covered box or chest well lined with thick felt and of capacity sufficient to contain bottles of developing, fixing, and other solutions—which, if allowed to get too hot, might endanger the safety of gelatine on plates or paper—will be found a prophylactic for the ills that may arise from heat. The trays employed in development should also be kept in this ice safe when not in actual use. An evil that has been complained of when employing a developer that has attained a temperature many degrees higher than the average one is that the image flashes out with unusual rapidity, and that this affords no time for density to be obtained. This trouble will cease if the hint here given be taken. A bottle of a solution of chrome alum should always be at hand to apply to the plate, and thus prevent solubility of the film of the negative when exposed to the air for the purpose of being dried. It may be borne in mind that a developer composed of pyrogallic acid conduces more to hardening the film and rendering it insoluble in warm fluids than one of ferrous oxalate. Before dismissing the subject of ice as a refrigerant, we may observe that its powers of producing cold are greatly increased by crushing it and mixing therewith some common salt, a fact well known to and taken advantage of by every vendor of ice cream.

Where ice cannot be procurable, by far the best and most economical substitute is one with which we have had much experience, and which we have more than once recommended in these pages. We refer to nitrate of ammonia. As we have formerly said, this salt is cheap (its present quotation is 42*s.* per hundredweight); when dissolved in water, it strikes a very low temperature, and it is practically inexhaustible, for it can be used over and over again. By way of experiment, we have just tried some which was in actual use in 1882, and it does not appear to have had its virtues diminished. Equal parts of the crystals and water, when mixed, will ensure a fall of 46° Fahr. in the temperature of the solution, whatever that of the water may have been at the time of mixing. When the solution is effected in a wooden or other trough, any desired number of inches in depth, bottles containing solutions, or anything that it is desirous should be cooled, may be placed in it, with the certainty of a fall in the temperature resulting.

There are other mixtures which will produce cold in even a greater degree; for example, a mixture of snow (two parts) and chloride of calcium (three parts) will produce a degree of cold equalling 50° Fahr. below the freezing point. But where the economy of the nitrate of ammonia comes in is here: as soon as the solution has done its work, and has again become of a temperature at which it ceases to act as a refrigerant, it is only necessary that it be poured out into a shallow tray, and allow the water to evaporate, leaving the crystals in the bottom.

These, when dried and put away in a bottle, are again ready, at any moment, to be used in the same way, and with similar results. Ice-making machines based upon this property of the salt are in use in some parts of the world.

By adopting the hints above given one may greatly ameliorate the effects produced by such great heat as we have been experiencing of late, and may prepare for its recurrence.

PURE OXYGEN.

That a review of this subject need not by any means be a purely theoretical disquisition any one who has taken an interest in lantern matters will readily understand, and prove by reference to our columns. On the one hand, we have had complaints of the poor quality of, at any rate, some samples of compressed gas; on the other, we have heard for years past how gas from chlorate of potash is so contaminated with chlorine as effectually to destroy eventually the indiarubber fabric of which they are made. With regard to compressed oxygen, the feeling that it is unequal in illuminating capacity to the older kind is felt very strongly by some large users; but its unparalleled convenience suffices to cause such objections to be over-ruled, unless the particular sample employed were of especial impurity. Nevertheless, it should not be forgotten that an admixture of even one per cent. of nitrogen must have a perceptible effect in reducing the heat of the flame, and in a proportion far greater than that indicated by a mean of ninety-nine per cent. and 100 per cent.; for, in the first case, there is in ordinary air about twenty-one per cent., and such proportion is useless for the purpose of the lime-light; and, secondly, as it is perhaps only about the last half of the excess of temperature in the "oxyhydro" over an "air-hydro" flame that can be said to count for illuminating purposes, the heat absorbed in raising the temperature of only one per cent. of useless nitrogen reducing the total available temperature to an extent equal to several times one per cent. The manufacturers, however, are strenuous in their endeavours to continually improve the quality of the gas they compress, and eventually, no doubt, the useless nitrogen will be still more diminished. Were it a commercially paying process to use oxygen from chlorate of potash for compressing into cylinders, we think it quite possible that it would be preferred by those who wish for the utmost attainable value from the gas employed in the production of the oxyhydrogen light.

A very singular light has recently been thrown upon this aspect of the subject during some investigations upon ozone lately made by Professor Brunck, of Freiburg. One of the most commonly held beliefs upon the peculiarities of oxygen as usually prepared is that the strong smell it possesses is owing to the presence of free chlorine. Marignac, it is true, when attempting to ascertain the actual amount of this impurity present, was only able to obtain three milligrammes of silver chloride from the gas from fifty grammes of chlorate—an infinitesimal proportion; and this fact might have caused suspicion in the mind of investigators. Dr. Brunck now proves that, when the saline residue left in the flask after driving out the oxygen is examined, it has a neutral reaction, while, if free chlorine had been evolved, the residue ought to be alkaline. Again, let the gas be washed frequently with strong solution of caustic potash, it will be impossible to remove the odour; yet, if chlorine were there, it ought to be all absorbed. Further, the gas so washed bleaches moistened litmus paper, and turns starch and potassium iodide paper blue instantly. Finally, the gas, passed through alcohol, causes the production of aldehyde, an effect of oxidation which free oxygen cannot bring about. From these results Professor Brunck draws the conclusion that the odorous gas present in oxygen made from chlorate of potash and oxide of manganese cannot be chlorine, and must be ozone. One proof of this is that the odour is entirely destroyed if the gas be passed over a layer of manganese dioxide at the ordinary temperature of the atmosphere.

The great objection to this theory is that it is generally held that ozone is decomposed by a high temperature; long ago, Andrews gave 300° as the temperature of decomposition. However, Professor Brunck shows that ozone, passed slowly through a tube heated to 350°, still retained twenty-five per cent. of the original quantity of ozone. He further instances several high-temperature readings in which ozone is liberated, and he points out Schönheim's statement that the oxygen obtained by heating several metallic oxides appeared to contain ozone, as it liberated iodine from potassium iodide.

From all these observations the inference is to be drawn that gas made in the old-fashioned way in all probability contains more than one hundred per cent. in volume of oxygen, which accounts in another way for the alleged superiority of that kind of oxygen. Finally, when gas is made and stored in bags, means must be adopted for decomposing ozone instead of removing chlorine where the lasting conditions of the bags is of prime importance.

MIXED DEVELOPING FORMULÆ.

In giving the following formulæ, we may remark that they have been so arranged as to represent as nearly as possible similar proportions and strengths of the different ingredients, the combination being such as has been found, after careful trial, to suit the average plate under what may be considered normal conditions. It is, of course, absolutely impossible to form a combination that will give the very best results with plates of widely different character, which is the reason why we prefer to recommend the separate solutions; but, at the same time, it is possible to so vary the composition of the single solution as to render it suitable for any class of plate.

The formulæ given are calculated to suit plates of the "ordinary" or moderately rapid type, which, with the usual pyro development, give printing density without much trouble. With such plates, and ordinary exposures, the development takes place with about the same rapidity as with pyro, and full printing density will be obtained simultaneously with the production of detail, without the necessity for any restrainer beyond that contained in the developer itself. In case of over-exposure the use of an additional restrainer may be resorted to as under ordinary circumstances, and it may consist of a sixty per cent. solution of bromide of potassium, or a plain solution of citric acid of half that strength. The latter solution is, we think, preferable, as it seems to exercise a more decided check, both on development and fog, than the bromide, and, especially with amidol, aids greatly in the acquisition of density.

With plates of a more delicate type—notably some of the more rapid ones—we have tried, it may be requisite to slightly modify the formulæ, either by varying the proportions of hydroquinone or of the alkali, or by directly adding a restrainer

to the solution. The first method seems to us the preferable one, and the variation is easily carried into effect for any given plate, but in a one-solution developer the range of power is not very great.

The advantages claimed for the system of mixed development may be briefly recapitulated here. In the first place, density is obtained with far more dilute solutions, one grain or one grain and a half of amidol or metol, in conjunction with a similar quantity of hydroquinone, serving the same purpose as plain solutions of four times that strength or more. Secondly, the addition of a restrainer may, under ordinary circumstances, be dispensed with, the hydroquinone acting to some extent in that capacity, with the result that there is a complete prevention of fog, with a minimum of action upon the feebly illuminated portions of the picture, a matter of the utmost importance in cases of very short exposure. In fact, it may be claimed that the mixed developer will "get more out of an exposure" than, under ordinary circumstances, metol or amidol alone.

The first formula we give is a single-solution one, which, as has been already remarked, may be found useful or convenient for studio work where one kind of plate is constantly used. The solution keeps fairly well, at any rate for a week or ten days, in the concentrated form in which we give it, but when diluted for use it very quickly discolours, and a few hours suffice to practically deprive it of its developing powers. The solution is made as follows, the substances being dissolved in the order named :—

Single-solution Developer.

Metol	40 grains.
Sulphite of soda	120 ,,
Hydroquinone	48 ,,
Carbonate of potash	240 ,,
Water	8 ounces.

Apply heat if necessary to dissolve the metol, and afterwards add the sulphite, and allow that to dissolve before adding the other ingredients.

For use under normal conditions, one part of the above is to be diluted with three parts of water. To some extent greater or less vigour may be obtained by using it in a state of greater or less concentration ; but the difference in action is not great, and, should greater density be required, it is better to increase the proportion of hydroquinone, or to add to the formula a few grains of citric acid.

The next formula is one in which the developer and alkali are kept in separate solutions, which will retain their properties for a much longer period than when mixed together. The proportions of the ingredients are practically the same when mixed for use as in the foregoing.

Two-solution Developer.

A.

Metol	40 grains.
Hydroquinone	48 ,,
Sulphite of soda	120 ,,
Water	8 ounces.

B.

Carbonate of potash	1 ounce.
Water	1 quart.

For use, mix one part of A with three parts of B for ordinary exposures ; for over-exposures use less of B, or else add a few drops of a ten per cent. solution of bromide of potassium, or of a five per cent. solution of citric acid ; for slight under-exposure, increase B.

But the best form of developer for general purposes is one in which the hydroquinone is kept in separate solution from the other ingredients, as it can then be used in any required proportions to suit each particular kind of plate or any length of exposure. It may, in fact, be added as required, in the same manner as the ordinary restrainers, during the progress of development. As citric acid is a better preservative for hydroquinone than sulphite of soda, advantage is taken of the fact by combining the hydroquinone with the acid, and the additional benefit of the latter is secured proportionately with that of the hydroquinone. The formula is as follows :—

Three-solution Formula.

A.

Metol	40 grains.
Sulphite of soda	120 ,,
Water	8 ounces.

B.

Hydroquinone	40 grains.
Citric acid	10 ,,
Water	8 ounces.

C.

Carbonate of potash	1 ounce.
Water	20 ,,

For use under similar conditions to those already mentioned, take one part each of A and B and two parts of C. It will be noticed that in this formula the proportion of hydroquinone is slightly less, and that of alkali greater, than in the others—an alteration rendered necessary by the presence of the citric acid, which, in addition to neutralising a portion of the alkali, very considerably modifies the general behaviour of the developer.

If required for use with plates of the more rapid type, or such as are difficult to work up to density, the proportion of B to A may be increased, as, for instance, making the mixture one part of A to two each of B and C. In some instances a better result is obtained by increasing the proportions of A and B equally, keeping C the same, say one and a half part to each of A and B to two parts of C. These, however, are details which each operator will do better to work out for himself.

In conclusion, we may say that, while considerable variations may be made in the formulæ, both as regards the proportion of the ingredients and the introduction of restrainers, the fundamental principle of the innovation is the utilisation of the restraining power that hydroquinone undoubtedly possesses in addition to its developing action. We should warn our readers who make a practice of using the same developer repeatedly that with the addition of hydroquinone the solution discolours very rapidly after use, and this very materially curtails the power in that direction. In any of the above formulæ sixty grains of amidol may be used in place of the metol.

The Poisons Act and Photography.—Last week a Madame Ruppert was proceeded against in Dublin by the Pharmaceutical Society of Ireland for selling a bottle of "skin tonic" containing eight grains of bichloride of mercury in solution, she not being licensed under the Pharmacy Act. The defendant was mulcted in a penalty of five pounds and costs. Bichloride of mercury is somewhat largely used in intensifying negatives, and we know it is vended by some dealers in photographic materials who are not licensed under the Pharmacy Act without knowing that they are doing wrong or rendering themselves liable to a penalty. They should take warning.

A Neglected Field for Photographers.—Mention of promising prints reminds us that a little while back, during a short photographic tour in west Sussex, a district remote from large towns, we were, on no less than three occasions, offered money for the photographs we happened to be taking. The offers emanated from the inhabitants of small villages, into which it is likely the professional photographer seldom, if ever, penetrates. The larger villages and townlets are doubtless, well looked after by photographers; but it has occurred to us, from our own and others' experience, that no inconsiderable harvest awaits those enterprising photographers who devote themselves to portraiture, cottage views, &c., in out-of-the-way places, such as those we have in our minds.

Promising Prints.—Some friends of ours who went the other day on a photographic expedition to an Essex village were chilled by a cold stream of rustic sarcasm on applying for permission to photograph one of the "show" subjects. They would not mind sending the custodian a print, would they? Not at all, he should certainly have a print. He hoped he would, but—several gentlemen had recently made him a similar promise and had not kept it. He supposed all their photographs had turned out badly, as they were "only amateurs." Our friends winced, knowing that in all probability, though it was possible the photographs had turned out badly, this was not the real cause why the proffered promises had not been fulfilled. Assuredly, where prints are promised, they should be sent, if at all practicable, otherwise a great deal of ridicule, and not a little obloquy, is cast on amateur photographers generally, who thereby stand in some danger of becoming just about as unpopular with large sections of the general public as are those self-constituted kings of the highway, cyclists.

A New Paper.—A new kind of paper from which, it is asserted ink writing can be removed with a wet sponge has excited some attention in Germany. Not only has a patent for it been refused, but its manufacture and sale are declared unlawful. The paper is said to resemble ordinary paper in appearance, and is made of similar materials, with the addition of asbestos and a parchment size. The pulp, however, it is stated, is treated with sulphuric acid, and, after washing, then with a solution of ammonia and further washing. So far as one can judge from the meagre description before us, it differs only from the well-known parchment paper by its containing asbestos, and the pulp being parchmentised instead of the finished article. When parchment paper was first introduced it was proposed to parchmentise photographs to enhance their permanency. We treated some salted prints at the time—now over thirty years ago, but we did not find that it added to their stability. Halves of the same prints, darchmentised and unparchmentised, mounted side by side, showed no difference at the end of twenty years.

Art Awards at the Chicago Exhibition.—The official list of awards in the Art Section of the World's Fair has just been issued. From this it appears that over a hundred come to Great Britain—the largest number taken by any country—namely, seventy-two for oil paintings, twenty-one for water colours, and nine for black and white. Germany takes about eighty, and other countries less. It is noteworthy that Japan is awarded thirty-eight, while Italy takes only fifteen, and Switzerland but two. America is next to this country in the number of awards. Since France and some other countries withdrew their exhibits from competition, that can scarcely be considered of such an international character as would otherwise have been the case. By the way, when the medal question at the Photographic Society of Great Britain has been discussed, it has often been suggested that the Society should follow the dignified example of the Royal Academy and not give medals at all. It is, however, worthy of note, on looking through the list of prize-winners, to find the names of so many of our most celebrated R.A.'s, including that of the President of the Royal Academy, Sir Frederick Leighton himself. If our most famous painters do not consider it too undignified to compete for medals, why, then, should photographers?

Duplicate Fixing Baths.—The paper recently published by Messrs. Haddon and Grundy goes far towards clearing up some of the causes of fading in albumenised paper prints, though, unfortunately, it does not provide a remedy. Therefore, so long as albumen paper continues to be employed, it seems that permanent pictures cannot be ensured. Against this it may be urged that, as some albumen prints have withstood the test of time for three or four decades, and are still as good as ever they were, fugitiveness is not a necessary accompaniment of the process. In the paper just referred to, the point, so well understood by experienced workers, is again strongly emphasised, namely, that perfect fixation is of even greater importance than the washing, and that two baths are again recommended. Of late years the perfect fixation of albumen prints has been a secondary consideration to the appearance of the pictures afterwards. Prints from very thin negatives, on some of the weakly salted and sensitised papers, will not stand the necessary action of the "hypo" solution without serious deterioration in their vigour. If prints of this character suffer so much in one solution, they will suffer more by treatment in a second one. The prints of old were often in the fixing and toning bath for several hours; but they were printed from vigorous negatives on very strongly sensitised paper, hence their stability.

Beach Photographers.—One class of photographers probably does not join in the chorus of lamentation over the alleged depression in photography that has recently lifted its melancholy note in our correspondence columns. We allude to beach photographers. This year the fine weather has rained a golden harvest on seaside resorts, the number of visitors being unusually large. At three or four of these popular places we made a point of observing to what extent the beach photographers were profiting by the visitors' patronage, and were agreeably surprised to find that business looked decidedly brisk. Our observations were confirmed by one or two photographers to whom we put a question on the subject. By the way, a good spirit of *camaraderie* prevails among these humble professors of the popular art. Competition is keen, but never unfair, nothing like an advantage being taken one of the other. We saw instances where a helping hand was freely given in the way of the loan of chemicals, operating one for another, and so on. Quite a number of these photographers belong to the fair sex, who sometimes operate themselves, and, where necessary, assist their husbands by subduing the sunlight on a group of sitters by means of a translucent screen. We were amused, one day, at the adroitness with which one of the photographers quieted a squalling baby whose vocal performances disturbed the equanimity of a group of nine people he was taking. Whistling for his dog, who was gambolling on the sands, he whipped the animal up in his arms, flourished it before the eyes of the recalcitrant infant, who instantly became interested in doggy and quiet enough to permit of the cap being removed. The "friend of man" is a useful accessory.

OPTICAL TRUTH AND VISUAL TRUTH.

No intelligent photographer can fail to be deeply interested in Mr. Van der Weyde's bold attempts to counteract what he supposes to be shortcomings in the optical delineation of the portrait lens. Without entering into the actual application of Mr. Van der Weyde's correcting lenses (about which he has not yet published full information), further than to remark that their successful application will always demand the very highest artistic judgment, or gross failure will be the inevitable result, I will pass on to deal with the vexed and yet unsettled question which was reopened in the discussion on Mr. Van der Weyde's paper on the *Pictorial Modification of Photographic Perspective* read recently before the Society of Arts. Here we have two most eminent authorities in practical and theoretical photography expressing diametrically opposite views concerning the optical delineation of the photographic lens: Mr. Van der Weyde, on the one hand, emphatically asserting that, even under favourable conditions, the perspective drawing of the lens does not truly represent or preserve the same proportions in parts of the subject as those which are present to the visual sense of the observer when looking at the same subject from the same point of view as the lens; and Mr. W. E. Debenham, on the other hand, asserting that the lens is in no sense to blame; that if some artists find fault with the optical drawing

of the lens, it is because they have been trained to conventionally idealise and flatter their subject, which, of course, the lens will not do: in short, that the properly taken photograph is perfectly true in its proportions and its perspective, and therefore should yield to the eye precisely the same visual impression as a direct eye-view of the subject from the same point of view.

Is there no way of reconciling these seemingly opposite views? When artists of the highest repute, who have gone through the most tediously painstaking training in the accurate delineation of the human figure, for instance, and whose eyes have consequently grown exquisitely sensitive to little differences in curves and proportions of parts, deliberately assert that a certain full-length photograph of a beautiful lady-sitter, taken by some eminent photographer, does not do her figure, on the whole, justice, that her foremost hand and her feet appear *larger than they actually do in life*, are we at once to shirk discussion by attributing his verdict to professional bias, or to the supposed fact that artists are *invariably* guilty of conventional flattery of their subjects, and therefore will not have a good word to say for an unbiassed mechanical process which will not do the like? On the other hand, if men of the highest scientific and optical training assert, equally emphatically, that the optical projection or perspective of a photographic lens yields precisely the same image (except for colour, &c.) on the retina, when a print is viewed by the eye squarely and at proper distance, as that thrown on the retina when directly viewing the same subject with the eye from the same point of view as the lens, are artists justified in simply poohpoohing such a verdict, on the false ground that a mathematical mind cannot, with any profit, deal with artistic matters?

I hope to be able to show that both sides are right in this controversy, and that both sides are wrong, *by omission*. I am not one of those who believe that photography cannot err, for I have elsewhere pointed out one very serious cause of the limited powers of photography (see "Nature's Light Scales as Rendered by Photography," *Photographic Quarterly*, vol. iii., Nos. 9 and 11); but what I here contend for in regard to this question of photographic delineation is, that the "mechanical" lens does not err, but that the human photographer does very materially err, inasmuch as he seriously expects to get the same visual impression by regarding a picture on the flat as projected by the *monocular* photographic lens as he gets when viewing the same subject from the same point of view by the binocular vision afforded by his *two* eyes. The whole controversy has been conducted, so far as I know, without making anything like adequate allowance for the apparent discrepancies which must arise in comparing together an effect of monocular vision with the more realistic effect of binocular vision of the same subject.

In order to explain my meaning fully, I must first set out with illustrations of a very well-known fact in connexion with the theory of vision; the fact that our instinctive estimate of the real sizes of objects is generally a product of *two* factors.

1. The visual angle subtended by an object; or, what comes to the same thing, the size of the retinal image of that object.

2. The distance from the observer at which the object is instinctively judged to be situated.

For instance, in fig. 1, E represents the eye. Suppose that *a b* is a plain wooden rod, two feet long, and *c d* is another such rod, four feet

Fig. 1.

long, but just twice as far from the eye, E, as *a b* is. Then the images of these two rods on the retina of the eye will be of the same size exactly, and, in the absence of any means of judging that the rod *c d* is further away than *a b*, the conclusion would inevitably be that these two rods are of the *same* size. The eye cannot differentiate their sizes without, in the first place, having some means of judging their relative distances.

At the risk of triteness, I will enumerate the principal means whereby the observer is enabled to judge the distances of objects.

1. In the case of near objects, the focal adjustment of each eye required for distant vision constitutes roughly a sense of distance, but it can be shown that this cannot be operative beyond the distance of about fifteen feet.

2. The knowledge of the absolute size of familiar objects, as derived from experience. A man knows well the usual size of a cow or sheep, and consequently he instinctively guesses, without other aid, the distance of such an object corresponding to the visual angle subtended by it at his eye.

3. In the case of very distant, but more or less unknown, objects the eye derives much help in judging their distance, and therefore their size, from the apparent thickness of atmosphere which seems to lie between—often a rather deceptive clue.

4. The effects of geometric perspective, especially in the case of buildings and other objects bordered or varied by straight lines.

5—and most important of all in relation to the main point which I hope to establish—the effect of what I may call *duplex perspective*, due to binocular vision. The view of any object within 100 yards' distance, presented to one eye, is essentially more or less different in its perspective and proportions to the view of the same object presented to the other eye, the left eye seeing more round the left-hand margin of the nearer objects, and the right eye seeing more round their right-hand margins. Examples of the accurate sense of distance derived from binocular vision, and the very vague and shadowy sense of distance derived when binocular vision is either absent or rendered ineffective, are well known to all of us. As an example of the first case, let anybody try to thread a needle with one eye shut. As an example of the second case, how notoriously difficult it is to judge the distance of a horizontally stretched rope without putting the head on one side, and, consequently, how vague is the idea derived as to the real thickness of the rope.

One or two further examples of the fact that our estimate of the size of objects depends upon both visual angle and imagined distance may be given. There is the well-known case of the full moon or the sun generally appearing considerably larger when rising or setting on the horizon than when high up in the sky. Yet it has been conclusively proved, over and over again, that the visual angle subtended by their horizontal diameters is exactly the same in both cases, while their vertical diameters subtend a visual angle actually smaller than when at greater altitude.

The only possible explanation of this phenomenon lies in the fact that nearly every one almost unanimously attributes a flattened dome shape to the sky, the parts overhead being thought much nearer than the parts near the horizon, doubtless because there are so many objects between us and the horizon, helped out by the effect of atmospheric perspective, all conspiring to throw back the lowest parts of the sky into an apparently very remote distance. Therefore the moon, when setting, although of the same visual angular diameter as when at higher altitude, is instinctively judged to be much further off, and therefore proportionately *larger*.

In the same way a distant hill is judged to be loftier and more imposing when an atmospheric haze gives the impression of its great distance than when extreme clearness leads to the impression of its near proximity, when it looks comparatively dwarfed in size. Yet the visual angle is the same in both cases.

Now, when we come to represent a natural object or scene upon a flat surface, according to the well-established laws of geometrical perspective, which can be done either by the tedious process of careful drawing and plotting out, or, far more expeditiously and accurately, by a rectilinear lens, it must be carefully borne in mind that the resulting view or picture is essentially a *monocular* one; it is projected with reference to one particular point of view—the nodal centre of the lens in the case of a photograph, and the *point of sight* in the case of plotted-out perspective. Therefore, in viewing such a picture on the flat, it is obvious that binocular vision is no longer operative; the picture is the same to both eyes, and the effect of looking at it with both eyes is, in the average of cases, rather to make the observer all the more conscious that he is looking at a flat picture—a fact borne out by the habit, common among artists, of viewing pictures with only one eye, whereby relief is *gained*, and not lost.

And, since binocular vision is no longer operative, the observer is deprived of one of the most important means of estimating the relative distances of the various objects represented in the view. However skilfully drawn or painted the picture may be, if it represents objects comparatively near to the observer and within the range of binocular vision (in which case the great relief imparted by atmospheric perspective would generally be out of place), still the principal natural means of instinctively estimating the relative distances of the objects represented is denied to the observer. And the obvious deduction from this is that those parts of the subject represented which are nearest to the observer will appear somewhat exaggerated in

size, while those parts furthest from him will appear somewhat too small.

For I have already dwelt upon the fact that the mental estimate of the size of objects depend upon *two* factors, visual angle and estimated distance. Here, then, in the picture visual angles are relatively all right, but, owing to binocular vision being inoperative, there is necessarily inability to mentally project the various parts of the subject to their proper relative distances. If it is a full-length portrait of a man seated in a chair, with his hands and feet projecting toward the lens, then, in the absence of binocular vision enabling him to see at a glance how much the feet are nearer than the body; they will, therefore, not appear small enough; in other words, they will tend to appear disproportionately large. And the same thing will happen with the hands and the forward projecting arms or legs of the chair. On the other hand, if one of the sitter's hands is extended away from the camera, then, since the observer of the portrait cannot properly project that hand to its proper relative distance further back than the sitter, he will inevitably tend to think the hand relatively too small.

A very instructive experiment will further illustrate this. Take a low seat a few feet in front of a substantial arm-chair, in such a position that the back legs are visible between the front ones, and the whole chair seen in somewhat violent perspective. Shut one eye, and with the other steadily regard the *tout-ensemble* of the chair. It will be noticed that the foremost parts of the chair bear certain apparent proportions to the more distant parts. On quickly opening the other eye and bringing binocular vision into play, a sudden apparent shrinking of the front parts of the chair at once takes place, thus showing that one-eyed vision is apt to over-estimate the relative sizes of objects near to the eye at the expense of objects more remote. Similar experiments may be made in the case of other near subjects presenting parts relatively very much nearer to the observer than other parts. But the most decisive experiment of all would be to take a full-length portrait of a sitter placed in such a position in an arm-chair as to bring out this apparent distortion to the utmost—the body reclining, one leg stretched out towards the camera, the other foot put back under the chair; one hand stretched forward, the other put far back. Let a portrait be taken with a *stereoscopic* camera, furnishing two simultaneous views of the subject, and taking care that the distance between the centres of the two lenses does not materially exceed the distance between a pair of eyes. Moreover, let the distance between the camera and the sitter be such as is usually found best for artistic results, a wide-angle picture being thus precluded. Yet each picture in itself would be found to give a disagreeable effect of distortion, the foremost foot and hand looking far too large. Let a stereoscopic transparency of the two pictures be made and viewed together in the stereoscope, thus virtually calling binocular vision into play again, and then it should be found that the apparent exaggerations of the advanced parts of the sitter and chair, &c., at once disappear, everything assuming its proper proportions true to fact; this taking place not by any modification of the relative visual action (or perspective) subtended by the various parts, but simply because the parts are projected to their proper relative distances, and therefore the twin factor in instinctively estimating real size is supplied. This experiment would supply a crucial test, on which the soundness of the theory herein advanced should rest or fall, and as soon as I can find time I shall carry it out and report upon the result, which I feel positive will turn out as anticipated.

This apparent distortion may exist in very various degrees, in some cases being far too slight to strike an untrained eye, but yet glaring enough to an artist, whose eye has been carefully educated to estimate subtle proportions as he sees them, and transfer his impressions to canvas. After all, then, is there anything to be surprised at if artists accuse photography of distortion of proportions? Where they are wrong is in blaming the lens, whose only error, if it is one at all, consists in being rigidly faithful to monocular perspective. The hand artist has fallen into the way of drawing in the nearer parts of his subject smaller than the laws of monocular perspective would demand, and thus, if he does not overdo it, he compensates in a perfectly legitimate manner for the absence of binocular vision and its consequent duplex perspective when viewing the portrait. We habitually use two miniature cameras situated about two and a half inches apart for forming pictures of objects about us, and gauging their relative situations and distances, and therefore relative sizes, and transmitting the information to the brain. The photographic lens justly demands that it should be put on an equal footing with the eye, that its own faithful picture should be supplemented by another picture taken by another lens like itself, but placed two and a half inches to one side, and that the right-hand picture shall be viewed by the right eye only, and the left-hand picture by the left eye only, and then no suspicion of distortion can be urged against the combined visual impression. Under these circumstances, nothing further can be urged against photography for portraiture and the like than its scrupulous fidelity to the proportions of the subject as we see them with our eyes. Hence, then, Mr. Van der Weyde's plan of modifying the proportions of his subject by a system of very shallow lenses is but the optical counterpart of the hand-artist's power of compensating in drawing for the apparent distortion following upon the absence of binocular vision, and seems to furnish the only solution of the difficulty of making a flat monocular picture truly represent a two-eyed impression. The only danger lies in the fact that so many sitters are satisfied with nothing short of the most flagrant flattery on the part of the photographic artist as well as the portrait painter, and that the method may, in some hands, be prostituted accordingly.

H. Dennis Taylor.

AMERICAN NOTES AND NEWS.

A New American Journal.—The palatial city of Washington, D.C., has not had, so far as we know, a journal to represent photography there until now that the *Photographic Adversaria* has been published. It is to appear fortnightly, and we give hearty welcome to our young contemporary. The most noteworthy article in the issue for the 5th inst. is one by Dr. Theodore Hansmann, in which he discusses the possibility of obtaining spirit photographs, and states that in course of his investigations he has obtained several that have been recognised. One of these is printed as an illustration to the article, and represents the author himself, together with a sharply defined portrait of Gen. U. S. Grant on the same plate. Dr. Hansmann is not quite correct in stating that a certain London photo-journalist, whom he names, lived in Washington ten or twelve years ago. The most that can be said is that he twice visited it for one day, *en route* for the south, about the time mentioned.

The Convention of the American Photographers' Association.—If the reports in American journals are to be credited, and we see no reason for not doing so, the recent Convention, which was held at Chicago, has proved a deplorable failure. Not a single paper was read, nor was there any discussion on a technical or scientific subject. In brief, says the *Photographic Times*, "the Convention amounted to this only: The members met, selected a location for the Convention next year, elected officers, and adjourned." By the way, the *Times* issued its July 14 number as a special "Convention Number," but quite omitted to say anything about the Convention in it, preferring to give the report a fortnight afterwards.

Coincidence or——?—Is it not due to the readers of the "Convention Number" of the *Times* afore mentioned, that some explanation be given how it happens that an article, by Mr. William Taylor, of Leicester, entitled "The Principles of a Lens' Action," should have appeared in its pages with the signature of Walter E. Woodbury attached thereto? True, the original title of the article has been altered to "The Action of a Lens Simply Explained," and a few verbal alterations, not corrections, have been made; but, in other respects, the article, together with its illustration, is essentially that of the clever Leicester optician, and forms an addendum to his firm's catalogue. Some explanation seems desirable.

On the War Path.—We understand, from the *Photo-American*, that the Duke of Newcastle, who is stated to have almost a craze for photographing wild beasts, especially those of a rarer class, has visited California along with Mr. Gambier Bolton, intent on his favourite pastime. One project these distinguished photographers have in hand is to photograph the big sea lions at the cliffs. It is not their intention to photograph those creatures from the shore, but to steal up to the seal rocks on a tug and get perfect negatives. After leaving California, they go to Honolulu. We trust that both will return safe to England, heavily laden with the spoils of the chase.

Their Loss is Our Gain.—The editors of the *American Amateur Photographer* announce that, although they lose the active personal aid of Miss Catharine Weed Barnes by her marriage with

Mr. H. Snowden Ward, and her consequent removal to London, where she will in future reside, yet is she to keep herself in touch with her former journal by still acting as an associate editor and English correspondent. This esteemed lady, during her visit to Britain last year, made many friends, who will gladly welcome her back again, and among these we include ourselves.

Half-tones in Colours.—Mr. F. Kurtz, of New York, has patented a process of printing half-tones in colours by carrying out the idea of the three primary colours, and using blocks in which the grain runs in lines of different directions. He prints two colours over a third, and thus obtains a combination print in which several different colours appear. The negatives have to be taken through special coloured screens.

Friction at the World's Fair.—Photographers appear to be resenting the restrictions put on them in connexion with making use of their cameras at the World's Fair, and are leaving them at their lodgings rather than be subjected to the exclusive and restrictive policy adopted towards them. Hence, says the *American Amateur*, the number who try the privilege is at least ten times smaller than it would be if some reasonable fee was asked, and, as a consequence, the income from fees is disappointing. The annoyances everybody has to put up with at the hands of the Photographic Department are patent and notorious.

Extemporising a Camera Stand.—There is an absurd rule prohibiting the use of a tripod; but this seems, in one case at any rate, to have been cleverly evaded by the photographer fixing his camera on the back of a chair by a bicycle clamp. It is said that the official photographer employs a force of fifteen men to look after camera permits and watch for camera users.

Soap-bubble Photographs.—In view of the desire that now prevails among some photographers to take children in the act of blowing soap bubbles, Mr. E. L. Wilson gives (in *Wilson's Magazine*) a formula, presented to the Academy of Sciences by M. Izard. He uses a resinous soap, made of ten parts of finely powdered resin intimately mixed with ten parts of carbonate of potash, and adding a hundred parts of water, these being boiled till fully dissolved. This keeps well. For use, it must be reduced with four or five times its bulk of water. The bubbles made with this liquid continue much longer than those made of common soap.

THE PHOTOGRAPHIC CONVENTION, 1893.

Delegate's Report to the London and Provincial Photographic Association.

In accordance with my duty as an elected delegate to the Photographic Convention of the United Kingdom, I have the honour to submit to your notice the following report, comments, and opinions.

By dint of a little personal exertion, I managed to get a small party together on Monday morning, July 3, for the 10.30 train from Paddington. Taking ten tickets, the reduced fares of a party were obtained. The party consisted of nine only, so the amount saved amounted to 7*s.* 11*d.* instead of 10*s.* 8*d.* each. But, as the remaining ticket was sold at Plymouth, I declared a dividend 1*s.* 3*d.* each, making the total amount saved 9*s.* 2*d.* I mention this to show what can be done, and to urge the importance in future of some combined effort beforehand—first, to secure a comfortable saloon carriage; and, second, to reduce the fare of the journey. My work was but a scratch affair at the last moment, but it is certainly an item that should be taken in hand in future, as there will probably always be a goodly London contingent at all Conventions.

The Excursions.

Whilst finding no fault with the local Committee, there can be but little doubt of the folly of arranging too many excursions for one day. At Plymouth, as at Edinburgh, the great majority went to one particular fixture, leaving a bare handful for the others. This must be particularly unpleasant for the leaders of both, or, as was the case at Plymouth, all three. Two or three of those arranged this year practically fell through altogether, and it should be a lesson for next year that the alternative excursions should not exceed two upon any one day. I will mention one instance only. The excursion to Looe and the Cheesewring on the Thursday was allowed to drop, with the result that the one to Totnes and down the Dart was patronised by nearly seventy instead of about twenty-five as expected. The consequence was that the flotilla down the Dart had to be augmented, and finally consisted of the steamer, a barge and two small boats. To me the pleasure of an excursion is the party, and therefore all arrangements for cutting up a good size gathering into fragmentary segments of five or six do not commend themselves.

The weather, with the exception of the first day, was particularly bright and pleasant, though hardly the best for photographic work. It was most unfortunate that the first day was so wet, because the special invitation steamer trip organized by the local committee was quite a new thing, and deserved greater success. By means of local subscription, a handsome steamer was chartered for the whole day free of cost to those attending the Convention. Had the day been fine, the chances of the hand cameras were simply magnificent. However, Mr. Handsford Worth, the local Hon. Sec., and Colonel Barrington Baker exerted themselves to the utmost, and their endeavours, together with the two excellent repasts served on board, the music, and collection for the Photographers' Benevolent Association fund, served to keep the large company in what, under such depressing circumstances, might fairly be termed good humour. The trip which was probably more enjoyed than any other was that down the beautiful river Dart from Totnes to Dartmouth, although there was but little photographic work feasible.

The Papers Read.

I fear in this instance that I must find serious fault. There were too many papers to commence with, some of them were not conducive to discussion at all, and there was no time in any case for it. It was rather surprising to me that, beyond the officials, who would feel compelled to attend the reading of the papers, even a small number of ordinary members put in an appearance. The papers are usually in print and handed round beforehand to the meeting, so that there is not even the charm of listening to something new, and the discussion, being so limited, is of no value. Consequently there is but small inducement for members to attend when varied enjoyments await them elsewhere.

The highly scientific nature of some of the papers is distinctly against any sort of discussion. Even the ablest scientist would fight shy of dealing with a mass of diagrams and tables without first digesting them.

The Social Side

Was, as usual, distinctly a success. Old friends met old friends, and newer members met those they had so often heard of or read about, but never seen in the flesh. With the slight exception of a little snarling by one or two members of the trade, everything passed off well. The post-convention meetings, where over a glass of stone ginger beer, old battles are refought, and song and story enliven the evening, have become quite a recognised institution. One of our members, Mr. Cowan, rendered yeoman services at these with his recitations.

To sum up, the Convention, in spite of the few matters which might be improved, was enjoyed by every one, and I hope Mr. Cowan or Mr. Hadden will bear me out in this. And I should like to recognise the valuable services of Mr. Handsford Worth, the local Hon. Secretary, who was most indefatigable in his efforts to please and assist; also those of Mr. Cembrano. They are both model Hon. Secretaries.

One more grumble and I have done. The receptions by the Mayors of Plymouth and Devonport were all right in their way, but I must certainly deprecate the increased use of evening dress. This year the number of times required was increased to three. Personally I should like it to be forbidden altogether. We don't go out photographing and for enjoyment in dress suits; and, when the local committee specially stated on the programme that they should make a point of attending the receptions in morning dress, it was nothing less than affectation for the visitors to disregard the hint. Of course it's just as well to show the natives that some of us possess such articles of clothing, and that we know how to walk about the streets to show them to best advantage.

A journalistic friend of mine, hearing of the new venture, the magazine I edit, said, "Oh, it's easy as easy; when you haven't much to say, shove in more pictures." This is my case now, and in the album in which this report is written you will find a few of my hand-camera shots, to make the report a pictorial souvenir as well.

Walter D. Welford

CAMERA SUPPORTS.

For years a light, portable, withal rigid, stand has been a *desideratum*. I have longed for such ever since my first essays, when I was wont to carry some five feet or so of ash and brass, yclept a tripod—nothing was better in its was, stronger or more rigid; the stand bearing the name of the the late Mr. Kennett was, and is, admirable, but weighty; the "Maudsley" is a model of beauty, and is light, neat and rigid, the perfection, in fact, of a tripod for general use. The large variety of stands may be somewhat confusing, they may be all that could be wished as regards *ingenuity*, but, when we come to consider their portability, opinions will vary; what one man looks on as *portable*, another would consider impracticable.

I once owned a "fishing rod and gas-pipe arrangement" of metal with a horn attachment, this was supposed to represent an umbrella. It required a strong arm to wield it, was only some three feet six inches high when extended, and was then practically of no use, being a veritable reed "shaken with the wind."

However, the ordinary photographer has little now to complain of with regard to tripods, he can get them one, two, three, or four fold—but none of these are suitable for those who, like myself, combine the art science with *cycling*. I believe the want of a good stand deprives many cyclists of the pleasures derived from the practice of photography. To such I commend the perusal of this short note and description of what I have so far found to be a really *light*, *portable*, and *rigid* contrivance for supporting a camera during exposure. My own idea was, to have made a hinged rod to attach to the handle bar of safety, the rod to have at the end a metal plate pierced for the camera screw and fitted with a universal joint. However, I saw just in time a really good attachment by Lancaster, which, though not, I think, perfect, is still so near the mark as to make it, considering the reasonable price, a good thing to have.

Now, what we want on the cycle is an arrangement which will enable us to dismount, and, without any unpacking, transform our machine into a steady tripod, the time expended being merely that required to unpack and erect the *camera*, entirely doing away with any bulky bundle of sticks strapped to the frame of the bicycle. With the camera attachment referred to (Lancaster), and a simple contrivance which any one could manage for himself, we have all we require. The cycle, of course, will be of no use without a third "leg" or support. This I get by attaching to the safety frame, just above the front fork, by means of a collar and nut, a light bamboo stick. This, when not in use, is held up under the saddle with a small strap, though a spring "clip" would be simpler. Drop this "leg" down, and we have at once a strong, steady stand, the safety leaning over somewhat. The camera attachment, being already fixed to the top bar of frame just behind the handles (the Beeston frame being understood), is at once ready for the camera. We get three movements—lateral, vertical, and horizontal. Each movement is controlled by a simple but powerful screw, and the whole arrangement *in situ* is barely noticeable. The total weight of attachment is well under one and a half pounds. The height may be reckoned at from three to four feet six, the rapidity being wonderful.

It is well, however, to remember that to secure the best results, and to ensure one's own comfort, the camera and its fittings must be perfect. Each part should move freely and easily, the dark slide inserted and the shutters drawn without undue exertion. This is on the face of it a simple matter, but is most important in practice. Above all, the exposure should invariably be made by means of a mechanical arrangement fitted with ball and tube; the focussing cloth, slightly weighted at the corners, is left hanging, and leaves no necessity for touching the camera or machine during exposure. It is by no means requisite to remove the camera every time between exposures, as where several views are to be had in one neighbourhood the machine may be wheeled or ridden, the camera being in place ready for work; at the same time all *unnecessary vibration* is to be avoided.

Many cyclists may prefer to add (with very slightly increased weight) a second leg or strut, *i.e.*, one *each side* of bicycle. This gives greater steadiness, takes no more time to work, and is undoubtedly an additional security against vibration. Another point worth mentioning is to line or pad the *clip* with *leather*; the latter is better than rubber. It may be securely fastened on with Prout's glue, making the metal hot, running in the glue, adjusting the leather and screwing up tight till secure and set.

J. Pike.

PLATINOTYPE.

[North London Photographic Society.]

There are, to my mind, but two other processes able to approach platinotype, viz., photogravure and carbon printing. As to the exact salts with which the papers are coated, I believe the chloro-platinite of potassium, in combination with ferric oxalate, are chiefly used. Ferric oxalate is sensitive to light, and by the action of light becomes ferrous oxalate. One of the properties of ferrous oxalate is, that in solution it has the power of reducing chloro-platinite of potassium to metallic platinum. Oxalate of potash, or kindred alkalies, which compose the developer of these papers will dissolve ferrous oxalate, and this in turn reduces the chloro-platinite of potassium to metallic platinum, forming the image of a platinum print, the unused portion of the iron salt being dissolved out by the acid bath. The foregoing brief outline of the process shows the extreme simplicity of this method of printing. Platinum is undoubtedly one of the most stable and unalterable metals known to chemists, and in the very fine state of division in which we find it in a platinum print is of a rich, pure black, unaffected by light and insoluble in hydrochloric or other acids, thus ensuring permanency. This quality is undoubtedly of high value, though its simplicity of working, its artistic colour, and the soft effects producible by it, quite overshadow, in my estimation, all other good qualities. To obtain an artistic print by any process, it is necessary to devote considerable study to the production of the negative most suitable to it, and the samples which I have here will, to some extent, explain the quality of negatives most suitable to the process under consideration. True artists admire a perfect platinum print as a thing of beauty in monochrome, while it is the envy of the mediocre painter who daubs on the canvas his abominable greenery-yellowy colours in sections like a child's puzzle, which colours externally refuse to blend together and can only be softened down by prolonged contact with the fuliginous atmosphere of the kitchen chimney. Some of the older generation of photographers were somewhat incensed at Mr. Guardia's remarks at the Plymouth Convention, *re* art productions with the hand camera, and claimed that equally good work was done by some of the early and earnest workers as by those of the present day, and that is undoubtedly true; but, however technically perfect their collodion negatives with their false shadows of absolutely clear glass may have been, and probably were, the photographers of old were almost confined to printing in silver, and lacked such splendid processes of reproduction as present workers may revel in, first and foremost among which I place the platinotype.

Having said thus much to express my admiration for the process, I will give a few details as to the working of the paper, &c. Firstly, the paper *must* be kept perfectly dry before, during, and after printing. Secondly, the negatives should be, in my opinion, fairly dense, but soft, with details to suit the subject, and free from stain, especially yellow, to which colour the paper is but slightly sensitive, in consequence of which the development may be carried on by gaslight, and so simple and cleanly is the process that you may with the cold bath perform the necessary operations in your own dining-rooms (if you can get the requisite permission) without the slightest detriment to the furniture. Thirdly, in printing it is necessary to back the paper with a thin sheet of vulcanised India rubber and by all means varnish the negative. Print till a faint grey image appears as if imbedded in the lemon-coloured sheet with a thin veil or film over it—a softness characteristic of the process without hard or decided lines obtruding themselves. In working the process it is not necessary to tie yourself down by inexorable rules (except with regard to the exclusion of damp) but every worker with intelligence may vary the composition of the bath or the extent of the printing to obtain different effects of tone ranging from silver grey to exquisite black full of transparency. I would advise beginners to print till the shadows and half-tones are faintly discernible, and to have two developing baths, one much diluted and the other of normal strength. Draw the face of the print over the surface of your first very dilute bath, and if the effect desired is obtained plunge the print into the acid bath to prevent further action; but, if through insufficient printing or weakening of No. I the desired end is not obtained, then resort to the stronger bath and complete development on that.

J. V. Brewer.

ART IN PHOTOGRAPHY: AN INTERVIEW WITH MR. FREDERICK HOLLYER.

[*The Studio.*]

A commonplace-looking room on the ground floor of a commonplace house in a quiet Kensington square, the demure plainness of its furniture relieved only by the soft grey tones of the countless platinotype reproductions of the pictures of that apostle of romanticism, Mr. Burne-Jones, which lined the walls. This is where I found Mr. Frederick Hollyer, a sturdy, broad-shouldered, good-humoured, and good-looking man of middle age, who comes nearer to the definition of artist-photographer than any other man in England. To the art-loving public in general, and to the section of the American community which deserves that title in especial, Mr. Hollyer is chiefly known and appreciated as the translator into a more popular medium of the poetic fancies of Rossetti and Burne-Jones. To a smaller circle, however, that appreciation is widened into recognition of what may be called, without prejudice, his creative work, as distinct from his reproductive work with the camera. It seemed to me, therefore, eminently fitting that I should come to this modest oracle for a word on the vexed question of art and photography. As luck would have it, I had made my pilgrimage at an opportune moment, for, taking advantage of the leisure afforded him by a rare holiday, Mr. Hollyer had, the day before, acquitted himself of a piece of work

which I think represents the high-water mark of photographic portraiture. He had deliberately set himself a task, the technical and artistic difficulties of which would, to the ordinary man, have seemed insuperable. The result, in the shape of a platinum print from the untouched negative, was hanging in his studio to dry, and I was gratified with the first outsider's glance at it. It was simplicity itself; a charmingly pretty girl, dressed in a simple summer costume of pure white, standing at an open door, with her fingers resting on the handle as though she were on the point of going out into the little suburban garden, a glimpse of which was caught beyond. The upper part of the figure was seen against a background of absolute sunlight, and yet face, arms, white dress, hair, and dazzling sunlight were all given with a fidelity to values which would not have been unbecoming to a Whistler. In face of this result it seemed to me almost impertinent to ask Mr. Hollyer whether, in his opinion, there could be such a thing as "Art" in photography, for was there not lying before me, as I hesitatingly put my query, a clear answer in the affirmative? He met me, however, with no expression of lofty scorn, but with a somewhat quizzical smile, replied, "I really don't know; but, to tell the honest truth, I have got rather tired of the very words 'art and artistic,' and at times am inclined to say rude things about those who insist so strenuously that they are artists, with a big A, and seem to forget that they ought first and foremost to be photographers. The fact is that my association with the eminent artists whose works I have been permitted to render into black and white by means of my camera has rendered me exceedingly diffident in making any claims at all. I am content to do the very best work I can with love as well as care, and to let the rest shift for itself. If there be art in the result, I am quite sure that those who have a right to be dogmatic on such questions will find it out; if there be no art, I am sure it is my fault and not the fault of my medium. I think that the fact is that, as regards photography as well as other things, we are inclined nowadays to talk too much and do too little."

"Very truly and modestly put, Mr. Hollyer," said I, "but I am afraid you have something more than an inclination to evade the real point at issue."

"Well," was the reply, "to speak frankly, I am quite convinced that something, call it art or what you will, but something apart from mere mechanical and scientific excellence, not only can, but should, find its way into every print from every negative that leaves the photographer's studio. In landscape photography, for instance, that something may be of the nature of selection, and selection is, as I understand it, an important part of the equipment of every painter. Observation, too, I think, must be fostered by the photographer as carefully as by the figure-painter, for, if his work show not the presence of this quality in itself, it will be a mere piece of mechanism. I have some prints here from negatives taken by me many years ago to which I may, I hope, without egotism, refer as showing the importance of proper selection. This view of Waterloo Bridge, for instance, might have been taken from half a hundred other points of view, and yet from a topographical and mechanical standpoint have been as correct as I here show it. To make it pleasing to my own eye, however, I found there was only one spot from which I could properly view it. Having found this spot, I had again to patiently wait until the cloud and mist effects, with the London sun just peeping through the murky veil, were as I thought they should be. Not only this, but selection came into play to tell me when the black barge was in the right relative position to the rest of the picture, and when other boats and floating objects, which might have formed discordant notes, were well out of the way. The result, whether good or bad, is practically what I had intended it to be from the very first, and is no hap-hazard accident, but the expression of a deliberate intention, gained by careful selection on my part. At that point, of course, I stop, and the rest of the work is done for me by the camera, but I might almost as well declare that the etcher was a mere mechanical workman because the biting of his line is done by the acid and not by himself, as hold that because some portion, granted even that it be the major portion, of my work is done by an agent which I only imperfectly control, I cannot introduce into my work that personal note which I take it is but a synonym for the 'Art' of which you speak. Of course I am aware that at one moment, and that perhaps the supreme moment, the actual recording of the observed facts is taken out of the photographer's hands.

"This is the moment of exposure. Consider, on the other hand though, at how many other points the personal equation enters into our problem. First, there is the focussing (and though some writers on photography have disagreed with me here, I maintain that I am absolutely correct in saying so); then there is the development; thirdly, there is the manipulation of the print from the developed negative. Don't for one moment understand me to mean that that fatal crime of touching and retouching negative or print is or has been laid to my charge. On the contrary, no one can have a greater abhorrence of such acts than I. I consider it almost as criminal to form a picture by the superposition of one negative upon another. I am convinced that two photographers, equally skilled in the mere mechanical processes of their profession, can photograph the same object from the same point of view with the same camera, and under exactly similar conditions, and that the finished print of one man may be a mere soulless transcript of what lay in his field of view, while that of the other may be something to which, for want of a better word, I must apply the term 'artistic.' How much or how little of art may belong to photography is another question, and one which I must refrain from entering upon. When, not so very many years ago, photography came into being, the marvellous results which were produced by the very earliest photographers caused an exaggerated opinion to prevail as to its purely artistic future. When, later on, its well-defined limitations became apparent, there was the usual reaction in the other direction, and those who claimed that art might in any form enter into photographer's work were sneered at as presumptuous Philistines. Surely there is safety in the middle course. If you do not deny artistic faculty to the man who reproduces in black and white a picture by means of his patient 'rockings' and 'scrapings' of a copper plate, relying in a large measure upon reproductive processes which are entirely mechanical, why should you not, then, attribute some degree of artistic personality to him who reaches the same end partially by means of the camera? Compare the work of different men in my own branch, and tell me whether there is not the greatest difference in the result, as regards not only the technical excellence but the artistic value of the translation as well.

"Perhaps I have talked too much, for I hold, as I said when I began, that my mission is to do and not to talk. But I am as irritated, on the one hand, when I hear the flat-footed declaration that photography can never be more than a mere mechanical trade as I am restive on the other when I hear a photographer aver that, by combining a set of views taken at various times and hours of the day, he has effected what he fondly calls 'a picture,' as distinct from a 'mere photograph.' In other arts, and especially the subsidiary, it is their very limitations which the craftsmen turn with instinctive recognition to their own advantage. If this principle were only to be recognised and honestly lived up to by photographers in general, we should have results which would be better art, because they would be better photographs." HORACE TOWNSEND.

THE PHOTOGRAPHIC CONGRESS AUXILIARY OF THE WORLD'S COLUMBIAN EXPOSITION.

SEVERAL papers have been contributed to this Congress, which was held on August 1, under the presidency of Mr. James B. Bradwell, Chairman of the Committee. We print the following at present:—

WINTER PHOTOGRAPHY IN THE ALPS.

ALTHOUGH it is now twenty years or more since winter visitors first came to the Alps, few photographs have been preserved which render faithfully an Alpine valley in winter. The subjects ready to hand are varied and beautiful, yet somehow one seldom sees first-rate photographs of these high-lying districts under snow.

Those who have so kindly asked me to prepare this paper have greatly over-estimated my capacity for telling you some new thing. Still, bearing in mind the fact just referred to, it is evident that few persons have made a study of landscape photography at that season in the Alps, and thus, perhaps, the experience of one who has worked in that direction may be of some interest.

Those taking up this branch of their art are usually handicapped at the start by their belief in an article of faith—and of little else—laid down by the majority of English photographers, who declare that snow should never be photographed in a bright light. I dare say that in your sunnier climate, which must offer many more opportunities for experimenting in winter photography than does that of Great Britain, you have already discovered that brilliant sunshine is essential to the best results. But, in case any among you still hold to the unsound maxim, I would ask him to bear in mind exactly what snow is; that it is unform in colour, almost smooth of surface, and on dull days without distinct outline against a grey sky. It must, therefore, be built up, so to speak, and modelled into that miracle of fairy delicacy and lightness which, under favourable conditions, it may become. We can have it at its best by working with suitable light at suitable hours, and now and then calling to our aid one or two artificial but inoffensive contrivances. At midday in winter the light falls too directly on the subject; the lace-like tracery with its system of innumerable tiny snow crystals, obtains no relief against the white robe, standing hard and stiff around rock and *châlet*. But go early in the morning or late in the afternoon, and note the change. You will find in the long, soft shadows a thousand exquisite half-tones. See how the highest and nearer lights are broken, and broken again, by the thin veil of surface crystals, each with its perfect modelling, its tiny shade throwing up its star-like form. Look at the rounded billowy flow of the snow where, half in sunshine, half in shadow, it sweeps around and over the inequalities of the ground. If there has been a mist, however slight, during the night, a fretwork of hoar-frost will cover all, and will complete the materials for as fine a subject as you can wish for.

You may find it desirable to use, in addition, the artificial contrivance to which I referred, and by shovelling some of the snow, or trampling out a track, break up any portion of the picture where the uniformity is too great.

And now, having placed your subject under the most favourable conditions, what is the best way of photographing it? My own experience leads me to think that slow plates are far the best, so that when used with a small stop the exposure can be as prolonged as possible. I have always used Wratton & Wainwright's "ordinary" plates for this purpose, with one of Ross's portable symmetrical lenses, and with the smallest stop. I give under the conditions of light just described an exposure of two seconds. In developing, I am careful to work up the plate very slowly and to carry the development very far, and when I have finished I expect to find a range of density from excessive blackness to clear glass; but, though there must be no mistake about the quality of these two extremes, there must be very little of either. It is on the variety of the half-tones that the success of the picture depends, and it is for this reason that, in photographing snow, correctness of exposure is of such prior importance; and therefore a slow plate, allowing of more laxity in exposure than a rapid one, is far easier to work with. A plate under or over-exposed can never, however skilful the development, give a perfect result if the picture is of a snow-covered landscape, as the half-tones must suffer from the error. I have used the iron developer, eikonogen, and pyro, and ammonia, and, for snow, have obtained the best results with the latter. I may add that, when developing photographs of large moving figures, taken in winter in the Engadine, on our skating rink, I get the most successful pictures by allowing the plate to flash up at once under eikonogen, and continuing the development until the principal object is hardly visible when viewed by transmitted light. For studies of this kind I have had the best results with Lumière plates.

But I have digressed from my subject—because, probably, I had so very little to say. I have now all but done; but, before concluding, I should like to draw your attention to the fact that very beautiful effects can be obtained in Alpine photography by facing the camera to the sun, which, of course, should be just *out* of the plate. For most subjects (water and clouds excepted) such lighting is rarely suitable—at any rate, in so extreme a form; but with snow I have obtained most charming studies in this manner.

In response to so great a compliment as has been paid me in requesting me to write this paper, it would have been ungracious on my part to have refused; but I must ask you to forgive the very inadequate manner in which I have responded, for I know but little of the technical side of photography, and of the practical side am but self-taught, by my love of an art the beauty of which has always warmly attracted me.

ELIZABETH MAIN.

PRESENT AND FUTURE POSSIBILITIES OF PHOTOGRAPHY.

To render an account of the present state of photography presents no difficulties whatever, the facts to its credit being recorded everywhere, so that we need only draw from recent sources, the very ancient facts being, so to speak, contemporaneous, in order to trace a complete history of photography up to the present hour, passing in review all its methods, all its countless applications.

And, while we are desirous of justifying the very title of this paper, the circumstances allow to foot on the past, admitting it to be well known to all of us, in order to arrive at a conclusion as to future possibilities which we are able to foresee, combining the progress of photography itself with the science of to-day.

We are witnesses of a scientific progress so continuous and wonderful that it would be rash indeed, even if aided by the most exalted imagination, to indicate the more and more extraordinary facts reserved to us even by the nearest future. New discoveries in the domain of general science will, without fail, result in unexpected photographic inventions, or in applications of photography to uses of which at the present time not the slightest idea can be formed. This is why we cannot approach the difficult subject which has been referred to us without a strong sentiment of our complete inability; in other words, this is a new world, inaccessible, which we set out to explore; we would have to give proof of the fervour of our imagination, of a kind of foresight, more than of true science. We would be well inspired if we could embark on a journey to the beautiful land of dreams to talk with the fairest fairies, and would return to describe our visions and to explain the most fantastic and most wonderful facts, while now we are obliged to appeal to reason—to the reason of to-day—it may be well understood, for our reason changes its basis at every moment according to the conclusions it has to draw from evidences and facts which yesterday it denied and thought wholly impossible.

But enough of philosophical contemplations, to which, however, we were prompted by a prudence which every one will appreciate.

Being thus under the protection of the unforeseen, we may now venture suppositions as fantastic as possible, and become prophets without much merit of our own, since the past serves as guide in discovering future possibilities, which, hypothetical as they are, may be admissible, because it has been shown that we need not doubt anything in the course of scientific facts.

The past belongs nearly exclusively to monochromy, designating thus any method which, by the aid of light, produces an image with more than one colour, whatever colour this may be, and even images of more than one colour, obtained by the aid of monochromy, each having its own colour.

The progress in this line has been very remarkable, especially since the production of single images took the place of a multiplicity of copies.

First, the paper prints obtained by a chemical process from one and the same plate; then the commercial prints, obtained in a mechanical way with plates prepared with the aid of light, have made photography one of the most ingenious and faithful auxiliaries of the art of illustrating all kinds of publications; in one word, the automatical means of copying the most wonderful and most instructive objects which have ever been imagined. On the other hand, the considerable increase of sensitiveness of the products exposed in the camera to the action of light, together with the invention of the dry film and the consequent portability and easy management, have caused an immense expansion of this art, which now in every respect is in the reach of all.

Science has, not less than arts profited by the progress of photography, which made it an indispensable aid for its most delicate researches. To prove this we only need observe the excellent and unsurpassed services rendered by it to astronomy, to physics, to the study of the infinitely small, to the rapid and complete registration of all phenomena of light and motion, even of the wonderful rapidity of the minutest organisms. Indeed, it is at the same time an eye and a draughtsman. Like the eye, it is gifted with the highest rapidity of vision, so much so that it sees objects as if they were stationary though they are alive with miraculous swiftness. Ah, it even sees what is invisible to the human eye! The stars bear witness—which, though unknown till now, have been discovered by the photographic eye in the depths of space, inaccessible to our most powerful telescopes. The reproduction of ultra-violet rays bears witness—which, for our power of vision, belong to the invisible.

As a draughtsman it is unrivalled, for nothing equals the definition of the lines it traces, the accuracy of the endless details it reproduces, the truth of which is such that it has the force of the evidence of a witness. We may add that it is also an artist. Indeed, thanks to entirely successful researches, we are able to obtain impressions on the sensitive medium by the aid of light of all colours, in proportion to the degree of luminosity of the different colours. This progress was achieved but slowly, and, now that it has become an accomplished fact and practically within the reach of all, it gains ground slowly; but this can be only a question of time. Since we are able to sensitise our products so as to render them susceptible to impressions of all colours, giving them a perfect orthochromatism, it must also be possible to render them more sensitive to one colour than to another.

This possibility of selection must lead to the production of monochromes corresponding to every one of the principal colours, and consequently to the representation of the colour effect of an object or of nature, by superposition of the different monochromes, each having its own colour.

Therefore, photography, being the most skilful draughtsman and lithographer, and the most admirable engraver, is also a wonderful expert of colour. But it is even more than this, it is already the artist of entire pieces of art, producing by one single action the colours of objects, much as it impresses the sensitive monochromatic plate.

And, what a really wonderful idea, we begin to trace on the sensitive film the true image thrown into the camera, with its reality of detail and of colours. And this is our present position.

The development during more than fifty years has been nearly completed, because we have succeeded in passing through all possible phases of the art of designing and of its applications, attaining even to the art of painting. We say "attain," by which is not meant that we have advanced in the subject of colour photography to a point which we did not gain in monochromatic reproductions.

The most characteristic name which might be given to the present epoch is that of a new era. We are on the threshold of the art of polychromy. Indeed, in scientific applications, the first step counts most, as perhaps it does in every other field. We have only to direct our attention to what is going on in the electric world, and then to proceed by analogy. There we have arrived at a point at which even the most fertile imagination could not pass beyond the scientific wonders of the future, even if its flight would lead us into the most fantastic dreams. No doubt electricity, with its power, its invisibility, its enormous rapidity of propagation, will become an ally of photography to aid in the creation of unexpected wonders. Already they speak of plates exposed and developed by the aid of an electric current. Edison is at work to construct an instrument intermediate between the phonograph and his kinetograph, which will enable us simultaneously to see the motions of a person, to hear his voice, his words, put in immediate harmony with his gesture, his attitude, the play of his lips and eyes, &c.

This has not only been taken into consideration, but can be realised—probably it is realised—at this hour. But this is not all. By electricity similar effects may be and are (why not speak affirmatively, since such is our opinion?) transmitted over a distance.

Thus, using the electric telegraph at the same time as telephone and as kinetograph, we will be able to communicate the complete effect of form, motion, and sound to points far distant from the scene of action.

So far we have spoken of the form, which involves the idea of outline and detail of objects. Will a transmission of colours become possible? Will we be able to complete the characteristics of an object by communicating through the electric wire not only its outline, but also its colours?

Why should we not admit this possibility, extraordinary as it may seem? How to get there? This is the point which no one yet knows; but, considering the present state of our scientific resources, based on the divisibility of matter, it does not seem impossible that we may arrive at results of this kind.

Passing in review the history of development of electricity, are we not convinced that about fifty years ago no one would have believed a prophet of the future foretelling all the present wonders of the spark?

We do not burn the wizard any more, at least in civilised countries, but they are still treated as fools.

Well, we can no longer denounce folly in view of scientific predictions of the most revolutionary character. All we are allowed to say is this: "*Who can tell? This may be very well possible.*" Thus we do not risk to engage in a dispute which sooner or later will be decided against us by the facts.

Speaking of the progress of photography which may be realised, we think at once of a higher sensitiveness, which would allow of instantaneous impressions even with the feeble light of interiors. The sensitive product, or at least its vehicle, shall have the fineness of the collodion or albumen film. The apparatus, perfect as it is, still shows an incessant tendency to improvement.

From the standpoint of expanding the field of photography until it reaches every home, the ideal will always be an apparatus essentially portable, of small weight and volume, permitting us to photograph without being observed, and containing a number of plates or flexible films, sufficient for a large number of successive exposures.

The favourite of the future is evidently the flexible film or the very small plate, so that, after a sufficient perfection of the rolling apparatus, an endless ribbon may be advantageously substituted for a certain number of single plates.

The rolling device lends itself better to a rapid succession of new sensitive surfaces, but its operation must be made more reliable and easier. This evidently is a field for the future.

The future will find enough work in the development of photography, and persons who believe that very little is left to extend its field are badly mistaken.

Well, what is it? they ask. There is the question of colours, and, saving some perfection in details, that is all, isn't it?

First, in regard to colours, it is by no means a small step forward to bring this branch of reproduction to that degree of perfection which we have attained in monochromes. If such a great step *has* been taken, inducing us to believe in a possibility of reproducing colours, and proving that the means of direct reproduction of colours exist, it is not less true that all is done with a view of applying it to industrial uses, either to obtain simply and easily direct prototypes from nature, or to multiply polychromes with the aid of these prototypes. The very day this possibility is recognised and justified by facts, nobody will do anything but take polychromes.

But the perfect realisation of this hope will not come without extensive further researches. It will be necessary to conquer step by step, with the aid of successive progress, and no one is able to foresee how many years it will take us to arrive at the perfection of this process. Occupied with this most attractive study, we may ask, what other applications remain to solicit our earnest endeavours?

Is it not surprising that so little has been done until now toward employing photography in industrial decoration of ceramic and tissue? And, besides, we have everything necessary to pursue this line with success. To the future, therefore, is left an application as important as useful, and we hope that this work will be accomplished in an excellent manner.

How long before the constables, policemen, and detectives will be provided with detective cameras, permitting them to add to their words as witnesses the proof of the crime and of the identity of the criminals? Though we have now all that is necessary for this application of photography, so simple and useful, yet it remains still to be realised.

How long before we think of introducing into our schools and colleges the study of photography practical enough to enable each scholar of either sex to constantly use the pencil of photography, according to the lessons of the course pursued, for gathering all the souvenirs on their excursions and voyages?

If this could be done, the application of the photographic lens to certain functions would cease to present difficulties.

We have already sounded far, very far, into the depths of infinite celestial space by photographic investigations, but they are less applied to terrestrial or submarine uses. Geology would find it advantageous to verify the symptoms of life in the depth of the abyss, aided by a photographic apparatus, combined with a magnesium flashlight, which may be lighted at a distance by electricity. The same might be done below the surface of the water, in depths which no eye has yet beheld, and thus an investigation of submarine landscapes, so to speak, would prove to be of priceless value to science.

We have not yet encountered any impossibility, and the well-known facts suffice to give immediate results of the highest value.

How much remains to be done in regard to the methods and nature of registration? We cannot form an idea thereof. Why, for instance, is not the portrait obligatory on the passport? What better proof that this *is* Mr. X. who speaks to you than the presentation of his duly executed passport bearing his picture?

On the train, at the hotel, at the public places visited by travellers, at the windows of the telegraph and post-offices, and of the banks, &c., every one appearing should leave, without his knowledge, the proof of his presence, in the shape of an automatic, direct, and permanent reproduction. What an aid would this be for the researches of the department of police, for the proof of *alibis*, &c.

We would find no end, would we venture an excursion, be it ever so summary, into the realm of future application of photography. We would only have to turn to every art, to every science, and say that the drawing of the light is called upon to render them much more valuable services than they can be rendered by any other means.

Until now we are concerned with flat monochromes or polychromes, but it is possible that images in relief may have to rely on the aid of photography.

Already it is used in engraving, either in relief or in impression. We have made, by photographic process as well, mouldings in relief, still somewhat imperfect, yet it is certain that we will learn the act of producing better reliefs, and, on the other hand, that we will obtain true copies of round ornaments.

The various trials in this line, known as photo-sculpture, did not give very satisfactory results; yet we have results at least, and to the future belongs the task of more and more perfecting works of this kind. In short, the question is only how to transform the plane into a relief, and we shall certainly find a solution in a more practical way.

It remains to consider what influence the art of drawing and painting with light exerts on the arts proper.

It is evident that photography teaches to see nature better, to give a better account for the rules of perspective. Notwithstanding, there are always fantastics. They will have difficulty in freeing themselves of the true representation of their objects, as well in composition as in colour; yet, at the same time, they try to use originality and impress the stamp of their personality on their pictures; and, besides, even the colour shows a tendency to approach more and more to reality, if we behold true pictures, painted directly by the aid of photography. Perhaps they wish to turn away from truth prompted by a desire for contrast, and imagine to find colour effects absolutely anti-natural.

This applies to some of them, but the larger number, though led by confirmatory proof to represent truth, are tempted to observe an exactness of colours much as if this question was one of perspective.

Will the art gain thereby? It will in correctness, perhaps it will not in originality. For it is probable that every artist will always have many means of proving his worth by impressing on his canvas the stamp of his personality, which will distinguish it from all the rest. Notwithstanding photography, Roybet would not cease to be Roybet, and Bouguereau or Meissonnier would not be less than what they are.

All we can say is, that as perfect an art of copying as the art of photography must naturally exert a favourable influence on theory and practice of the beautiful arts.

We do not understand how it may be detrimental to ideal art, which at all times will be able to assert its rights. If photography compels it to become more accurate, where is the disadvantage? Is it for fear of invasion of a certain monotony due to this very excess of accuracy? It would be the same to say that we might ever become weary of the beautiful works of nature because they are always correct in outline and in effect of light and colours.

In our humble opinion, the ideal, the beautiful art, the art of creation will gain, not lose, thereby, because the artist, not embarrassed by difficulties of composition, will be more at liberty to dart forth into the realm of dreams and pure vision of his imagination. As basis, he will have the infallible guide of true effects rendered by the photographic printing, and nothing will prevent him from embellishing this reality with all the children of his brain.

As a result of the foregoing, we may predict the most brilliant future for the art of drawing, painting, and sculpture with the aid of light. It will ever be useful to all, and for every purpose. Nothing seems to exist capable of taking its place, and we cannot foresee how it might ever become hurtful to the beautiful arts, whose most powerful ally it is already at the present time. LÉON VIDAL.

THE DESIRABILITY OF AN INTERNATIONAL BUREAU: ESTABLISHED (1) TO RECORD; (2) TO EXCHANGE PHOTOGRAPHIC NEGATIVES AND PRINTS.

THE international photographic survey of the heavens has now been in progress for six years; some thousands of negatives of the stars have been obtained, and when this survey is completed the present face of the sky will be known with an accuracy which the astronomers of a pre-photographic age never dreamt of, and which will possibly enable the structure of the universe to be worked out, or, at all events, will afford a means of detecting the changes which we now know so frequently occur in the heavenly bodies.

But is not a photographic survey of the *face of the earth* at least as important as that of the celestial sphere?

Even such physical features as hills and coast lines change slowly but surely: the influence of man upon nature brings about far more rapid changes in the face of every country, while the successive generations of mankind pass away and leave but little more record of their physical peculiarities than the waves which beat in turn upon the seashore.

I have advocated a systematic photographic survey of the British Isles for many years, and the details of my scheme will be found especially in two papers:—

(*a*) "Notes upon a Proposed Photographic Survey of Warwickshire," read before the Birmingham Photographic Society in December, 1889. This was printed in the journals, and a thousand copies in pamphlet form were sent to all the photographic societies in the British Isles and in America.

(*b*) "Proposal for a National Photographic Record and Survey," read before the Photographic Society of Great Britain in May, 1892, and also printed as above.

In these papers the idea advanced was that in the British Isles the photographic societies of each *county* should band themselves together to secure, by the aid of photography, a more or less complete record of the physical features of each county, its fauna and its flora, of its architecture and archæology, and its ethnology, &c. The aid of the leading men in science, literature, and art in each county was to be invited, who should be requested to furnish lists of places, persons, and things worthy of being grouped together to form this "True Pictorial History of the Present Day." As a unit of work the sheets of the excellent ordinance survey map were taken. These sheets are on the scale of six inches to a mile; each sheet or map includes six square miles; upon them is marked every house, field, and tree.

One or more sheets of this map may be allotted annually to each photographer who expresses his willingness to take part in the task.

This photographic survey work is now being actively prosecuted in about eight English counties. In most cases the local free libraries and museums have been selected as the best places in which to deposit complete sets of prints. In the case of each of the two counties (Warwickshire and Glamorganshire) the number of mounted prints of local places, &c., handed over to municipal authorities during last year (1892), exceeded one thousand in number.

It is greatly to be desired that this systematic survey work should be extended largely, both in England and America.

It supplies a definite and useful object both to each photographic society and to each and every member of such societies. In the British Isles we have now nearly three hundred photographic societies, and in the United States about two hundred.

There is no reason, however, why the "unattached" workers—men who belong to no society—should not also lend active aid in the work.

That such survey work will be continued and will prosper is obvious; but it seems a great pity that the results secured should be confined to the locality in which they are produced. And the main object of this paper is to point out how the usefulness of the scheme might be largely extended.

In each country there should be some central place—the British Museum, for example, for the British Isles, and the Smithsonian Institution for the United States—where a *record* of all the negatives should be kept. This record should be limited to negatives (*a*) of good technical quality; (*b*) of local interest. A complete set of the prints from these negatives would also be stored at each of these centres. Such prints might either be furnished as gifts by the producers of the negatives or they might be printed by the special staff of the central institution. They should be in either carbon or platinum.

As the workers in the majority of cases would be amateurs, it is probable that they would not object to handing over the negatives themselves to such central institutions; the negatives could then be stored in fire-proof and damp-proof rooms, and could be printed from by a special staff as desired.

Printed lists of negatives added annually should be published, and should be widely circulated among free libraries, museums, &c. A complete set of the prints should also be exchanged annually between the two great centres one on each side of the Atlantic. It is certainly lamentable to consider how many thousands of valuable negatives are wasted annually for want of any method for their preservation and publication. Moreover, the establishment of some such scheme as is here advocated would lend an incentive to steady work by supplying an object, and this is just what nine out of ten of the great and growing army of amateur photographers stand in need of.

And, as each earnest worker "joins the majority," it would certainly be satisfactory to think that his store of fine negatives—accumulated at so much expense and with such pains—would be preserved and used, instead of being wasted and lost, as is at present almost invariably the case.

EXCHANGE OF PRINTS.

Every donor of negatives or of prints might be credited with a certain sum (according to the number and size of his contributions), and he should be allowed to select prints to this value from the published lists.

The working expenses of the scheme may be derived from such sources as (*a*) grant from government; (*b*) subscriptions, the subscribers being allowed to select a certain number of prints in return; (*c*) sale of prints to the general public.

How many thousands there must be in the United States who would welcome the opportunity of examining the lists of British photographs which would be furnished to their local institution (library, or museum, or municipal offices), and of selecting therefrom pictures of the village, town, or county from which they or their forefathers came; or of the places of which they read in history or in their daily paper. And we in England would many of us gladly hail similar opportunities of obtaining pictures of that wide land where our relations dwell, and of its wonderful physical phenomena.

Although such a scheme ought ultimately to be conducted at the national expense and by national institutions, yet it would probably be necessary to inaugurate the work on a smaller scale so as to show its desirability and its possibilities. In England the Photographic Society of Great Britain is now endeavouring to affiliate to itself all the local societies; and, if there is (or could be established) a similar union of societies on the American side, the matter could be negotiated between these two central institutions. Or direct relations might be opened up between societies of equal numbers (of members) and importance on either side of the Atlantic.

In conclusion, the points to which I wish to draw attention are :—

1. In every county it is desirable that a photographic survey should be initiated. By the term "survey" I here mean a pictorial record of the state of things, physical and general, as now existing.

2. In each country there should be (*a*) local dépôts containing complete sets of permanent photographic prints of the district; and (*b*) a central bureau containing negatives and prints.

3. Facilities for the exchange (or purchase) of prints, &c., should be provided.

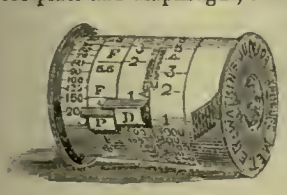
It has been well said that "all photographers are brothers," for it is certain that the study of this light science, though black art, tends to bring its fellow-workers together in no ordinary degree. Moreover, photography is more and more employed every day as a means of record in every branch of science and of art. It is of the utmost importance then, that the students of this subject, both in England and in the United States, should become acquainted with each other's work, and should be able to avail themselves of it. If this principle be once recognised and approved of, then the details by which it can best be carried out might safely be left to a committee appointed by the conference, should they see fit to do so.

W. Jerome Harrison, F.G.S.

Our Editorial Table.

The Watkins' "Junior" Exposure Meter.

A new and simple form of the Watkins' Exposure Meter has been issued under the above name by Messrs. R. Field & Co., 142, Suffolk-street, Birmingham. In this, when the adjustments are once made for plate and diaphragm, the different exposures due to variations of light during the day can be read off without further adjustment of the instrument. By comparing the cut with that which has previously appeared in connexion with descriptions of the Watkins' Meter, it will be seen how much it has been simplified. This will conduce to further popularising an instrument which is one of great reliability. An improvement in the "Junior" consists in transmitting the light to the sensitive paper through an end piece of blue glass. The price of the "Junior" is *7s. 6d.*



News and Notes.

Northern Photographic and Scientific Association.—August 26, Hatfield.

Hackney Photographic Society.—August 26, Excursion to St. Margaret's. Take excursion ticket for Rye House. Leave Liverpool-street by quarter past two train. Tea at Pied Bull, Stanstead. 29, *Daylight Enlarging.*

Leytonstone Camera Club.—August 26, Buckhurst Hill. Leader, Mr. A. Frost. The Club will proceed by the train leaving Liverpool-street, Great Eastern Railway, at thirty-five minutes past two p.m., calling at Leytonstone at eight minutes to three, arriving at Buckhurst Hill at seven minutes past three. Open Social Evening at Headquarters, eight o'clock.

Midland Camera Club.—The First Annual Exhibition of the Club will be held at the Botanical Gardens and College Grounds, Moseley, Birmingham, to open on Monday, October 2, and close on Saturday, October 14, 1893. Particulars and forms may be obtained on application to the Secretary, Mr. C. Jevons Fowler, 4, Woodstock-road, Mosely, Birmingham.

Accident to Mr. Birt Acres.—We are sorry to learn that an accident of a serious nature has happened to Mr. Birt Acres. He was experimenting with sodium for the production of hydrogen for a particular purpose, and was making use of about sixty grains of it wrapped in fine gauze to prevent the gas from becoming ignited. But as soon as the sodium touched the water a terrific explosion ensued which tore a large hole in a thin sheet iron drum he had in his hands; he was also holding the sodium with a pair of ordinary pliers. How he escaped without still more serious injury than he has sustained is a mystery, but it is probable that the water having been dashed in his face by the force of the explosion saved him. From Tuesday (last week) until Saturday he was totally blind, but on the latter day he recovered the use of one eye, and the doctor holds out the hope of a similar recovery of that of the other one shortly. We know that sodium ignites when it is brought into contact with water, but were not aware that such ignition was accompanied by an explosion, and we shall await with much interest such details as, on his recovery, Mr. Acres may be enabled to give us. Meantime we accord him our sympathy, and rejoice that the consequences, serious though they be, are not still worse.

Improvements in Photographic Apparatus on the Pinhole Air Lens Principle.

No. 13,632. Archibald Campbell Ponton, Viewfield, Parkstone, Dorsetshire.—*July* 26, 1893.

The invention relates mainly to the construction of cameras for taking pictures rapidly through very small pinhole lenses, the focal lengths of the air lens or, what is the same, the depth of the camera being apportioned to the rapidity of exposure. I find that I may use pinholes as small even as $\frac{1}{250}$ of an inch in diameter. These may be formed in metal foil, such, for instance, as of platinum or brass, and are inserted in the lid of a box-shaped camera. The latter may be made of cardboard or sheet metal, and may be pressed up. The interior size of the camera should be that of sensitised plate to be used, and of the depth of the focus of the air lens. I prefer to make the camera in two parts, one fitting into the other like the ordinary cardboard box in which sensitised plates are sold. The box lid may, by partition or partitions, be divided into two or four compartments for the production of several photographs on one sensitised plate, thus, for instance, adapting it for stereoscopic pictures. On the outside or inside of the lid I provide a movable lever-shaped or other shutter, which, for two pinholes for stereos may be T shaped and working on a pivot.

This apparatus may be made so light as to only slightly exceed the weight of the plates themselves, at the same time it can also be made at a very low price indeed, so as to bring it within the reach of the million.

From the small negatives produced by this apparatus the positives can be printed in an enlarging camera of the size most suited for trade purposes. Negatives taken with an air lens of $\frac{1}{100}$ of an inch in diameter for stereoscopic pictures are found to give a sufficient field to be printed from direct by contact.

Improvements in and relating to Photographic Cameras.

No. 14,753. Walter Griffiths, Highgate-square, Birmingham, Warwickshire.—*July* 29, 1893.

My invention has for its object improvements in and relating to photographic cameras, by which I obtain a much more durable article, which is particularly suitable for export by reason of its freedom from liability to be affected by the intense heat or cold of other climates, while it is much stronger in construction, without losing the delicacy of movement and adjustment of the various parts, which is so essential to a first-class camera. At the same time it is simple in construction, and my improvements are embodied without in any way increasing the cost of the camera. By my improvements in relation to the dark slides for use in cameras, I also obtain a much more durable article, which, at the same time, is more compact, and also does not increase the cost of manufacture, such dark slides being cheaper than the ordinary ones of equal quality.

In carrying my invention into effect, I form the bottom, or under frame, of my camera of metal tubes, with, say, two longitudinal tubes, and two cross tubes attached, as to form a square base, and with the longitudinal tubes mounted upon the cross tubes within each longitudinal tube, a second tube is telescoped, and upon the front ends of these two inner tubes another cross tube is mounted, to the centre of which one end of another longitudinal tube is attached; this latter longitudinal tube passes through a socket formed upon the front lower cross tube, and is tapped at the back end to receive a screw, which has its shoulder socketed upon the rear lower cross tube, being provided with a thumb-screw end, which enables the screw to be turned, and thus adjust the distance between the lens and the back frame.

The front for receiving the lens is mounted upon the front upper cross tube, and thus travels with it, while the back frame is mounted at its bottom to two outside longitudinal tubes by means of two metal sockets, which slide on the

said tubes. The ends of the metal of these two sockets may be bent up to form a flange, and to these flanges the back frame is pivoted so as to be pitched to an angle or shut down on to the bottom, and it is secured in the required position by a metal strut, having a slot working on a thumb-screw on the back in the usual way. The front frame for lens may be kept up in a vertical position by a snug formed upon its bottom side, having a screw which engages with the boss, which forms a finish to the end of the central longitudinal tube. The back and front frame are cased on their outer edge with thin metal, having an inner lining of wood, upon which the grooves for receiving the dark slides are fixed. The bosses forming the connexion between the longitudinal and cross tubes at the two front corners and the centre boss on the back cross tube have their under sides shaped, or are provided with studs to receive the top of the tripod, which is fixed in the usual way.

The ends of the bellows are clamped between the metal casing and wood lining of the back and front frame, which thus forms a very strong connexion, and throughout there are no joints dependent upon wood.

In place of forming the bottom of tubes, I may form them of metal rods of other section, such as hollow V-shape or any equivalent of the tubes.

In the case of the dark slide, I form the centre partition of two thin sheets of metal, which are bent over at the sides to form grooves to receive the plates, and these two sheets are bound together at the top by velvet, which is padded out to the thickness of the grooves. A square metal frame of channel section on two sides and the bottom is provided to receive this partition containing the plates, and the top ends of the two sides of the frame are connected together by a sheet-metal band, which is turned out to form a flange at the top, thus strengthening the band, and preventing it from being sprung open. The insides of these bands are lined with velvet, the top edge of which is secured by the flange being turned back with the edge of the velvet between. The shutters are of sheet metal, and slide in between the velvet on the inside of the frame and the velvet on the outside of the partition, and, as there is a spring within between the two sheets of the partition to expand them at the top, all possibility of any light entering is thus prevented. By these means an exceedingly simple, substantial, and portable camera is obtained, in which all the latest requirements are embodied, and which will stand the varying climates of other countries, while it is not liable to be destroyed by those insects or worms which, in the case of wood, are so destructive in warmer climes, and the dark slide, while being much more substantial, is much more portable and compact, without any increase in the cost of production.

Improvements in Racks used for Soaking or Drying Photographic Plates.

No. 16,074. Josiah Pumphrey, 160, Angelina-street, Birmingham. *July* 29, 1893.

I construct a frame and hinge on it, in a suitable position, two corrugated plates, furnished with feet, each having a fence on one side. Handles are attached to the upper edges of the corrugated plates. The measurements are so calculated that in one position the corrugated plates are at such a distance as to take plates of a required size between them, and, by reversing the apparatus, the same number of a dissimilar size are equally well accommodated without any readjustment of loose or fixed parts.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

At a meeting held on Tuesday last, the 22nd inst., Mr. G. Scamell occupied the chair.

Mr. T. Bolas, in giving a demonstration of *Flashlight with the metal Aluminium as a Combustible*, mentioned that an assertion had been made that aluminium could not be usefully burned in such a flash lamp as is used for magnesium, but this statement had arisen out of the somewhat dangerous practice of positively asserting a negative proposition, merely because the speaker had not seen the positive side demonstrated. It was then pointed out that a very fine state of division is essential in the case of a flashlight with aluminium powder, as otherwise the metal passes through the flame without being heated to the somewhat high ignition point of the metal. When the aluminium does burn, it produces a more intensely actinic light than magnesium, as the temperature of combustion is higher.

The commercial aluminium bronze powder, as manufactured at Fürth and Nürnberg, but sold in London by Mr. W. C. Horne, of White Horse-alley, Cowcross-street, was then shown in three degrees of fineness, costing about seventeen shillings per pound, and was recommended, the minute scales composing this being about one-five-thousandth of an inch thick. This powder, as sold, is covered with a very minute trace of the oily matter used in its manufacture and this causes it to hold together in clots when blown through a flame, and so, as was demonstrated, if used just as sold the greater part escapes ignition.

In order to fit it for use in such an ordinary flash lamp as that of Mr. England, this oily matter must be removed, and Mr. Bolas showed how this may be done. The powder was merely heated to about the temperature of melting zinc, in a test tube, and after this treatment it had no tendency to clot, and it is blown about, with each grain separate, by the slightest breath.

About a grain and a half of the powder was now burned in an England's flash lamp, and by the light Mr. W. E. Debenham took a fully exposed portrait of the Chairman.

Other ways of using aluminium (leaf in oxygen, and the powder mixed with potassium chlorate) were now shown, but Mr. Bolas said the object of his demonstration was principally to show that aluminium can be used in the flash lamp, and that it can be much more completely burned than is usually the case with magnesium powder. If magnesium is so finely powdered as to burn completely, it oxidises or rusts very quickly, and so becomes useless. The aluminium dust may be kept without fear of deterioration by slow oxidation or rusting.

Mr. Andrew Pringle and Mr. Clifton both spoke of the inconvenience of the magnesia smoke, which is peculiarly irritating to their lungs, and they remarked that the alumina smoke did not appear to have irritating qualities to the same extent.

Mr. Bolas said this was easy to understand, as magnesia is a caustic earth almost as irritating as lime, while alumina is bland or neutral.

Mr. Pringle now made a communication on photo-micrography with lenses not specially corrected for photographic work, and his results fully confirmed Dr. Piffard's observations that such lenses will work to focus if a yellow screen and orthochromatic plate is used. Such microscopic lenses as those of Powell, a Lealand, or a Ross will give excellent and sharp results if the screen and the orthochromatic plate are used.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

The usual weekly meeting was held on August 17, Mr. R. Beckett in the chair.

Notice of a special general meeting was read, the object of which was to discuss a recent alteration of rule 7, respecting the election of members. August 31, was fixed as a suitable evening for the purpose.

Mr. P. Everitt showed a lens mount made by Mr. Haddon, and remarked upon its being a good piece of amateur workmanship.

The Chairman passed round a negative having markings upon it. A general opinion was formed that they had been caused by mechanical abrasion whilst moist.

Mr. Fry had had similar experiences during hot weather, the defects appearing after development, and during the period of drying; he considered them as being caused by decomposition of the gelatine in the presence of heat and moisture.

Some results of the recent meeting at the "Zoo" were shown by Messrs. Boyston and Steinmetz. It was suggested that the members who were present on that occasion should show their pictures at the meeting on August 31.

Mr. Welford read his report upon the Convention meeting as a delegate of the Association [see page 543].

After reading the report, he handed round the small album which contained it, as well as prints from negatives taken on the occasion.

After a few remarks from Mr. Fry, the other delegate,

Mr. Haddon proposed a vote of thanks to the delegates, agreeing that the excursions were too numerous, and saying how much non-members of the Convention lost by holding aloof.

Mr. Everitt supported the vote of thanks, and moved the adoption of the report.

The Chairman and Mr. Debenham agreed that great benefit was derived from these meetings.

The Hon. Secretary seconded the adoption of the report, which was then carried.

Mr. Welford acknowledged the thanks.

Mr. Debenham quoted a letter which appeared in the current number of a photographic paper, stating that some lenses would not work to focus with a yellow screen. He pointed out that this occurred through the operator focussing before introducing the screen, instead of with the screen in position, inasmuch as the screen has the effect of lengthening the focus about a third of its own thickness.

After a discussion involving a slight modification of the delegates' report, the meeting closed.

Hackney Photographic Society.—August 15, Mr. T. H. Smith in the chair.—Work of the members was shown. Mr. Vining asked what was the particular advantage with tabloids? The Hon. Secretary said they saved measuring, and were convenient when away from home, but care must be used that they are thoroughly dissolved before use. Mr. Wire asked what caused yellow spots on amidol-developed bromide paper? Mr. Welford thought

amidol itself was not the cause. From the question-box: "Which is the best illuminant for printing in clouds on lantern slides?" Mr. BECKETT said gas was more regular. The HON. SECRETARY agreed, and said gas was more under control, and printing-in also. Mr. PARRY said he had been troubled with yellow P.O.P. prints. Mr. BECKETT said perhaps the first washing water did not carry off the silver, and doubtless the sulphocyanide was impure. Mr. W. L. Barker had recently tested the heat of water. In cistern exposed to sun it was 78°, and from main 63°. Mr. Welford then demonstrated his toning bath. He claimed finality of tone and rapidity, and quite substantiated both of these. In the former it was demonstrated by toning half a print, then immersing the whole; no difference was apparent. The favourite bath was bicarbonate of soda, one and a half drachms; chloride of gold, four grains; water, six ounces. New paper has a great deal to do with rapidity. The HON. SECRETARY asked for approximate keeping time of bath, and was informed not more than two hours. A diluted bath is slower, but gives warmer tones; but finality is lost.

Brixton and Clapham Camera Club.—August 15, Mr. F. F. Buckle in the chair.—Mr. Belton, representing the Paget Plate Company, gave a demonstration on the printing-out plates and opals of the Company. The special methods of printing, both by means of special and ordinary frames, were explained. As regards the printing, Mr. Belton said it was a daylight process, as the plates were very slow. The opals are of two qualities—matt and glazed. The process is precisely the same as for gelatino-chloride paper, but, owing to subsequent reduction in the fixing bath, printing should be deep, the rule being, the colder the tones desired the deeper the printing. Density and colour must be judged by reflected light. When finished, Mr. Belton recommended mounting the prints under glass, as they are then less liable to damage from dirt. They may, however, be mounted and used as transparencies. Printing of lantern slides may be performed in an ordinary frame, and the judging of density will not necessitate the removal of the plate owing to the thinness of the film. At the conclusion of the practical demonstration, several plates and opals having been toned and fixed in combined and separate baths, Mr. Belton passed the slides through the lantern, and the tones were very satisfactory. Next meeting, September 5, Mr. W. H. Harrison, *Some Useful Photographic Standards.*

PHOTO-MICROGRAPHY.

To the EDITOR.

SIR,—Mr. Smith calmly assumes that "cheap French triplets" cannot produce fairly good negatives of microscopic objects, his experience being that "it is impossible they can give a sharp picture of anything."

As a simple test I have hunted up and have forwarded to you an old album containing upwards of two hundred prints, and would be obliged by your looking over it and giving your opinion as to whether I am or am not correct in stating that "I got fairly sharp definition up to, say, 400 diameters."—I am, yours, &c. JOSEPH H. WOODWORTH.

Booterstown, Dublin.

P.S.—As I am not an "expert" in optics, I would be glad of an explanation of how an isochromatic plate can correct a difference between the actinic and visual foci.

[The photographs in the album are certainly very excellent considering the class of object-glass by which they were produced. Our experience goes to show that, while cheap French object-glasses will often show fairly well such low-power objects as the itch insect, bed bugs, fleas, the proboscis of the blow fly, sections of wood, crystallisations, wings of flies, and suchlike objects as those so neatly and systematically displayed in the album, yet is their angular aperture too small for higher-class objects such as those sent us by Mr. Smith, and which include the *podura* scale, *pleurosigma angulatum*, and others of like difficulty of brilliant resolution. We have a foreign triplet by a good maker (Oberhauser), and, although it is one of the best of the kind we have seen, it quite breaks down on objects of the class last named when compared with a good English objective of the same power.—ED.]

TELE-PHOTOGRAPHIC SYSTEMS FOR MODERATE AMPLIFICATIONS.

To the EDITOR.

SIR,—There is little to be said in reply to Mr. Hancock's letter in your last issue, except to thank him for his clear expression of the advantages of the above systems, and his intelligent criticism of the possibilities of errors arising from too high an enlargement.

If the original positive element is corrected with great care, I have abundant proof, and have publicly shown it, that, however great the enlargement may be, the direct method is always greatly superior to secondary enlargement, as from a negative taken by the positive lens alone, to the same dimensions. Further, a ratio of two to one, as between the foci of positive and negative, I have found to give sufficient "sparkle," consistent with a useful and striking amount of magnification, but there is no reason at all that a more even ratio of the foci of the positive and negative lenses should not exist with less magnification.—I am, yours, &c., THOMAS R. DALLMEYER.

THE WORLD'S CONGRESS OF PHOTOGRAPHERS.

To the EDITOR.

SIR,—the following report of the first business at the Thursday session of the World's Congress has not been reported in the general press, but I think it might be of interest to your readers.—I am, yours, &c.,
H. SNOWDEN WARD.

On Thursday, August 3, before the programme was commenced, Mr. H. Snowden Ward pointed out that a suggestion contained in Judge Bradwell's opening address had been overlooked by the Congress, and proposed that it should be acted upon. The suggestion was that Mr. W. Jerome Harrison's paper on *The Desirability of an International Bureau, established* (1) *to Record;* (2) *to Exchange Photographic Negatives and Prints*, should be read in advance of its proposed order, and that a Committee should be appointed to carry out its suggestions. Mr. W. A. Cooper seconded the proposition, which was carried. Mr. Harrison's paper recommended an international bureau connected with national bureaus for the collection, preservation, and exchange of photographs of historical, scientific, or literary interest. The meeting voted that the President should nominate a Committee to undertake what might be possible in furtherance of the scheme, and Judge Bradwell therefore nominated.

H. Snowden Ward (*chairman*), London.
Gayton A. Douglass (*vice-chairman*), Chicago.
W. Jerome Harrison, Birmingham.
John Carbutt, Philadelphia,
Shapoor N. Bhedwar, Bombay.
Léon Vidal, Paris.
W. K. Burton, Tokio.
Mrs. Elizabeth Flint Wade, Buffalo.
Dr. John Nicol, Tioga Centre.

CELLULOID FILMS.

To the EDITOR

SIR,—In reply to Mr. W. J. Stillman's letter in your last number, wishing to know the experience of amateurs as to the deteriorating influence of celluloid on the emulsion, I do not think that the celluloid has any deteriorating influence whatever on the emulsion, although *great* pressure might perhaps tend to cause some fog, but could easily be prevented by packing the films in a flat box. It has also been said that the image on films deteriorates after exposure if kept for some time. To test this, when in the Riviera last winter, I exposed two 10×8 films from the stone pier at Mentone for exactly the same time, no clouds, strong sun, 16-in. lens, *f*-16, and Stanley's Shutter, one-tenth of second. One I developed a day or two after, the other was kept nearly two months. If any difference, there was a little more detail in the shadows of the latter, the same developer used for both, viz., pyro and ammonia.

I exposed in the Memorial Church at Cannes a 10×8 instantaneous plate, and a 10×8 isochromatic medium film, both from the same maker, the rapidity of each supposed to be the same—the plate I developed with the hydroquinone developer, now so much used in France, and the film with pyro and ammonia. The plate was much underexposed, the window being very much blurred; the film was a good negative, with scarcely a trace of blurring. Both were exposed twenty-three minutes.

Films doubtless require more careful treatment than plates, but I think they will soon replace glass to a very great extent.—I am, yours, &c., F. BRASLEY.

INVERSION OF THE RETINAL IMAGE.

To the EDITOR.

SIR,—Many of your readers would, no doubt, be interested in Mr. W. I. Chadwick's paper on stereoscopy. As one who has taken an interest in the curious fact of an inverted image, a fact which most people are quite unconscious and ignorant of, I must say that I cannot consider Professor Fick's theory, as stated by Mr. Chadwick, to be the "most reasonable." To my mind, the difficulty is better explained by the "law of visible direction."

We are all aware that we may roll about our eyes as we choose, and yet all the objects around us remain in the same directions, as they always appeared to us to be in. Now, no camera on earth would stand the same test, for, move about the lens, and a corresponding movement will take place on the ground glass; in fact, the directions of all objects will apparently be changed.

From this it may be argued that there must be in the eye somewhere a *fixed point*, and that through this point the rays of light forming the picture pass to the brain. As I said before, this seems to me a more reasonable theory than that which holds that the nerves of sight and feeling are co-operative.

The amateur and professional photographer, no doubt, does become accustomed to the up-side-down image on the ground glass, but he never sees that inverted image erect, nor will his knowledge of its true position help him in the slightest degree.—I am, yours, &c., DAVID R. ROSE.

Dalhousie-terrace, Edinburgh, August 19, 1893.

Exchange Column.

*** *No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance. The full name of the advertiser must in all cases be given for publication, otherwise the Exchanges will not be inserted.*

Will exchange a 5×4 hand, or stand, camera complete for a light half-plate camera or lantern.—Address, H. COUCH, 11, Waterloo-crescent, Dover.

Will exchange a Derogy's seven-inch focus cabinet portrait lens for a good cabinet rolling press.—Address, J. HOBTON, Central Photographic Studio, Caroline-street, Cardiff.

Retouching desk for half-plates and under with mirror, &c., never been used, cost 10s. Will exchange for half and quarter-plate printing frames in good condition of same value.—Address, W. H. BROWNE DRAKE, 4, Charles-street, Cambridge.

Wanted, modern half-plate camera, with three double backs, in exchange for 7×5 rapid rectilinear lens and quadrant camera carrier to fit on tricycle, made specially to avoid vibration.—H. MANISTRE, photographer, St. Mary-street, Chippenham, Wilts.

Answers to Correspondents.

*** *All matters intended for the text portion of this* JOURNAL, *including queries and Exchanges, must be addressed to* "THE EDITOR, THE BRITISH JOURNAL OF PHOTOGRAPHY," 2, *York-street, Covent Garden, London. Inattention to this ensures delay.*

*** *Correspondents are informed that we cannot undertake to answer communications through the post.*

*** *Communications relating to Advertisements and general business affairs should be addressed to Messrs.* HENRY GREENWOOD & CO., 2 *York-street, Covent Garden, London.*

*** *It would be convenient if friends desiring advice respecting apparatus, failures in practice, or other information, would call at the Editorial Office either on Wednesdays from* 4 *to* 6, *or Thursdays from* 9 *to* 12 *noon, when some one of the Editorial staff will be present.*

PHOTOGRAPHS REGISTERED:—

Alexander Campbell Hutchison, North Berwick.—*View of Bass Rock.*

Thomas Bramwell, Alston.—*Two photographs of the 66th Field Battery.*

Sydney Victor White, Reading.—*View of the foundation of a Christian Church discovered at Silchester.*

COLLODION.—We are in hopes of having a special article on the subject soon.

COUCH.—The Convention group given in the JOURNAL was not an enlargement.

C. A. M. W.—Under the circumstances, we would certainly tilt the camera and use the swing back.

LENS.—If you send the lens, we will tell you what we think of it. The other may or may not be good. Try it before you make the purchase.

B. C.—The idea is not patentable. George Mason & Co., of Glasgow, manufacture a similar adaptation to the camera stand to keep the legs rigid.

F. E. G.—It is probable that the transparent spots in the negative arise from tiny bubbles in the emulsion, and are not due to faulty manipulation on your part.

B. T. (Yarmouth).—As the spots, identical in their character, occur on different brands of plates, it is clear that they must be due to something in the development.

BUBBLES.—See "American Notes" in present number. Such pictures are not done by double printing. Let the child practice blowing bubbles for a little time previous to being taken.

D. H. W.—There is no *false* perspective in the picture; it is violent, owing to its being taken with an extremely wide-angle lens; but, if it be viewed from a distance equal to the focal length of the lens, even that will disappear.

ZENO.—Without saying positively that the spots on the prints are caused by particles of bronze powder, we strongly suspect, from their appearance, they are. The name, &c., are printed in bronze, not gold, and particles of bronze powder are plainly to be seen on the uncovered portions of the mount.

T. NICHOLS writes: "Would some kind readers give me a formula for and directions for preparing a printing-out gelatine paper that will yield better colours than those now supplied, and which can be blotted off or mounted wet, like albumen paper?"—Perhaps some "kind reader" will oblige our correspondent.

R. H. THOMAS.—We can say nothing as to why the plates will not work in your hands, unless it may be want of experience. The peripatetic workers in the streets of London and its suburbs appear to get tolerably good results upon them. If the house named cannot supply the Phœnix plates, apply to Mr. J. J. Atkinson, Liverpool.

T. NORRIS.—The titles of subjects can be conveniently put upon the negatives with the simple appliances advertised in our columns as the "Nameit." The titles on the subjects issued by the firm mentioned are written upon the negative with a sable brush and a black varnish. Of course, the latter system requires some skill to do it neatly.

COUNTRY TOWN.—Your case is precisely similar to many others. The "big illustrated," as you term it, has pirated your views of the neighbourhood without let or licence; but, as you failed to make them copyright, you have no remedy. Common courtesy ought to have secured an acknowledgment of the source from which the pictures were obtained. But that is not possessed by some of the illustrated periodicals.

G. SIMMONDS.—As the condenser you require is only eight and a half inches in diameter, you will find it more economical to purchase it complete, or to get a pair of plano-convex lenses and mount them yourself, than to attempt to build them up out of clock glasses—that is, if time is of any value. Although condensers that will answer well may be formed with suitably curved clock glasses, plate glass, and water, it requires some degree of skill to make them so that they will not leak after a short time. For so small a size as this, we should say it would be cheaper to buy lenses and avoid future trouble.

INVENTOR.—If, while you were an ordinary weekly servant, you invented a great and valuable process, which is now being worked as a secret one, and for which you received no remuneration, but, instead, were shortly afterwards discharged, we see no reason why you should not work it on your own account, or in connexion with any one else you may be associated with. We presume that there is no agreement that your invention is the property of your late employer.

H. M. asks: "1. Could you inform me if there is a protection granted prior to taking out a patent for an invention? 2. If so, what would be the cost, and where to apply for the same? 4. Would the specification be sufficient to send?"—In reply: 1. A provisional protection can be obtained for nine months for a Government fee of 1*l*. 2. Make application, on the proper form, to the Comptroller of the Patent Office. The Office supplies the forms. Or the application can be made through a patent agent. 4. Yes; the complete specification can be lodged and a patent secured for four years, the Government fee in this case is 4*l*. The third query has been omitted.

JOURNAL OF PHOTOGRAPHY.

No. 1739. Vol. XL.—SEPTEMBER 1, 1893.

IMPROVEMENTS IN TELE-PHOTO LENSES.

A communication on the tele-photo lens, by Mr. T. R. Dallmeyer, which appeared in our issue of July 28, has now been sufficiently long before our readers to enable them to note his statements. Since that time, we have been permitted to occupy the strong vantage-ground of being able to speak of the subject from the experimental point of view.

While, in his earlier telephoto lenses, Mr. Dallmeyer seemed to have had in view solely those who aimed at an exceedingly high degree of magnification, in his new series he has realised that there are many who do not care for the extreme of amplification, but would be content with a moderate degree of direct enlarging. In this we think he is right. The former having been attended to, he has now turned his attention to the latter.

While his general system of a compound amplifier, composed of a *pair* of achromatic concave lenses, has been adhered to, Mr. Dallmeyer has altered the internal structure of these concave appliances, and has pressed into his service certain properties obtainable only by the employment of Jena glass. His original concaves were composed of flint and crown glass, and were combined by what is known indiscriminately as the Gauss or Grubb forms inverted. In this, it need scarcely now be said, the flint glass had a much higher degree of refraction than the crown, although the familiar shapes of "crown" and "flint" are reversed. But in the present one—and, so far as we can see, he has no more worlds to conquer in this direction—he has adopted a form of double combination, each separate combination having a contact between two separate lenses, one of which, although it has a higher refractive index than the other, is convex in shape, these contacts tending to a better cure of astigmatism. If this form were adopted for very high magnifying systems of this nature, the reverse curvature of the field introduced would be more than is allowable. If a powerful negative lens be used, the reverse curvature of field is best remedied by the other form referred to. There are planes curved *towards* the lens, planes flat and very nearly flat, and planes with "reverse" curvature, dependent upon the camera extension. In some cases an unsymmetrical form has been adopted in which there are two planes of perfect flatness at considerably different extensions, this being arrived at by reversing the negative combination in its cell.

The practical result of this is that a lens much larger in diameter can be employed, transmitting a ray of light considerably exceeding in obliquity anything previously obtained; that the astigmatism of the oblique pencils caused by the front lens is annihilated or practically so; and that the distortion of curvilinearity is done away with.

This improved back concave or tele-photo attachment can be employed in conjunction with any lens, whether a portrait combination or a rapid rectilinear. We have had it applied to a Petzval *carte* portrait combination of six inches focus, although warned by the maker that it was not by any means the best for such an attachment, and have found that by its agency (its diameter is nearly one and a half inches, and its focus, negatively, four inches) the old *carte* lens, which was corrected to cover a plate of three and a quarter inches, now covers a plate the full size capable of being contained in a 10×8 camera, the largest on which we have as yet tried it. In doing this there is so much light transmitted as to admit of the employment of a drop shutter in good light, or the giving of an exposure of from half a second to three seconds in light of a less intense character.

The distance apart of the front positive system and the back negative one is the factor which determines the magnitude of the image, of course taken in conjunction with the position of the focussing screen relative to both. No matter how much or how little the camera is extended, there is a relation between the two lens systems which, when ascertained and adjusted by actual trial, ensures sharpness. The smaller the separation of the positive and negative systems, the greater will be the magnification of the image, and the farther must the camera be extended. This cannot be explained by instituting a comparison between it and the ordinary camera and lens in which, if the focussing screen be placed either within or without the focus, the image will be blurred without the power of being sharpened. But an analogy exists between it and the screen of the optical lantern, on which to project an enlarged image. An equally sharp result is not obtained on a screen shifted from the twelve-feet position on which the focus had been adjusted away to twenty or forty feet. But sharpness at any distance is obtained by readjustment of the objective. And thus it is with the tele-photo objective. A slight manipulation of the rack and pinion ensures perfect sharpness, no matter how much or how little the camera is expanded.

This constitutes one of the beauties of the system of mounting that has been adopted, for, by its agency, the photographer can, within certain limits, make a distant object of any size he chooses either to cover a quarter-plate, or one of 12×10 inches or more in dimensions. A short time since an American optician applied for a patent for a rigid tube in which to mount both positive and negative elements of a tele-photo objective. But from what we have said it will be seen that this adaptability of size of image to the space which it is found desirable to cover is totally wanting in such a system; whereas, by that adopted by Mr. Dallmeyer, there is absolutely no practical limit to the dimensions to which an object at a distance may be carried.

With regard to exposure, it will, of course, be well understood that, the greater the magnifying of the image, the less is the rapidity, seeing the intensity of the lens is reduced by magnification; so that, according to the intensity of the entire instrument, must one determine for himself whether he will choose a positive lens, *per se*, of high or moderate intensity.

DISCOLOURED NEGATIVES.

In spite of all that has been written in these columns and elsewhere on the subject of imperfect fixation, we are constantly being asked to explain the cause of, and supply a remedy for, discolouration in negatives, that can only be traced to the want of the most ordinary care in treatment during and after fixing. In most instances, by the time the evil has been recognised, it has become irremediable, although, if taken in time, it is often possible to arrest its further progress or even to remove any slight discolouration that may have occurred.

There are many different forms in which this discolouration may arise, and, although they may one and all be traceable, in the first place, to imperfect fixation, or insufficient washing afterwards, yet it does not follow that the immediate result is the same in all cases. For instance, we may have a negative which shows a yellow discolouration as soon as it is dry, or perhaps even before that, and then, again, may exhibit signs of change soon after it is put into the printing frame, while others only develop the fault in the course of weeks or months, and quite independently of whether they are exposed to light or not. Quite another kind of discolouration is met with in the case of negatives that have shown no symptoms of the evil, until, for one reason or another, intensification is resorted to, when it appears in full force.

The chemistry of the changes that occur has never, so far as we are aware, been carefully studied in connexion with gelatine films, and the result is set down, in a general way, to sulphuration in some form or other; but that it is the same in all cases is, we think, far from true. In one class of cases the image itself is involved in the change that goes on, while in others the discolouration appears to be confined chiefly to the film of gelatine. In some instances, too, the colouration is removable, while in others it resists every attempt to get rid of it.

If we glance briefly at the chemical changes that are supposed to go on in the process of fixing, it is not difficult to understand that the after-discolouration may partake of different characters. The nature of the double salts formed under varying conditions has been over and over again pointed out; for instance, it is known that, with a weak fixing bath, or when insufficient time is allowed, an insoluble silver compound is formed, which, with a stronger bath, or under more prolonged action, is converted into a more soluble form, which is removable by washing. It is here where the distinction between imperfect fixing and imperfect washing comes in, the two being only too frequently confounded or considered synonymous.

In the case of an imperfectly fixed negative—that is, one from which the unaltered bromide of silver has been barely removed, and which is *apparently* fixed—there will still remain in the film a quantity of silver, either in an insoluble form, or, what is practically equivalent to it, in a state in which it is precipitated or rendered insoluble by washing. On the other hand, the perfectly or sufficiently fixed film may contain, like the other, a quantity of silver; but it is in the soluble form, and is not precipitated in the course of washing, but may be entirely eliminated if the washing be properly performed. This constitutes the essential difference between imperfect fixing and washing.

It may be accepted, we think, as an undoubted fact that, in order to have discolouration of the film from the action of hypo, there must be silver present in some form, as the hypo itself will not stain the gelatine. The familiar term "sulphuration" as applied to prints or negatives describes the effect produced by the combination of silver and sulphur, these being supplied by the unremoved products of fixation. Sulphur, or rather hypo, alone will not produce the result, as has been proved by immersing a perfectly fixed and washed print in a fresh solution of hypo. The extent and nature of the discolouration will depend upon whether the silver is present in the soluble or insoluble form, or, in other words, whether the fault is insufficient washing or imperfect fixing.

If a plate be cut in halves before fixing, some instructive light may be thrown upon the matter. Let the two halves be placed together in the hypo bath, and allowed to remain until the silver haloids have just disappeared and no more, then let one half be taken out and washed very thoroughly, the second half being allowed to remain for a further period equal to that already given, and then simply rinsed sufficiently to prevent crystallisation of the superfluous hypo on the surface. If the two halves be carefully preserved from the action of light until quite dry, they will probably show no sign of anything abnormal, unless, perhaps, in the case of the portion which has received the shorter immersion in the fixing bath, there may be some slight opalescence, especially if the film be thick; but, directly they are taken out into a strong light, they will both be found to discolour, assuming a yellowish brown tinge of greater or less depth, according to circumstances.

But, in the case of the shorter fixing, the discolouration will be denser, and of a more opaque character than the other, which will be clear and transparent, and apparently confined to the shadows of the negative, whereas, in the first case, the change of colour appears to affect the image itself, and to alter its density. If, instead of immediate exposure to light, the two portions of the negative be carefully put away in a dark place for some weeks, it will be found on examination that, while the imperfectly fixed portion remains unchanged in appearance, the other will have undergone spontaneous discolouration in much the same manner as under the action of light.

Assuming that both halves have been equally protected from abnormal atmospheric conditions likely to bring about decomposition, these two experiments show that there are influences at work quite distinct from sulphuration as commonly understood, and that the effect produced differs according to whether the silver is present in the form of the insoluble or the soluble double hyposulphite; for, while both are sensitive to light, it is found that the latter is more liable to spontaneous decomposition in the presence of gelatine. This is quite as might be anticipated, if we consider the behaviour of gelatine after treatment with, or in the presence of, a soluble silver salt such as the nitrate.

It is not our purpose to enter into the question of the ultimate changes that would occur under circumstances favourable to "sulphuration," suffice it to say that either of the plates mentioned would exhibit it in its worst form. What we particularly wish to point out is how the two faults, imperfect fixing and washing, may be recognised and remedied if taken

in time. It will be readily understood that both may be present in the same plate; and, though the proper treatment for one is not the correct remedy for the other, still, means may be adopted that will effectually cure both.

In actual practice it is surely seldom that the work is so carelessly performed that the whole surface of a negative suffers from either of these forms of neglect. The results are generally seen in the form of patches, arising from inequalities or irregularity in the thickness of the films, against which it is often impossible for the most careful operator to guard; but, by carefully examining his negatives after drying, and especially after exposure in the printing frame, he will often be able to detect the evil in its incipient form, and arrest its further progress.

The result of imperfect fixation is, as we have said, sometimes visible in the form of a slight opalescence before exposure to light, and this is more especially the case when it occurs in patches. When thus apparent, it is easily removed by reimmersion in a fresh solution of hypo. If, however, the negative be exposed to strong light before the discovery is made, more or less discolouration will take place, and this will be intensified by each successive exposure. All that can be done under these circumstances is to arrest the further progress of the decomposition by refixing, and if this be done at once the injury will not be great.

But a negative may be perfectly clear and free from opalescence before exposure in the printing frame and yet show in a short time a clear yellow stain, generally along one edge or over one corner. Reimmersion in the fixing bath if done at once will often remove this, especially if it be simply the result of insufficient washing. But it is seldom that either fault exists alone, and, in order to satisfactorily treat both, the best plan we have found is to soak the film first of all for two or three minutes in a strong plain solution of salt, and then without washing to plunge it into a dish containing a very dilute solution of nitric acid, about fifteen or twenty mimims to the ounce; after this, wash to remove the acid, and refix and wash in the usual way, when in nine cases out of ten the stain will have disappeared.

But, after all, prevention is better than cure, and it is a very easy matter, without adding greatly to the trouble of finishing a negative, to test whether it is properly fixed and washed before running any risk. All that is necessary, as we showed a few weeks back, is to immerse it in a solution of iodide of potassium, when any silver remaining is at once rendered visible as iodide.

KEEPING QUALITIES OF FILMS.

Of late the question has been raised at several of the societies, and at different times in our columns, as to the relative keeping qualities of plates and flexible films, and diverse opinions expressed. In our last two issues the subject is again referred to in letters from two well-known amateurs—Mr. W. J. Hillman and Mr. F. Beasley. In the majority of instances, when the question has been previously raised, several important points in connexion with the subject have been entirely ignored, the various commercial films being treated almost as if they were a standard commodity. As a consequence, the alleged deterioration, if any, has been attributed mainly to the support of the gelatino-bromide of silver.

Glass may be fairly classed as being, so far as gelatino-bromide of silver is concerned, a perfectly inert material. Yet we all know quite well that plates prepared with some emulsions will remain good for several years, while others, with different ones, will sometimes become almost useless after only a few months' keeping. Therefore, in the consideration of this subject, it must be borne in mind that the emulsion itself is a most important factor in the case, quite independent of the material upon which it rests, whatever that may be. Then, again, flexible films themselves are not alike either in their composition or mode of manufacture, not even when they pass under the generic term celluloid, while some are of an entirely different material.

Celluloid or, as the English manufactured article is named, xylonite, is a modification of what was at one time called, after the name of its inventor, Mr. A. Parkes, Parkesine. Numerous improvements have been made in it since, and many patents in connexion with the materials used and its manufacture, have from time to time been taken out, but whether all, or even any, of them are being worked we are unable to say. As a matter of fact, the whole of this manufacture is treated very much in the light of a trade secret, and its working is in the hands of a few large firms only. Indeed, we question if, in connexion with any material having so many applications, and being employed for so many general purposes, so little has been published with regard to the details of its manufacture. It is, however, safe to affirm that it is essentially a compound of nitro-cellulose and camphor, although it may be made by different methods. According to one of the Eastman Company's patents, their film is composed of soluble pyroxyline, camphor, wood naphtha, amyl-acetate—more familiarly known to some as essence of jargonelle pears—and fusil oil. The solution is spread on glass plates and allowed to dry, when it is coated with the emulsion.

What are known as cut films are made quite differently. In this case the camphor is really the solvent of the nitro-cellulose, but this is not of the same kind as the soluble pyroxyline used for collodion, but a lower nitro compound known as xyloidine. It is almost insoluble in ether and alcohol, but when kneaded and rolled, camphor, by reason of the latter's solvent action, heat also being applied, becomes a plastic mass, which can be wrought in various ways. In connexion with the solvent action of camphor, it may be mentioned that there are several substances that are not solvents of nitro-cellulose by themselves, but they become so by the admixture of camphor. When required for such purposes as knife-handles, pianoforte keys, photographic dishes, &c., colouring and other matters are added to the compound, according to requirements. For transparent articles, such, for example, as photographic films, the pigment is, of course, omitted. One important point in connexion with the manufacture of celluloid is the seasoning. When freshly made, it is termed green, and if used in that condition articles formed with it are liable to warp, shrink, or otherwise lose their shape. The "seasoning" is effected by keeping the celluloid exposed to the air, at a warm temperature, for a long period—sometimes for months. The longer it is kept the more unchangeable it becomes, and the more it loses the smell of the camphor.

So far as we are aware, the manufacture of the celluloid used for photographic films is chiefly confined to America, and this, we are informed, is how it is made: The transparent celluloid is first formed in large slabs, which afterwards undergo a lengthened seasoning. When sufficiently seasoned, it is cut into thin sheets and rolled between heated rollers, as it can still be softened by heat, and finally polished, as met with

in the market. When it is required with a matt surface, we were told by Mr. Carbutt, who has given a great deal of attention to the production of flexible films, that it is produced after the sheets have been polished.

From what has now been said, it will be seen that what are classed under the head of celluloid films vary in composition and manufacture. Again, some films are of an entirely different material, having gelatine as its basis. Furthermore, we have met with films having a cellulose basis, that have had an intermediate layer of a gelatinous character between the support and the sensitive film.

The object of the present article is not to express any opinion as to the keeping qualities of flexible films, of whatever they may be composed, but simply to point out that, in discussing the subject, there are films (supporting) *and* films, also emulsions and emulsions. These are conditions that do not seem to be sufficiently taken into account by some who have expressed opinions on the subject, and who, as we have said before, treat "films" as a constant product.

The Origin of Photography.—We are accustomed to the statement of scientific facts in epigrammatic fashion by our neighbours across the Channel, but it is a decided novelty to hear as, according to Mr. Bashford Dean, in the *American Naturalist* of July, Professor Lacaze-Denthiers has stated, that "the observation of tarnishing of silver . . . . was the origin of photography!"

Photographing the Invisible.—This is a feat which, in the production of photographs of the ultra-violet rays and of stars never seen by the human eye, is no novelty, but it is to the general public more in the nature of an abstract problem. At the Academy of Sciences of Paris, however, M. Zenger gives it concrete form by exhibiting two photographs taken the 17th of last August, two hours before and two hours after midnight. They exhibit two faint images of the Lake of Geneva and Mont Blanc, which were at the time absolutely invisible to the naked eye. M. Zenger, however, stated that to some extent the invisibility was relative only, as it depended upon individual idiosyncrasies as regards visual power.

A New Source of Error in Scientific Photography.—The absolute rigidity and freedom from tremor that are essential requirements in such photographic work as spectrum photography, and, in astronomical photography, the ascertaining of polar distances, has lately been shown by Dr. E. Von Rebeur Paschwitz to be subject to hitherto unknown disturbances. He finds that the earth's surface is subjected periodically to wave motions analogous to those disturbing a sheet of water, and often persisting for several hours with great regularity. He observed the motions of a horizontal pendulum, and obtained memoranda on photographic plates moving at the rate of twenty-four inches per minute. He suggests that all observatories should be fitted with instruments to register these tremors, and that they should be systematically examined.

Lord Rayleigh Questions the Need for Large Astro-telescopes in a letter to *Nature* last week. Noting that it is in contemplation to spend over 2000*l.* on a special photographic telescope for Cambridge Observatory, he asks whether astronomers have duly considered the facilities afforded by modern photography? "There is now no difficulty in preparing plates sensitive for all parts of the spectrum. . . . The interference bands of sodium light may be photographed with the utmost facility on plates sensitised in a bath containing cyanin. The question I ask is, Whether the time has not come to accommodate the photographic plates to the telescopes, rather than the telescopes to the plates? It is possible that plates already in the market may not exactly meet the requirements of the case, but I feel sure that a tithe of the sums lavished upon instruments would put us in possession of plates suited for object-glasses that have been designed for visual purposes." He refers to Captain Abney to give an opinion on the probable sensitiveness of plates prepared for such purposes.

A Sensitive Spherometer.—The spherometer is an instrument for measuring the curvature of the surfaces of lenses, and the first constructed was the design of the late Andrew Ross, and obtained the silver medal of the Society of just over half a century ago. It is a tool of great value to the manufacturer of either photographic or any kind of lenses, and has been gradually improved upon by succeeding inventors. It is a sort of low tripod, carrying a screw in its centre, the number of turns given by this screw before it meets the surface of the glass, when placed upon a lens, giving the depth of the curves. Ross's original form could measure to the thousandth of an inch, and by estimation to half that amount. The ordinary instrument will gauge to the ten-thousandth. Mr. A. A. Common proposed to the Royal Astronomical Society to increase this sensitiveness by placing the screw on one of the arms of the tripod. He now publishes a note describing a method he has devised for still further extending this suggested improvement. The new spherometer he describes in *Nature*, and he states it capable of measuring to the marvellous minuteness of the three-hundred-thousandth of an inch!

Light Rays as Sound-carriers.—At the World's Congress of Photography, the Chairman of the Committee, Judge Bradwell, in the concluding remarks of his address said, "I have no doubt there are those within the sound of my voice who will live to see the time when photographic reproductions will be sent from country to country as quickly as we do telegraphic messages to-day." This is a bold prophecy; but almost ere the words were uttered there was on view in the Electricity Building an instrument which, for marvellous utilisation of the rays of light, would almost make one ready to believe in any such prophecy as Mr. Bradwell uttered. We refer to Professor Bell's Radiophone, which is founded entirely on the utilisation of light rays, and as such of interest to photographers, though in this case it is not the lineaments of a friend which are conveyed, but the actual sound of his voice. Not to make the description too technical, we may say briefly, it consists of an instrument for emitting parallel rays of light of great brilliancy, reflected from a thin diaphragm mirror to a receiver placed in one instance an eighth of a mile distant. Opening into the chamber behind the mirror is an ordinary speaking-tube mouthpiece. This is spoken into, the mirror vibrates, the vibrations are carried forward by the rays of light, are received into a special apparatus at the other end, and by a hearer placed in a room freed from sound are distinctly heard, though in slightly muffled tones.

PHOTOGRAPHICAL SOPHISTICATION: ITS TRUTHFULNESS OR OTHERWISE.

Mr. H. Dennis Taylor, in dealing with my criticism of Mr. Van der Weyde's claims with respect to "Optical and Visual Truth," refers to my remarks on one branch of the subject only, without touching those on the other branch, which I considered as more important. I regret to have to differ from Mr. Taylor, the value of whose writings in exposing fallacies of so-called naturalistic focussing is so deservedly recognised, and shall be much interested to learn whether he is with me on this second branch of the subject now under discussion.

The consideration of any such means as that of the so-called photo-corrector for varying the visual angle, and consequent apparent magnitude of any particular object in a picture, may be divided into two parts; the one being the shrinkage of near and the enlargement of distant portions of a picture, so as to destroy the effect of natural perspective, in virtue of which the nearer object occupies proportionally a larger angle to the angle and in the picture; and the other, the modification of the size or proportion (width, height, or both) of particular objects, independent of whether they are enlarged or diminished by perspective, to suit an ideal, conventional or otherwise.

The claim to "correct" photographic perspective Mr. Taylor

defends on the ground that, for near objects, we are able by the aid of binocular vision to estimate the relative distances of their various parts, and so to make allowance for the greater apparent magnitude of the nearer planes. Whatever truth there may be in this proposition, I think it is a mistake to import the question of binocular vision and binocular perspective into that of affording the truest obtainable representation in a single picture. No single picture can give binocular effect, and painters and photographers alike (except when a pair of stereoscopic pictures are used) have to content themselves with what can be shown upon a single surface.

Mr. Taylor draws a distinction between objects within the range of binocular or stereoscopic recognition, which he puts at 100 yards, and those outside that distance. Of course, the actual distance for stereoscopic recognition will vary with the class of subject; thus a twig or other small clear upright line standing some distance in front of another object of distinctly different colour and having well marked lines or pattern on it, will show stereoscopic effect at a distance where on any such object as a cake or a house such effect may not be recognised, but the 100 yards limit may be accepted as approximately near enough for the argument. Suppose, now, a photograph to be taken including a building, the nearest point of which is 100 yards distant, and that it is at the corner of a street, and our camera is placed so that we see one side almost or quite at a right angle to the line of sight, whilst we also see other houses of a similar height for a considerable distance down the street at the corner of which it stands. The houses will regularly decrease in height on the picture, so that the one which is in a plane at double the distance of our corner building will only occupy half the vertical space in our picture. Will it be said that the photographer or the draughtsman is wrong in representing these buildings in the same proportion that they bear to that image on the retina, or to the visual angle included? In Europe and in modern times such a picture will be accepted as true, whatever might be thought about it in China. If this is true of houses at a distance, why should it be otherwise than true of, say, a row of dog kennels so near at hand and at such elevation as to bear the same relation to the eye that the houses do in the first case?

An objection to altering the perspective of the photograph, which has not been dealt with by Mr. D. Taylor, is that it is impossible to diminish one part and leave the rest of the picture unaltered. If some near object is diminished, there must either be something shown which the object actually hides, or immediately adjacent objects must be stretched to fill up the space created. In the case of the "photo-corrector" it is the latter event which happens—the neck is stretched out to make up the deficiency left by the shrunk head, and, whilst there is a fashion for admiring small heads and long necks, no doubt the double sophistication will be approved of by those who desire flattery rather than truth.

My own view is, that pictorial representations are generally preferred by the spectator not so much to the original subjects as to other pictorial representations of similar subjects to which he is accustomed. It is thus that the toleration of the book of beauty of pre-photographic period for small Cupid-bow mouths, eyes preternaturally large and wide apart, ridiculously small hands and feet, &c., can be accounted for. It is also thus that we may account for the rocking-horse position which did duty so largely in hunting and battle scenes, and which has been so much accepted that since the more truthful representations, such as those shown by photography, came to be generally adopted by the best artists, there has been a wail set up that such positives represent "arrested motion," "positions never seen by the human eye," and so on. True, there have been observant sculptors as long since as the classic ages, who have left us much such representations as photography gives us, and some painters, like Meissonier, who have gone direct to nature, and, producing drawings which are found closely to resemble the photographic representations, should therefore also incur the censure of those who accept only the commonplace conventions.

This brings me to the point that, whereas it has been customary for painters and draughtsmen to represent most subjects in linear perspective, buildings with retiring lines, groups of figures with the farther ones represented smaller than near ones, it has been conventional to disregard this effect with single figures, and the public, judging of photographs by what they have been accustomed to see in paintings and engravings, object to the increase of size in the advancing portions of a single-figure subject, whilst they accept it in subjects of any other character. In my criticism, referred to by Mr. Taylor, I recognised the hold which this Convention had obtained, and said (see *Society of Arts Journal*, April 28, 1893): "As people are not thoroughly accustomed to perspective in single-figure pictures, there is something to be said for sophistication to the extent which brought the picture more into accordance with what they were accustomed to."

The other branch of the subject deals with alterations of the dimensions of the subject, where it is not suggested that perspective has had anything to do in causing such alterations to be desired. Mr. Van der Weyde, in his paper, speaks of sitters who "are prone to lament that their hands, to say nothing of their heads and waists, come out much too large. Others, again, fancy themselves much taller and slimmer than they optically, perhaps I may say architecturally, really are, and I have always been compelled to admit that they are right—that is to say, visually right, artistically right—and that photography, in their case, could not do justice to one's visual impression." I maintained on the night of the discussion, and I have seen nothing yet to convince me to the contrary, that heads and waists do not come out too large for truth and nature, but only too large to accord with some conventional ideal.

Mr. Taylor, in his concluding paragraph, says: "The only danger lies in the fact that so many sitters are satisfied with nothing short of the most flagrant flattery on the part of the photographic artist as well as the portrait painter, and that the method may, in some hands, be prostituted accordingly." Does Mr. Taylor consider that the reduction of hands and waists, the making the sitter taller and slimmer in the picture, and the photographer's assent to the proposition to this in accordance with visual truth, is in itself a truthful proceeding, or would he consider it to come under the censure of the sentence last quoted from his article? W. E. Debenham.

CONTINENTAL NOTES AND NEWS.

Eliminating Hypo from Prints.—M. Ommeganck recently informed the Antwerp Section of the Association Belge de Photographie that of all the means employed for the elimination of hypo he found the best to be the immersion of the prints in a bath of borax solution (strength one-half per cent.) and their washing in pure water, the small traces of borax remaining in the prints being advantageous for toning purposes. Toning, however, we may remark, usually precedes fixing in the albumen process. Possibly, however, the idea would be applicable after toning and fixing.

A Permanent Acid Fixing Bath.—The following is recommended by the *Bulletin* of the Photographique Club de Paris:—

Water	350	c.c.
Bisulphite of soda	10	grammes.
Hyposulphite	40	„
Chrome alum	2	„
Citric acid	15	„

The bath is said to keep indefinitely, fix rapidly, and obviate staining of the plates.

Increase of Rapidity in Gelatine Plates by Keeping.—Mons. F. Burle writes to *La Nature*, giving an instance where, as he alleges, gelatine plates have gained in rapidity by keeping. Some Beernaert plates, he says, in the seventh year of their existence were five times more rapid than in the first month of their manufacture. We should like to know what tests Mons. Bourle applied to attain such a result.

Development by Electricity.—Following up the experiments of Schützenburger and Eder, Herr Liesegang has succeeded in developing plates by electricity. Two vessels, one of which is of porous ware, are filled with a solution of bisulphite of soda; the porous vessel is placed in the other, and a current of electricity is passed through by means of two platinum electrodes. The exposed plate is placed in the vessel containing the negative electrode. The image develops in a few minutes, and is of a brownish colour. The deposit is considerably reduced in the fixing bath.

New Method of Development with Diamidophenol.—M. Balagny gave the following plan at a recent meeting of the Société d'Etudes Photographiques:—A three per cent. solution of anhydrous sodium sulphite is made. To develop an instantaneously exposed plate (130 × 180 mm.), 100 c.c. of the solution are taken

half a gramme of diamidophenol being added to it. For a plate having had a time exposure, five to ten c.c. of a solution of acetic acid are mixed with the developer.

A Combined Toning and Fixing Bath without Sulphocyanide.—Herr Valenta recommends the following:—

Distilled water	1000	parts.
Lead nitrate	10	„
Soda hyposulphite	200	„

For use, add fifty parts of a one per cent. solution of gold chloride. The bath is said to answer with most commercial chloride papers. It does not work at its best at the first, and it is therefcre recommended to tone one or two prints by way of trial.

Removing Yellow, Green, Red, or Dichroic Fog.—Dr. Meniéré, of Paris, advises the following treatment:—Soak the negative in ordinary water for five minutes, and then immerse in—

Water	100	parts.
Bromide of sodium	3	„
Bromine water	3	„

Leave in for ten to fifteen minutes. The bleached image is well washed and dried, and the image redeveloped with an amidol-sulphite developer.

UNSUSPECTED SOURCES OF FAILURE.

There can be very little doubt that by far the greater proportion of the failures that occur in dry-plate work are attributed to wrong causes, and that, in very many instances, the poor platemaker or some equally innocent individual receives the blame that is really due to the carelessness of the operator. This happens not infrequently even when the operator is an old and experienced hand; but, undoubtedly, most such cases are to be met with in connexion with beginners, whose knowledge of photography is not yet sufficiently extensive to have taught them how easy it is to err.

Photography has now become so extremely simple and easy a process that, to the average amateur, it is impossible to conceive how he can possibly go wrong, at least in the merely mechanical details of manipulation, although he may, perhaps, recognise the possibility, if not the probability, of there being at first some little difficulty, or at least something to learn in development. But whether novice or veteran is the more really blameworthy it is impossible to say; the first errs from want of knowledge, the latter in spite of it, and he should therefore, perhaps, be deemed the greater sinner.

Several cases, serious, comic, and instructive, have recently come under my notice, and a narration of one or two may, perhaps, serve to impress upon some of your readers the folly of coming to too hasty a decision in such matters, and, above all, of recognising the possibility that they may themselves be in fault, and thoroughly sifting the matter before laying the charge on other shoulders.

In one case, which promised to be a rather serious one, and possibly to lead, if not to a lawsuit, at least to "strained relations" between two hitherto old friends, I was asked to arbitrate on the subject of the quality of certain plates, a large number of which had been supplied through a dealer to a customer who condemned them as worthless. The maker, on testing a sample returned to him for the purpose, pronounced them all right, and declined to take them back; the dealer, on testing the plates, moreover, found them free from fault, but, as they were an uncommon and unsaleable size, he could scarcely agree to have them on his hands as useless stock. In the dilemma, I was appealed to to give an opinion on the plates, and, on trial, pronounced them good in every respect.

The customer accepted the decision; but, though he went earnestly to work to discover where he himself was wrong, so many verdicts being against him, his compliance was of that character that left him "of the same opinion still." By chance I happened to be at his place of business when the matter of the plates was mentioned, and it was proposed to make a joint trial of them, and certainly they turned out all that he had alleged them to be from the first, foggy and hopelessly bad. The fog extended over the whole plate, even to the margin representing the rebate of the dark slide, and that fact, in conjunction with a careful examination of the camera, proved that the latter was not in fault, while there was no reason to lay the fault to the dark room. I accordingly carried away with me two or three plates from the same box to try in my own dark room, when, strangely enough, they again worked without the slightest blemish.

Returning to the charge, another plate was exposed in the professional studio, and that, together with a second that had not been exposed, were placed together in the same developing dish, when the exposed plate came out precisely as previous ones had done under the same circumstances, while the unexposed one remained perfectly clean. Here, at least, proof was positive that the fault lay in some way with the exposure. The camera, as I have said, appeared perfectly light-proof: but, to place that beyond dispute, a plate was cut in half, one half being kept in the dark room without exposure, the other placed in the dark slide, with a portion protected with opaque paper, and exposed as before. On developing the two halves, the unexposed portion was, as before, perfectly clear, the other completely and equally fogged.

Now it became evident that, while the fog arose in the camera, it was certainly not in front of the plate, but behind; so a plate was placed in the slide—a single one with hinged door—and one half of it covered with opaque paper placed behind it. As a matter of form the plate was exposed in the camera, and on development the protected half proved perfectly clear; the other badly fogged, as on previous trials. On carefully overhauling the dark slide, it was discovered that from shrinkage—no doubt caused by the protracted dry weather—the back door of the slide did not lie closely in the rebate, and light leaked in nearly all round the edge of the plate, and so the mystery that had so nearly caused much unpleasantness was explained.

In another case a batch of plates was condemned in a very similar manner, the fault in this case being that many of them—sometimes three or four, or even more, in a box—were marked by a diagonal line of fog across the middle of the plate, one side being clear. In other boxes the whole of the plates might be perfect. The theory formed by the victim in this case was that a light had been taken into the drying room while the plates were in the drying racks, and that some of the batch had thus got fogged in this partial manner. The theory was ingenious, but it was shown that at the particular factory it was impossible. It turned out in this case, after a long series of investigations, that the fault was again due to a defect in the camera, aided by circumstances. The camera was one of the reversible-back pattern, and at one corner of the reversing frame, that which was at the right-hand top when the plate was in the upright position, admitted a leak of light, at least when in that position; for when placed in the horizontal direction, in which case the defective corner was at the bottom and did not get the benefit of the direct skylight, the diagonal streak of fog did not occur. This discovery, of course, put a very different complexion upon the drying-room theory.

Another case in which the blame was sought to be fixed wrongly on the camera—not, in this instance, on the platemaker—gave a good deal of trouble before it was accurately diagnosed. The defect took the form of an irregular blur of fog, occurring only occasionally, but always in the same position on the plate. It was not sufficiently well defined to give the idea of being caused by any minute aperture in the camera front acting as a "pinhole," less still of its being caused by a perforation in the back of the slide—this also being a single slide. However, its always falling in exactly the same position proved that it was caused mechanically by some internal defect in the camera. Examination of the slide with a plate in position showed that the "blur" fell just where the spring pressed upon the back of the plate, this spring being of "blued" steel, nicely rounded at the extremity. Further investigation showed that when the camera was employed in a certain position out of doors, for portraits or groups, the light from the sky, entering the lens, passed through the plate, and was reflected back by the curved and polished extremity of the springs. The application of a little dead black varnish in this instance removed the trouble.

As an example of the comic side of matters, I may conclude by mentioning an incident that occurred to myself, and which for a time presented all the features of an inexplicable mystery. A friend who was just entering on the novice stage brought to me for my opinion a new camera that he had had offered to him, and of course the instrument had to be tried. This was done by each in turn taking the other's portrait, the slides containing the two plates being then taken into the dark room for development. One plate, however, turned out to be hopelessly fogged, while the other gave not the slightest trace of an image. The slide was refilled and the exposures repeated, but with a precisely similar result. That one or other of us should have omitted to draw the shutter once would not have been remarkable, but that it should be repeated after the contingency had been mentioned was scarcely likely; but even then it would not account for the fogging of the other plate, and it seemed too extra-

ordinary a coincidence that twice in succession a good plate and a bad one should be placed in the slide, and the good one in both instances escape exposure.

A third pair of plates were placed in the slide, and for the third time one of them developed a mass of dense fog, while the other was quite innocent of exposure, and the situation began to be decidedly interesting if a little exasperating. It was my friend's plate that had escaped exposure in each case; so, after sitting for the fourth exposure, determined to solve the mystery, I placed my hand under the focussing cloth in order to be perfectly certain that the novice understood what drawing the shutter meant. He proved to be quite capable of performing that simple operation in a fashion, but where he had erred was in drawing *the wrong one!* In fact, one of each pair of plates had been exposed twice, once in the camera and once out of it, while the other was not exposed at all. W. LINDSAY.

SPOTS AND PINHOLES.

WE have heard of late many complaints of spots and pinholes on both paper and plates, but afflictions of this kind seem to be of periodical recrudescence, more perhaps in the summer than at other seasons of the year, which may be reasonably expected owing to the extra dryness of the atmosphere at this period, and the great quantity of dust that is everywhere in evidence. There is nothing new in the phenomenon, and, knowing it, extra precautions should be taken to counteract its evil influence by both manufacturers and users of paper and plates. Considering the immense quantities of both that are yearly consumed, the faults in this direction can scarcely be termed excessive. That occasional batches of defective material are sometimes on the market there is no disputing, for which possibly the makers are the greatest sufferers.

In these days of keen competition loss of popularity is a serious matter. Advertising does a good deal, but the production of uniformly good plates or paper is more to the purpose. Photographers getting hold of a thoroughly reliable brand of either are very conservative, and it depends entirely on the manufacturers to keep their customers or send them roving for something better. That we shall get absolute perfection at all times is simply out of the question. Not until paper is made of rags from angels' clothing and boiled in liquified air, as a photographic expert once put it, shall we get paper without faults of some kind; the less there are, the more we have to be thankful for. The wherewithal of which spots are made may be introduced from the very beginning of the paper manufacture to the final mounting of the print. Firstly, there is the paper itself, faults or oversights of manufacture, and mostly consist of metallic particles of some kind incorporated with the paper pulp, and more or less visible on the surface of the paper. Many are also invisible except by transmitted light, and make their appearance as faults later on in the preparation of the prints.

At one time Rives paper had an unenviable notoriety in this direction, and Saxe was of equally good repute, from which we may infer that more care was observed in one manufactory than the other, and that this particular fault is preventable, and ought to be. Metallic particles make their presence felt, as soon as they come in contact with silver salts, by the reduction of the silver to a metallic state. If large spots are carefully examined, the silver will be seen reduced to a foliated form and attached to the original speck, the bulk of which determines the amount of reduction, specks that were unnoticeable before spring into existence, to the great detriment of the print. As far as my own observation goes, it is only spots of a metallic nature that are of serious inconvenience; other kinds remain as they appear at first, neither increasing nor diminishing. If the prepared paper is held up to the light, the locality of the spot is easily seen, and the paper, by judicious management, may be placed on the negative so that the fault will come in some dark part of the picture where it will be of little or no consequence. Supposing the paper itself is free from defects, they may be introduced either in rolling, albumenising, sensitising, storing, or in the printing frame. If free up to this point, they may be contracted in washing or drying afterwards, and, finally, by the mountant and mount. From one end to the other of the preparation of silver prints they are more or less liable to become defective from spots. The process of albumenising, if carefully performed, is not very likely to introduce them. The only way spots are contracted at this stage is by dust settling on the surface during the drying, although the albumenising is responsible for streaks and markings of another character. The most prolific source of spots is dust during the sensitising process.

A peculiar class of defects is produced by the silver bath settling in tears and drops on the surface of the paper hung up to dry, as if the paper had been greasy. This is sometimes produced by the too dry condition of the paper, or too great strength of the silver bath, or to the albumen itself not being properly ripened before use. Blotting off the surface liquid before hanging up the sensitised sheets will prevent it. Ready-sensitised paper, as purchased, is rarely, if ever, troubled with these spots. In most photographic workrooms the dust is of a very complicated nature. Organic, inorganic, and metallic matter enter its composition, and are more or less dangerous according to the predominance of objectionable chemical substances. Iron, hyposulphite, and pyrogallic acid solution being spilled on the ground dry, and friction by footsteps aid in their distribution in the atmosphere, and are perhaps the chief offenders in this connexion. Sulphur in various forms is also very pernicious. Great care is necessary to avoid dust wherever any moist surfaces containing silver salts are being prepared. Gas and coke stoves give rise to trouble unless the products of combustion are thoroughly removed by good ventilation. If the paper gets to the usable stage without accident, a frequent source of spots is found in dirty pads in the printing frames, or by metallic particles ground off the springs and hinges by the friction of opening and closing. New printing frames are very liable to cause trouble. Every crevice of a pressure frame should be thoroughly dusted before being filled in, especially the rebates and pads. A piece of stout blotting-paper that has been saturated with a solution of carbonate of soda, and dried, should be laid between the paper and the pad. This will not only prevent the paper yellowing, but protect it from any deleterious matter that may happen to be on the pad itself. Spots are sometimes, but rarely, caused by bad hyposulphite of soda, and by imperfect manipulation in toning and fixing, letting the prints stick together, so that they are only partially acted on by the solutions.

Another source of spots is dust settling on the surface of the prints during the time they are washing. This is more likely to happen when they are left soaking all night face upwards and float to the top of the water. New unvarnished zinc in the washing trays will also cause spots if the face of the print lies in close contact with it for a little time. If the work passes through all these ordeals safely and intact, only sheer carelessness will spot them whilst they remain unmounted. When many processes are carried on in the same apartment nothing is more likely to cause defects on a finished silver print than particles of liver of sulphur, the most minute speck of which will in a short time do irretrievable damage by entirely destroying the liver image, and substituting an ugly yellow spot that increases in size from a pin-point to that of a pea, when it seems exhausted. Any print being in contact with this chemical is ruined. It may be a day or two or more before the spot is noticed, but then it soon spreads, and the destruction is complete. A lump of this substance (sulphide of potassium) may have been broken up for intensification purposes or for precipitating residues, and, being very hard, is apt to splinter and fly about, unless great care is taken to prevent it, and so a few particles may get on to the prints. I cannot call to mind anything else likely to cause spots on the finished print in the course of ordinary photographic work if care and cleanliness are fairly observed.

With the gelatino-chloride papers, spots may exist in the unprepared paper, or from the emulsions being imperfectly prepared, or the process of coating carelessly done, or dust settling on the surface during drying. The preparation of this kind of paper is chiefly in the hands of a few manufacturers, who, by the aid of machinery, can produce a more perfect article than it is possible to do at home, and it is a matter of importance to their business that a good paper is turned out; at the same time, it cannot be disputed that we occasionally purchase gelatino-chloride paper that is afflicted with minute spots that increase during toning and fixing, to the great detriment of the pictures, especially those of the vignette order, where a perfectly pure margin is necessary. The nuclei of these spots are easily seen on holding the paper up to the light as tiny opaque specks, and during the toning and fixing develop a kind of aureola that destroys the image where it exists. The more protracted the toning, the more conspicuous these spots become, but with rapid toning they show very little. The tubes in which gelatino-chloride paper is sent out are not a safe protection for the paper from the light, they being perforated by minute holes that let in sufficient light to darken the papers, in patches varying from the size of a sixpence to a crown piece. This may be easily remedied by giving the tube a coating of asphalt varnish or pasting some orange paper on it. Of course, if the paper is wrapped in orange paper inside, it is safe so far as it goes; but the tubes are sometimes again used for untoned prints or sensitive paper, so, unless some extra precautions are taken against the action of light, there is a probability of spoiling the contents.

We occasionally hear of the mysterious appearance of spots with

nothing to suggest their origin, and their rare occurrence does not give one the opportunity of tracing them to their source. Water, when supplied under high pressure, although sufficiently pure, is sometimes the cause of spots; the imprisoned air settles in tiny bubbles over the surface of the print, and thus prevents the proper action of the water on those parts. I have seen water supplied that looked quite *muddy* from this cause, and remained so for some little time after being drawn, when it gradually became clear, but the slowness with which the air separated from the water seemed to me phenomenal. Occasionally impurities are introduced into the water supply by repairs going on to the supply pipes, which may have a deleterious effect on the prints. In some circumstances the pipes themselves contribute to this end, but, generally speaking, the spots can be traced to some more controllable origin; but, when they happen unexpectedly, the photographer is thrown off his guard, and the cause is apt to be overlooked, or, having righted itself, the cause of the defect is enveloped in mystery; but dust, in some form or another, has more to answer for than all other causes put together.

Spots on gelatine negatives are mostly attributable to either dust or bubbles. If we examine an unexposed plate, we may find round spots of clear glass or depressions, where the emulsion is much thinner than on other parts of the plate. These are produced by bubbles in the emulsion, which, as the emulsion sets, break, and leave clear glass, as the gelatine then becomes too thick to flow to fill up the space equally, or some part of the plate may not have been perfectly covered in coating. Such plates as these never ought to be sent out, and I have no doubt it is quite an oversight that they are not thrown to the waste instead of being packed, as no firm with any care for their reputation would put such on the market knowingly. Dust, again, is a prolific source of pinholes on exposed plates. Specks of dust adhere to the film, and protect the part they stick to from the action of the light, and the developer and fixing, of course, develops a pinhole wherever they have been. No plates ought to be placed in the dark slides without first carefully dusting them and the slide too. Backed plates are apt to cause pinholes. Unless extra care is bestowed on them, small particles of the backing get loosened by the springs, and find their way to the surface by the shaking and vibration of travelling. It is an excellent plan to line round the edges of the rebate of the dark slide where the plates fit with strips of black velvet. It will not prevent the backing being loosened, but it will prevent it getting round to the front of the plate. It is a good plan to line with black velvet all those parts that give access to the plates where it can be done without putting undue strain on the slide, for it is a most effectual method of preventing access of dust, which will find its way through the best-fitting woodwork unprovided with such extra protection.

A pad of *cotton* velvet, such as used by hatters for polishing up silk hats, is better than a brush for removing dust from the surface of a plate before putting it in the slide. There is *no fear of scratching* the film even with considerable pressure, and it does not leave it in an electrical condition, as will the frequent passing over the surface of a camel's-hair brush, the film thereby becoming an attractive surface for stray motes. The slides and plates being free from dust, they should be kept in a close-fitting waterproof case until required. We now come to a division of the work where all sorts of defects may be produced *ad libitum*.

Development.—Pinholes are mostly caused by small bubbles which, protecting the film from the action of the developer, dissolve out in the hypo, leaving clear glass. This is, perhaps, the most prolific source of pinholes on the negative of any. The best way to get a good crop of them is to give the plate a preliminary wetting before pouring on the developer. I could never understand why this plan was ever advocated as a preventive of bubbles, as it acts in the very opposite direction, a statement which will be corroborated by any practised worker. What we do when we first bathe the plate in plain water is to partially fill the pores of the gelatine with an inert fluid. We then pour on another fluid (the developer) of a different density. In the act of mixing there is much more tendency to form bubbles than when the developer is used without this preliminary wetting. The film itself is more soluble in plain water than in the developer, which has somewhat of a hardening tendency, and which has probably something to do with the persistency with which bubbles adhere to the previously wetted film. It is almost impossible to avoid bubbles in the weak light of the dark room, unless the whole of the surface of the plate is rubbed or brushed over after the application of the developer to the wetted surface, or the result will be strings of small bubbles that pertinaciously adhere all through the development, and provide a crop of excellent pinholes; but, when the developer is poured carefully over the plate in the *first instance*, it penetrates as it goes something like pouring water over blotting-paper, and causes no bubbles whatever. Every time the *same* developer is used, each application increases the chance of bubbles. The developer becomes more and more glutinous, which will be seen by the persistence of the froth caused by pouring it backwards and forwards from the plate into the developing cup, and with this increase of glutinosity we get increase and persistence of bubbles. A curious thing is that, if the developer only begins to act before the bubbles are removed, their removal then will not prevent the defect, showing, however long the development may be continued, the protected parts never catch up with the rest.

Dust and bubbles are practically the main cause of pinholes on plates. Spots occur from a very different cause, and the use of dry pyro has something to answer for in this connexion, a speck of pyro getting on to a plate will inevitably cause an opaque spot. Splashes of other solutions may accidentally fall on a plate and cause spots; the developing cup may be set down on a sloppy table, and the liquor may drop off the bottom, when pouring on the developer on to the plates, or on the edge of the dish, and so splashing the film. Spots are seldom seen when care is used in the conduct of the dark room, for they are almost always dependent on the carelessness of the operator.

Of course, mistakes are more likely to occur when the operating chamber is only lighted by a small quantity of ruby light, what to many is practically darkness, and the work is really done by guess. The more light, so long as it is a safe light, the better the results will be, and, if the dish in which the development is progressing is shielded as much as possible in the initial stage of development it is astonishing what an amount of light may be used without any detriment to the clearness of the image during the latter part of the process, although I certainly do not recommend exposing the plate unnecessarily to any light whatever. A clear operating room and plenty of light conduce not only to comfort but to the abolition of these annoyances, pinholes and spots.

EDWARD DUNMORE.

NOTES ON A TOUR IN THE HIMALAYAS AND ON THE NORTH-WEST FRONTIER.

II.

THE number of plates to be carried is the next consideration. I made a rough guess, and took with me two gross—one gross of Wratten's ordinary (a plate which never fails in its high standard of excellence for all landscape work), and half a gross each of Edwards' XL celluloid films and Edwards' XL plates. I used the latter for all figure and close subjects, it being a plate that I had always been accustomed to, and which I never had any cause to complain of. This was a rough guess, but it turned out fairly correct, as of the lot only one dozen Wratten's were smashed while being carried on a mule, and one dozen of each kind I left in India on my return, not having required them. I found that, though in the Himalayas I took pictures of everything that I thought would be interesting to give a complete idea of the country, the number of plates I exposed in one day never exceeded eight, and the average over three months' marching was under two a day.

I will now endeavour to give some idea of the details of the kit I used, and which, speaking from experience, I may say I found complete in every respect. I took a whole-plate camera of Chapman's (Manchester), which I have had in continual use for eight years, having used it out yachting in Scotland, in the plains of Italy, and in the mountains of Switzerland. It is of the simplest construction, having no especial struts, and is not brass bound, and, though it will not carry a heavy lens when racked out to eighteen inches in a high wind (what camera will?), yet not one single picture of the 250 I have taken in India has been spoilt by any break-down or shake in the camera or its three double backs. The camera design has one fault, in that the bellows does not rise and fall with the rising front, and in extreme cases the corners of the picture are cut off. When, however, one has to put up and take down the camera so constantly on the march, simplicity and absence of all fancy swings, stays, and screws is the thing one values most, providing no efficiency is sacrificed thereby. Certainly this camera, with its three double backs, speaks well for the soundness of first-class English work, and I can congratulate Messrs. Lane of London, who made it, on the fact that it is now as good as new, while it has never in any way been repaired since I had it.

The only addition I made to my kit was to get three more double slides, numbered from 7 to 12, which fitted tight into a tin velvet-lined box. This was carried by my gun-bearer, always slung over one shoulder by a strap, and was only used to contain Edwards' rapid plates or films, the slow plates always being in slides 1 to 6 in the camera-case. I was thus always ready for either landscape or figure subject as they came. On a march of this kind the portability of the camera legs is not a necessity.

Before leaving London I looked everywhere for a strong, simple set of legs, with a single sliding joint. Not finding anything suitable, I fell back on my old ones, which, though theoretically weak, yet were strong enough to stand the keen winds on the high passes without shaking. The legs were always carried ready fixed to the triangle, with their joints slid in, to reduce them to half their length, the whole being carried on the top of the camera case as it rested knapsack-like on the man's back. In this way I could erect the legs at once, put on the camera, and I found from eight to ten minutes' halt was all that was necessary to get a picture.

Of lenses I took three, an eight-and-a-half-inch focus Dallmeyer landscape, a twelve inch Rose's rapid symmetrical, and an eighteen-inch Swift's landscape. All were fitted with carriers to go into the same flange on the camera front, and all were bayonet-jointed, so that they required only a quarter turn to screw them home. The eight-and-a-half-inch lens is a necessity for all mountainous countries. The angles from the heights to the depths are so enormous, that frequently one can get no picture on one's plate unless a wide-angle is used. The rapid symmetrical remains the most useful all-round lens, and a long-focus lens enables you to take many a beautiful and effective picture of distant mountains, embracing, as it does, an angle much more nearly resembling that of one's eye. All my lenses were fitted with iris diaphragms, and the slight extra expense will be amply repaid in the saving of time these little conveniences effect. I used a shutter of my own making, but any time-and-instantaneous shutter, such as Thornton-Pickard, will do, though, without doubt, it is an advantage to have one's shutter behind the lens. Each lens was carried in a little chamois leather bag, differently coloured, so that the men, in opening the camera case, were always able to hand me out the one I required.

Last, but not least, comes the focussing cloth, which should be of thin white macintosh, lined with some thin non-slippery cloth. The white colour keeps off the great heat of the sun's rays at high altitudes, and prevents the heating of the camera and condensing of the damp on the cold lens. The macintosh is an excellent cover to the camera, and, if buttons and loops are sewn on the front edges, in rainy weather the coolie can take it out of the camera case, and, throwing it over the whole knapsack, can, by buttoning it in front round his neck, use it as a complete waterproof for the camera case on his back and himself. The whole kit in the camera case, including the six plates and the camera legs, made up a load of twenty-three pounds, which is a fair load for a man who marches behind you all day. The other three double-backs, loaded in their tin case, weighed seven pounds, and were, as mentioned above, carried by my gun-bearer. Both these men were permanently engaged, and became soon experts at helping me to set up and pack away the camera, the gunbearer going even so far as to pick up an idea of posing the villagers naturally in the picture, always a work of some difficulty, for, needless to say, the natives' idea is always to stand in a row, at attention, facing the camera. In no country, however, are figure subjects easier than in India; the patience of the natives far exceeds one's own, and they will stand any length of time immovable if carefully posed. Even with the wilder Pathans across the frontier, I had no difficulty in photographing either them or their villages; they seemed only surprised that the operation was over so soon, and a peep through the camera, under the focussing cloth, was the greatest reward to them.

III.

I made for myself a small view-meter, consisting of a small frame of brass, the opening of which was in the proportion of 8½ to 6½. Through, and at right angles to the longest side, ran a stiff brass wire, the end of which was held against the bone just under the eye. By sliding the frame along the wire, which was marked in three places for the three lenses I used, the different angle on the landscape which each lens would embrace was shown, so that, by the time the camera was on its legs, I knew which lens would be required. This view-meter I always carried loose in my pocket, and I found it invaluable.

All my plates were packed as the boxes came from the makers, on edge in two tin-lined cases, each holding about nine dozen plates. This kept the weight of each case down to fifty pounds. I made a dépôt of these in India, and took with me on the march as many plates as I required, packing some four or five of the makers' boxes in each yakdàn, or wooden mule trunk, filling the spaces with clothes. By keeping the weight of each yakdàn below fifty pounds, it can either be carried by a coolie or by mule. The most important packing was, however, the repacking after exposure. In order to be quite safe in this respect, I had prepared, at the kind suggestion of Signor Sella, whose great experience in the Caucasus made his advice invaluable, a number of whole-plate cut sheets of Rivess plain paper. These were dipped in a weak solution of Nelson's gelatine, in which enough chromate of alum was mixed to render the solution a pale greenish colour. The solution must be weak enough not to glaze the paper when dry. Exposed plates, packed face to face with this paper between them, will keep an indefinite time, and those I have exposed six months ago I have now unpacked, and they develop as freshly as if exposed twenty-four hours ago. It is a long business packing away exposed plates. It is most difficult to get a dozen Wratten's plates, with all their paper wrappers, back into the cardboard boxes again. It can be done, however, and it is worth while spending every effort to pack the exposed plates carefully once for all. Two grooved light-tight wooden boxes, each to hold one dozen plates, will be found the greatest help, so that a whole dozen may be opened at once, worked through the slides as required, numbered, and put back into the box. As soon as the whole dozen is worked through, repack all of them, at one operation, into their cardboard boxes. If only one rapidity of plate is carried, one wooden box will suffice; but each rapidity of plate requires its own box, which had better, for convenience sake, be painted a different colour. I wrapped each cardboard box filled with a dozen exposed plates, in brown paper, and then in a sheet of that most excellent Indian Momjáma (cheap waxed calico, bought in every bazaar), which is a good waterproof. Each dozen plates had a label on the outside of the box, with the numbers corresponding to those in the exposure-book. I had no difficulty, in this way, in finding those that I wished to develop first. Finally, on my return to India from across the border, I packed all the boxes of exposed plates again in the tin-lined cases they came out in, and, for safety's sake, enclosed each of these small heavy cases in a larger packing-case, hay being well stuffed between the two.

I will conclude with this advice, that those who go out to bring back a series of photographs of a new country should not confine their pictures only to the prettiest subjects, but should endeavour to take every landscape that is characteristic, even though it be ugly. For instance, all Central Asia (including in this Affghanistan and our own North-West frontier) is a vast barren, stony desert, in which, here and there, where there is irrigation, you find green and fertile valleys, cultivation, fruit trees of all sorts, many of which bowers remind you of an English coppice. One is tempted to pick out these refreshing bits, to leave alone the twenty miles' march over the barren, stony waste, and so bring back to England a number of pictures which convey the idea that Central Asia is a Garden of Eden. In landscapes, as often as possible, get some of the natives of the country to make a foreground, making them look away from the camera, and stand or sit in their natural attitudes. A group of such figures will always localise a picture, add the human interest, and throw back the distance in your landscape by making a bold foreground.

Nothing can add to the interest of travel so much as the wise use of a camera. It makes you observe so much more the characteristics of the country; it takes you off the beaten track in search of something more interesting; it is an excellent passport into native villages and corners, for, children-like, they are all interested in the "picture man," and in return for a few kind words they do all they can to offer assistance; and, finally, it is the best school of all for patience, without which a photographer is no photographer.

F. St. J. Gore, B.A.

PHOTOGRAPHERS' EFFORTS AT UNION.

[Read at the World's Congress on Photography.]

When first I was asked to read a paper before this Congress, I purposed to use the title "Union Among Photographers." A friend objected that if I took that title, and treated the subject truthfully, the paper would be as brief and to the same effect as a certain famous essay, "On Snakes in Ireland," which consisted of three simple words, "There are none!" While this statement is too sweeping to be absolutely true, it contains the germs of truth; so, in deference to my friend's suggestion, I speak of photographers' *efforts* at union.

The subject is such a vast one that I cannot pretend to treat it exhaustively. I shall not trouble you with the reading of the whole, even of the particulars that I have been able to collect and that are contained in the printed slips distributed about the hall. The subject is one that will be taken up, that *must* be taken up, by abler and more leisured writers than myself, and the present is merely a first contribution. It is also a bait thrown out to catch information, and I shall be indebted to any one who will send me additional particulars, or correction of errors that occur in the present brief summary. Such particulars I will endeavour to have published in an English and an American photographic annual.

In order to keep the subject within limits that are at all manageable, I have confined myself almost entirely to professional efforts, and, with one exception, to organizations in the English-speaking world. The matter may well be divided under four heads:—1. Brief historical notes. 2. Efforts now existing. 3. The ideal union. 4. Present possibilities.

The history of the subject is largely a history of failures. But from those very failures we can learn much that will be valuable if we of the present are true to our opportunities. In the history of the subject, both of success and failure, America plays a far more prominent part than the other sections of the English-speaking world, so I give her the first position. The earliest records are those of—

The *Daguerrean Societies*, national, State, and local, which flourished in the '40's and '50's. They were professional bodies, discussed manipulation, prices, &c., and for a time flourished. Gradually jealousy and dissension appeared among them, and before the Daguerreotype was killed the societies formed in its interests had killed themselves.

I have obtained particulars of some forty-five unions, or professional societies, of which no trace appears now to exist, and place their names and brief particulars on record. They are arranged in the order of the earliest dates at which trace of them is found, although some of them were, no doubt, old before the time at which I have met with particulars. They embrace Canadian societies as well as those of the United States. Most of them are defunct, possibly some may feebly exist, and probably many have been merged into amateur societies.

The Photographic Club of New York City, existing in 1845, before professionals and amateurs were separated. Date of dissolution not known. *Photographic Section of the American Institute*, 1859. The oldest now-existing society. Is now purely amateur, though originally largely professional. *San Francisco Photographic Artists' Association*, founded 1866, to remedy price-cutting, and flourished for a few years. *Michigan State Photographic Association*, founded in Detroit, 1866. *German Photographic Society of New York City*, founded 1867; a branch of the Photographic Society of Berlin. Last heard from in 1889. *The Ferrotypers' Association of Philadelphia*, 1868, was a strong and active though small society. Fell to pieces after 1879. *Northern Ohio Photographic Association*, active in 1879, when it attempted, and with fair success, to enforce Sunday closing of studios. *Photographic Association of West Virginia*, founded at Wheeling, West Va., 1869. No subsequent history. *Toronto Photographic Association*, founded 1869 (or early '70). Fell to pieces at once through price cutting by members. *Boston Photographic Society*, founded 1869. Languished till early seventies and was then reorganized on a broader basis as the *New England Photographic Association*, which held several well-attended meetings, with much discussion, but little practical result. *The Indianapolis Photographic Society*, founded 1870. In 1872 became the *Indiana State Association* and flourished for a while. *St. Louis Photographic Association*, founded 1870. *Pennsylvania Photographic Association*, founded in 1870 as a State Association. Had about one hundred members, embracing all the best men, and for a while did good work. *Central Ohio Photographic Association*, 1870. Had no fees or meetings, but had a well-arranged scheme of mutual help by correspondence and the regular exchange of specimens of work. *Brooklyn Photographic Artists' Association*, 1872. Met regularly at various studios for a time. *Photographic Association of Western Illinois*, 1872. Had quarterly meetings. *Photographers' Association of District of Columbia*, founded Washington, 1872. *Maryland Photographers' Association*, Baltimore, Md., 1872. *Buffalo Photographic Association*, founded 1873. *Northern Michigan Photographic Association*, founded 1874, and held meetings to draw up a constitution, but did little else. *Photographic Artists' Society of the Pacific*, San Francisco, 1875. Had some fifty members, but died ere long. *Chicago Photographic Association and Photographic and Fine Art Institute of Chicago.* Were active in 1881; founded some years before. No record since 1889. *Chicago College of Photography*, first session announced 1881. Apparently a good scheme, in theory at any rate, for a college for training professional assistants. No record since 1881. Gayton A. Douglass, Treasurer. *Photographic Society of Nashville, Tenn.*, founded 1881. *Photographic Stock Dealers' Association of America*, founded at Cleveland, O., 1882. *Rochester (N.Y.) Photographic Association*, founded 1883. *Detroit (Mich.) Photographic Association*, active in 1883. No later record. *Northern Michigan Photographic Association*, in existence in 1883. *Photographers' Association of Syracuse (N.Y.)*, founded 1884. *Photographic Association of Fort Wayne (Ind.)*, founded 1885. *Photographic Merchants' Board of Trade*, held its seventh meeting in February, 1885. No later record. *The Secret Order of Scientific Photographers*, founded in Minneapolis in 1885, and issued a printed constitution. Was intended to include all professional photographers, assistants, stock dealers, and manufacturers in America. Last record, 1886. *Jackson (Mich.) Photographers' Union*, founded 1886. *Association of Operative Photographers of New York City*, had an employment bureau and held social and business meetings. Formally dissolved in 1886, after a long and useful career. Cause of dissolution: lack of interest. *Pottsville (Pa.) Photographic Association*, founded 1886. *Texas Photographers' Association*, founded 1887. Held one (or two?) conventions. No record since 1889. *Kansas State Association of Photographers.* Held a convention at Wichita (Kans.), 1888. No later record. *Southern Tier of New York Photographic Association*, founded 1888. Met at various towns. No record since 1890. *Toledo (Ohio) Photographers' Association.* Last record 1890. *Photographers' Association of Lancaster (Pa.)*, founded in 1891. Held one or two meetings. *United Retouchers' Association*, founded, St. Louis, 1892. Intended as a national union with local centres. No records.

To this list I suppose I must add that ill-fated Association which seemed to start under good auspices, but which turned out a fraud rather than a failure, and which has done much to increase the distrust with which many photographers regard all efforts at union. The Photographers and Artists' Mutual Benefit Association. It is to be regretted that such a promising association was not honestly worked, but I think it is more to be regretted that the large number of good and honest men who joined it had so little cohesion as to allow a valuable scheme to be wrecked by the treachery of one or two men.

From the British side I have no such record, partly, no doubt, because I have unfortunately been able to devote but little time to investigation, but mainly because there have not been the numerous efforts. Unions and combinations have often been suggested, but seldom formed. In fact, there are only two of any importance that I can record as failures. The first of these was—

The Photographic Manufacturers and Dealers' Association, founded in London, 1891. It arose out of an informal meeting of photographic advertisers called to take concerted action against one of the photographic magazines. It became a trade-protection society, employed a paid secretary, and opened and furnished an office in London. It made status inquiries, collected bad debts, and held meetings to settle questions of discount and prices. Through jealousy and mutual distrust it broke up within a year.

The Photographic Artists and Assistants' Union, founded in London, 1891. Was intended as a trades union on the ordinary lines, to grant sick-pay, burial-money, and out-of-work grants to its members; to keep registers of assistants, to act as an employment bureau, and to generally work in the interests of the assistants. It held preliminary meetings and drew up a constitution, but only some thirty odd applications for membership were received, so the society never floated.

From other parts of the English-speaking world I have records only of two spasmodic efforts. In 1891 the photographers of Christchurch, N.Z., formed a successful combination to stop price-cutting. And in the present year a number of the Australian photographers made common cause with other members of the public to expose and ruin the free portrait swindlers.

Efforts now Existing.

So far as I am aware, the efforts at union existing at the present time, and likely to be of use to professional photographers, are:—

1. The Photographers' Association of America, with the various State associations, which I consider as its auxiliaries.
2. The Photographers' Association of Canada.
3. The National Association of Professional Photographers.
4. The Photographic Convention of the United Kingdom.
5. The Photographers' Benevolent Association.
6. The Affiliation of Photographic Societies, in connexion with the Photographic Society of Great Britain.
7. The International Photographic Congress.

A very brief outline of the history and constitution of these societies may not be out of place.

1. *The Photographers' Association of America* (Secretary, Adam Heimberger, New Albany, Ind.) may be said to be a continuation of the National Photographic Association founded in Philadelphia in 1868, after a preliminary convention in New York in 1867. The National Photographic Association was a strong and useful association, which fought patent claims, circulated special formulæ, helped the needy, and took up such questions as apprenticeship, insurance, &c. At one time it had 1500 members; it held conventions in various cities, and did much good until 1879, when it practically expired, and in 1880 was merged in the present Photographers' Association of America. The new Association has not been conducted without great friction. Its membership at present is stated as 2936 and the average attendance at its annual conventions (1885–91) has been 588. It has grand and noble objects, few of which have been attained or attempted, mainly (apparently) owing to unsatisfactory management in the past.

Among the State Associations which I consider as its auxiliaries are:—

The Photographers' Association of Ohio, founded 1891, and absorbing the *Photographers' Association of North-Western Ohio*, founded in 1890. It has some two hundred members, and appears to be flourishing. Holds an annual convention.

Photographers' Association of Iowa, founded in 1890. Holds annual convention. Is not so successful as the above-named. Has about one hundred members.

Photographers' Association of Nebraska, founded 1890. Holds annual conventions. Not well supported.

2. *The Photographers' Association of Canada*, founded 1884. Holds annual conventions, and seems flourishing.

3. *The National Association of Professional Photographers* (Secretary, D. J. O'Neil, 47, Charlotte-street, Birmingham, England). Founded 1891, in the interests of the profession. Holds meetings about once a quarter, in the principal English cities alternately. Has some one hundred and sixty members, including most of the best British professionals, but has not done much practical work, owing to the small extent to which it has been supported.

4. *The Photographic Convention of the United Kingdom* (Hon. Secretary, F. P. Cembrano, Cambridge-gardens, Richmond-on-Thames). Founded 1886. Holds an annual convention for reading of papers and

discussion, exhibition and excursions. The "social element" has become predominant. Membership, two hundred and fifty to three hundred.

5. *The Photographers' Benevolent Association* (Hon. Secretary, H. Snowden Ward, Memorial Hall, London, E.C.). Suggested by Mr. A. H. Wall in 1864, but not founded until a meeting of assistants was called in 1873, when a Photographers' Benefit Society was established. At a later date it became purely benevolent. It does considerable good in a quiet way, derives most of its funds from manufacturers and amateurs, and dispense them entirely to professionals and assistants. Has been generally neglected by the profession. Has a fund of nearly 400*l.* in hand, and has the making of a valuable insitution.

6. *The Affiliation of Photographic Societies* (Secretary) R. Child Bayley, 50, Great Russell-street, London, W.) An affiliation started by the Photographic Society of Great Britain, and consisting of a number of amateur and mixed societies, might prove a valuable factor in a comprehensive scheme of union.

7. *The International Photographic Congress.*—Suggested by the jury of the Brussels Photographic Exhibition, 1885. Initiated in 1886, with the King of the Belgians as patron, but did not meet until 1889, when a Congress was held in connexion with the Paris Exhibition. A second Congress was held in Brussels in 1891. On both occasions large Congresses of the best-known photographers devoted several hours a day for several days to the careful discussion of various practical questions, and made recommendations as to standards, &c. Of the intrinsic value of their work there can be no doubt, but to English-speaking people it has been rendered practically useless because they have not been adequately represented, and because the Congress has no adequate means of conveying to them the results of its deliberations. These difficulties would be at once cleared away under a scheme of union that embraced federation with the Congress.

These Societies, as they stand, do not furnish the materials for

The Ideal Union.

And, in order that we may see what can be done towards attsining the ideal, it will be well for me to state what the ideal seems to be.

In each country there should be:

1. A National Association, including as sections or affiliated Societies:
   - *a.* A manufacturers' and dealers' union.
   - *b.* A strictly professional union.
   - *c.* An assistants' union, on benefit-society or trades-union lines; and
   - *d.* State, County, or District Associations, and, where possible, Town Associations, affiliated to the National Association and directly represented in its management.

And, in addition to these, there should be an International Union, with a separate section for dealing with professional questions, but also including the fullest possible representation of amateur societies and workers, for combined conference on all subjects that are of interest to amateurs and professionals alike.

This brings us back to

Present Possibilities,

And to a consideration of what ought to be attempted forthwith for the realisation of the ideal.

1. In the United States, the increase of State and other local associations, and their affiliation with the Photographers' Association of America should be encouraged as far as possible. The possibility of reviving or forming a Dealers' Association and an Assistants' Union, either independently of or within the Photographic Association of America, should be carefully considered. The formation of a benevolent or a provident fund, or both, should be taken in hand.

2. In Canada, the Photographers' Association of Canada should work on similar lines.

3. In Britain, the National Association of Professional Photographers should be immensely strengthened and every effort made to increase the number of its local branches. It should consider the possibility of forming an Assistants' branch, or of encouraging the formation of a separate Assistants' Union; and it should give what attention and assistance it can to the Benevolent Association, as to an institution which ought naturally, and is likely eventually, to be under the control of the National Association. The effort made last year to co-operate with the Convention should not be relinquished, even though it did prove a partial failure; and the advantages offered by the affiliation scheme of the Photographic Society of Great Britain should not be overlooked.

In India, Africa, Australia, New Zealand, and elsewhere attempts should be made to form professional societies similar to those above mentioned. Every such effort should be encouraged and aided as far as possible by the older associations.

Finally—

An International Union

is much needed, and, as it is always economy to use existing institutions rather than to create new ones, I would suggest that a great effort be made to have at least one delegate, and, of course, as many more as possible, from each of the national associations in attendance at the International Photographic Congress. Though that Congress at present is rather scientific than professional in its tendency, most of its subjects of discussion are of great practical importance to the professional worker. Moreover, any subject suggested by delegates or by the societies they represent would be accepted for consideration; and, if even two or three professional representatives joined, there would be no difficulty in arranging a separate professional section.

The suggestions that I make as being immediately practicable are not novel; they are not revolutionary. You will see that I almost entirely suggest procedure on present lines. The only new thing that I ask is that photographers will consider their present societies not only as ends in themselves, but also as means to a greater end. There is much to be done in perfecting the machinery before we can hope for much in the way of results, and the work must be done in the good old-fashioned way, "line upon line, precept upon precept; here a little, and there a little." That much could be done by the ideal Union no photographer doubts. But many, the immense majority, look upon the thing as Utopian. And so it is if we are to wait until the whole is in our grasp before attempting to realise it. This has been the bane of too many photographic efforts at unity. It is their bane to-day. The men who should support them, and often the men who do support them, are unable to do the things that they would, and unwilling to do the things that they can. For the great things they are powerless, and the multitude of little things that they can do they despise. But in our present unions there is so much promise that we ought to feel encouraged to trust and to work for the future. And this year, when international courtesies are being exchanged, when parties of Old-World photographers have been visiting this New World, and when this series of congresses is holding up the ideal of unity, I have felt that we could have no better or more profitable subject of discussion than "Photographers' Efforts at Union." It may be that from our deliberations some practical good may spring. I should like, if possible, to have some resolution sent from this Congress asking the various bodies that I have named to consider what is possible in the way of federation, immediate or prospective; and, even if we have no practical photographic result, I trust that our meeting may twist one small strand in the tie of fellowship that binds the nations, and help us one step nearer to

"The parliament of man,
The federation of the world."

H. Snowden Ward.

ADAMS & CO.'S TWIN LENS IDEAL CAMERA.

Since we, in May, 1891, described Adams' Ideal camera, it has been subjected to several improvements, one of which is hinted at in the heading of this article, and which is of such a nature as may be termed revolutionary.

The leading feature in regard to improvements consists in this: that, whereas the first, or original Ideal contained two finders of the usual small class so well known, as being constructed with a mirror placed at an angle by which the image was shown upon a small ground-glass plate, in the new form the image is thrown upon a white plaque, which reflects it into the eyes of the observer with a singular degree of brightness. But, in order to this, the extraneous light must be prevented, in as large a measure as possible, from falling upon this receptive white plaque, which, we may observe, occupies the same plane as does the sensitive plate in a lower compartment of the camera.

The construction is such that the Twin Lens Ideal is really a double camera, one above the other, and, so far as admission of light is concerned, the one is entirely separated from the other. Both, however, have lenses of identical focus. When operating, the photographer keeps his eyes upon the reflected image in the upper compartment, which, by the folding arrangement shown in the cut, he is enabled to do through a slot without light having access. The moment the object is seen in proper position and sharp focus, the "button is pressed," and the picture is taken.

As there is a similar folding hood on the side, it follows that the full-size picture is seen both ways, both horizontally and vertically. The front, on which the lenses are fixed, is movable in both directions, rising and cross.

The shutter is one of the class which requires no setting. It has a pneumatic release, and is marked in speeds varying from a second to the one hundredth part of a second. Of this shutter it is here enough to say that it has been specially designed for this camera, and is fitted with a patent pneumatic regulation, which permits of exposures being made with certainty and exactness. It works in the diaphragm slot, and has a direct movement across the lens.

Taken all in all, it is an instrument of which Adams & Co. may well feel proud.

Our Editorial Table.

The "Birmingham" Dry Collodion Plates.

Birmingham Dry Collodion Plate Company, Stechford, Birmingham.

We have received samples of the Birmingham Dry Collodion Plates; "yellow label" for landscapes, and "green label" for line transparency work. We find on trial that the landscape plates are of medium rapidity and with pyro-soda development are capable of yielding negatives of excellent quality, having all the characteristic features of a good collodion plate. The makers say:—

"These plates being isochromatic, should only be developed in a ruby light, ordinary canary medium alone is unsuitable.

The exposure required is about the same as that of the best gelatine plates on the market.

These plates while wet being soft and pappy like wet collodion, must not be touched or brushed during development. They may be put straight into the developer, *i.e.*, without previous wetting; the latter does not recede from the surface as in the case of gelatine, neither do any air-bells attach themselves to the film.

Enough developer should be used in a suitable dish to keep the plate always well covered with the developing solution.

All the customary reducing agents, *e.g.*, iron, pyrogallol, hydroquinone, eikonogen, can be used, but ammonia is not so good an accelerating agent as the fixed alkalies, and the latter, inasmuch as they allow less exposure to be given, are therefore to be preferred. These plates can be built up with silver and pyro, after fixing, as in the old collodion process. The temperature of the developing room and solutions should not be below 60° Fahr."

A very useful panoramic album has been made, in several sizes, by Messrs. Percy Lund & Co. It is shown, opened out, in the cut. There are slots in each corner of the leaf under which the corresponding corners of the photograph are slipped, thus dispensing with further mounting. A series of portraits or landscapes can, by its means, be instantly displayed. This is a new series, differing in some respects from one of a similar nature we noticed some time ago.

News and Notes.

Photographic Club.—September 6, *Toning Baths*. 2, Outing to Sutton.

Northern Photographic and Scientific Association.—September 2, Chingford.

Manchester Amateur Photographic Society.—September 2, Lower Peover. Leader, Mr. Davenport.

Hackney Photographic Society.—September 5, Open Night. Members are requested to bring up questions, &c. Morley Hall has been secured for the Exhibition for October 17, 18, and 19. Members' classes will be—1, Not previously medalled; 2, Lantern slides; 3, Hand-camera pictures (enlargements permitted); 4, "Excursion" class.

Gosport Photographic Society.—September 2, Bosham; leaves Portsmouth Harbour at twenty minutes past one p.m.

Tooting Camera Club.—September 21, *Stereoscopic Photography*, Mr. Dollery. October 12, Members' Exhibition of Prints. 26, *Artistic Photography*, Mr. Berger. November 9, *The Sandell Plate*, Mr. Fry. 23, *Double Printing*, Mr. Child.

East London Photographic Society's Exhibition.—This Exhibition will be held at the New Tabernacle, Old-street, E.C., on Monday and Tuesday, October 30 and 31. There are six classes, two of which are open to any amateurs. The prints sent in for competition will be judged by two Judges, who will be nominated by the Editor of the *Amateur Photographer*, after they are sent in, which must not be later than October 10, 1893. The open classes are—Class E, General Photography; and Class F, Lantern Slides. There is an entrance fee of one shilling in each case. A silver medal, bronze medal, and certificate will be awarded in each of these classes. Applications for entry forms must be accompanied with a stamped directed envelope, and sent to the Hon. Secretary, Walter R. Gould, 61, Gibraltar-walk, Bethnal Green, London, E.

"Dagonet," of the *Referee*, is so hard up for matter that he has to give his readers an account of a trip to Portsmouth. He saw the *Victory* there, and professes to be shocked at the sale of photographs on "the grand old sea cathedral." In what way the sale of "cheap photographs" "desecrates" the deck of the *Victory* Mr. Sims does not explain. People with the liver complaint say—and write—funny things. "I saw the spot where Nelson fell, and the cockpit where he died, and the guns that were used on that memorable day, and many a relic of the ever-glorious past; but, do what I would, nothing seemed *real* to me. It was a show—a Portsmouth side-show—and when we came to a table spread out with photographs, 'one shilling each,' I felt inclined to cry out to the crowd of holiday-makers behind me, 'England expects that every man this day will do his duty,' and then explain to them vaguely that I considered it an Englishman's duty to take that table of photographs by storm and cleanse the sacred battleship of England's greatest naval hero from such an iniquity. I hated these photos—loathed them. They made my blood boil. I went down, all alone, to the place where Nelson died, and I apologised to his shade for those photographs. To me they were vandalism of the vilest kind. Let us give tips to the guides; let us pay a fee; let us do anything; but, oh, my brothers, sons of Britannia, heirs of Trafalgar's deathless fame, do not let us desecrate the deck of the grand old *Victory* with a stand of cheap photographs, to be sold for the benefit of somebody or other. If we do, why not have apples, and nuts, and ginger-beer sold on board, and put up a set of put-a-penny-in-the-slot-and-the-figures-work boxes, and a try-your-weight machine, and have all the fun of the fair? If the photographs must be sold in connexion with the *Victory*, then let the naval hawkers of them pitch their stand on the hard. They will do quite as good a trade there—probably even a better one. Britons!—ye in whose veins the blood of the old Vikings flows—on board the grand old *Victory* they first show you the spot where Nelson fell, and then ask you to buy a shilling photograph! Shall this thing continue? No! Rather will I be an indignation meeting all by myself, and meet—show me a more appropriate place—in Trafalgar-square, under the shadow of the Nelson Column, and call upon the Lords of the Admiralty to surrender those photographs or perish."

PATENTS COMPLETED.

Improvements in Means for use in producing a Plurality of Photographic Images on one Plate.

No. 13,241. Thomas George Hemery, 13, Hanover-street, Peckham, Surrey.—*July* 19, 1893.

This invention relates to the production of a plurality of portraits on one plate, obtained by successive exposures on the same plate without removal from the dark slide, each and every one separately exposed, as in the case with an ordinary portrait, with or without a subsequent exposure before development of the ground surrounding the portraits, the same being plain or ornamented according to will. This is effected by a screen pierced as the combination of photographs requires, and held in position within the camera on a permanent support as near as may be to the dark slide, such screen giving place to others for other combinations. Each space in the screen is covered by a disc, which, on removal, leaves a vacant space suitable for the exposure of a portion of the plate, and, on being replaced, protects it so that each space may be successively exposed. The lens must be centred on each particular space by the usual perpendicular and horizontal sliding fronts, both slides being carried beyond the margins of camera to allow the lens to travel to every corner.

When the spaces are all exposed, the negative when developed will have a series of portraits on an unexposed ground. That part may be masked in the ordinary way, and the portraits printed with no further trouble, after effects being by double printing as with an ordinary negative. The unexposed portions may be further exposed, and the after effects done on the negative before development in the following manner:—A thin card replique of the above screen, without any discs, must first be placed in the dark slide, angled to secure future correctness always in one, say, the left-hand corner of the slide, and upon it, also angled in the same corner, is placed a sensitive plate. It is exposed to gas, or diffused light, and developed. When dry it is kept for future use for any number of plates, and is the shield of that particular series. The same replique must be again angled in the same corner, and a sensitive plate, similarly angled, placed upon it. The exposures being made, the plate is lifted in the dark room, and the card replique replaced by shields, both plates being angled as before. The series of developed discs on the shield fit accurately the exposed portions of the superimposed plate, and protect the portraits from the momentary exposure to gas. Subsidiary effects can be introduced by paper negatives or positives, litho prints or devices, signatures, mottoes, birth-dates, and the like, by interposing before the exposure to gas, the position being easily determined by fitting the same on the shield by daylight. Each camera will require a special frame or holder fitted in to receive and hold the new screen. The supplementary exposure need not necessarily be made in the same dark slide; any will do, provided that the shield be angled in the left corner, and the exposed plate similarly angled on transfer from its proper dark slide.

An Improvement in the Manufacture of Sensitive Plates or Films for Photographic Purposes.

No. 12,304. Francis William Edwards, 87, Bellenden-road, Pecham Rye, S.E., and Harry Ransom, 122, Newington-butts, S.E.—*July* 22, 1893.

Our invention relates to an improvement in the manufacture of sensitive plates for photographic purposes, and its object is to give a grain, stipple, or line to the pictures printed therefrom, and also to diminish the liability to halation and solarisation (or reversal of the image), which are incidental to photographic plates prepared in the ordinary way.

By employing plates made according to our invention, it is possible to produce photographs in which the subject appears as a series of fine lines or dots, instead of the usual flat tones, thus obtaining in the one operation of printing the special character required for photo-mechanical reproductions.

Our invention consists in giving to the surface of the sensitive film, or its support, a series of fine lines or dots by any of the ordinary printing or stencilling methods, preferably by a specially prepared roller, or a perforated plate. These lines or dots, consisting of a suitable medium, will thus allow the action of the light on the sensitive parts only, and hence the resulting negative will appear as a series of fine lines or dots.

By this method of graining the negative, with a medium easily removable, in whole or in part, after development, the light and shade of the print can be modified as required.

This lining or graining of the sensitive surface will also have a tendency to break up the rays of light reflected from the surface of the support of the sensitive medium, and thus prevent halation or solarisation.

The claim is:—The preparation of sensitive photographic plates or films, with a grained, dotted, stippled, or lined surface, such lining or stippling consisting of any suitable medium applied by any mechanical or other method.

The Employment of Diamidodioxybenzol in Combination with Sulphites of the Alkalies for Developing the Latent Image in Layers containing Halogen Silver for Photographic Purposes.

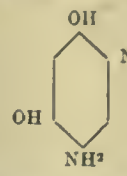
No. 22,576. Julius Hauff, Feuerbach, near Stuttgart, Germany. *July* 22, 1893.

This invention relates to the employment of diamidodioxybenzol for developing the latent image in layers containing halogen silver for photographic purposes, consisting in dissolving, in suitable proportion, in water, diamidodioxybenzol with soluble sulphites, or with soluble acid sulphites, to which latter if added the quantity of soluble bases or carbonates required for the purpose of neutralisation, so as to obtain solutions ready for developing purposes, the action of these solutions being intensified by the addition of a few drops of preferably a five per cent. solution of a carbonate of the alkalies, and enfeebled by the addition of a few drops of an acid solution, or of a few drops of a solution of bromide of potassium.

The orthoamido compounds of the phenols and cresols have not yet been utilised as developing substances for photographic purposes, nor have they been as yet included in patents referring to such purposes.

Without the use of caustic or carbonated alkalies, they are too weak bodies for reduction purposes in order to bring out the latent image, while, if such chemicals are used, they are too energetic as reducing means, and impart a black colour to the whole image.

As a result of my experiments on the preparation of such developing substances which develop the image in weak acid or neutral solution, I have discovered that, by introducing a further amido group in amidophenols which only operate in alkaline solutions, these amidophenols will be able to develop with sulphites only, and that my opinion is capable of the most extensive generalisation. The chief representative of this new group of developing substances is the already patented diamidophenol, which gave me, since the short time that it has made its appearance in the market, the most conclusive proof of its sterling properties for developing purposes. The theoretical testing of other substances under consideration led me to the thought that, by doubling the OH : NH^2 = I : 2 group in the benzol kernel, I may be able to likewise double the developing power, which is not very great, if the above-mentioned orthoamido compounds are employed for developing without carbonates of the alkalies, so that the said orthoamido compounds may be able to develop the image with sulphites only. In testing these orthoamido compounds, the substance of the following constitution presented themselves in the first place:—



that is to say, a diamidodioxybenzol, with two hydroxylamido groups existing together in the ortho arrangement. As a matter of fact, this compound is a very advantageous developing means, which, without the use of caustic or carbonated alkalies, slowly developes the latent image in from three to four minutes, with a deep coating and fine details or outlines. It develops much more slowly than the diamidophenol developing agent, a fact which may be already expected from the other grouping of the developing radicals. For many purposes, however, this is a distinct advantage over the diamidophenol developing agent to which I have given in commerce the name of amidol. Moreover, the new developing means unites the advantage of the dihydroxyl developing means, *i.e.*, a deep black colour, and covering with the advantage of the hydroxylamido developing means, that is to say, clear work, sharply outlined in all its details, and entirely free from mist or haze, without requiring the use of caustic or carbonated alkalies, which are injurious at many points of view.

Example.

In 100 parts of water I dissolve 0·5 parts of diamidodihydroxybenzol and eight parts of crystallised sulphite of soda. With this solution, several successive developments may be effected. To intensify this development, I may use a concentrated solution of a sulphite or a few drops of a five per cent. solution of potash in water, whereas, to retard the development, a few drops of an acid, or of a five per cent. solution of bromide of potassium, may be used.

To obtain greater durability for the solution, I may use, instead of a neutral sulphite, an acid sulphite of soda, only it would be necessary in such a case to add, before developing, the required quantity of a base, or of a soluble carbonate, to neutralise the double sulphite of soda.

The claim is:—The employment of diamidodioxybenzol for developing the latent image in layers containing halogen silver for photographic purposes, consisting in dissolving, in suitable proportions, in water, diamidodioxybenzol with soluble sulphites, or with soluble acid sulphites, to which latter is added the quantity of soluble bases or carbonates required for the purpose of neutralisation, so as to obtain solutions ready for developing purposes, the action of these solutions being intensified by the addition of a few drops of preferably a five per cent. solution of a carbonate of the alkalies, and enfeebled by the addition of a few drops of an acid solution, or of a few drops of a solution of bromide of potassium.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

AUGUST 24.—Mr. E. H. Baystoo in the chair.

The Hon. Secretary passed round an album containing views of the Tower of London, which he had recently taken as a guide, to the members visiting there on the following Saturday.

METOL AND GLYCIN.

The subject of the evening, "Demonstration by Mr. Morgan (Messrs. Fuerst Bros.) of Development by Metol and Glycin," then commenced.

Mr. MORGAN said that as glycin was slow and peculiar in its action, and therefore not a fit subject for demonstration in public, he would proceed at once with metol, which he said was a suitable developer for bromide prints, negatives, and lantern slides. The mixed developer did not stain the fingers, although the dry powder would do so. The solutions used and recommended were as under :—

SOLUTION A.

Water	100 parts.
Metol	1 part.
Soda aulphite	10 parts.

SOLUTION B.

Water	100 parts.
Carbonate potash (or substitute)	10 ,,
Crystallised carbonate soda	20 ,,

3 parts A to 1 of B, with 40 minims of bromide of potassium solution (1 : 10) Metol had a great advantage over other developers, inasmuch as it would keep indefinitely, even as a one-solution developer mixed with free alkali. The exposure was stated to be only one-half of that for pyro. With a normal exposure, the image comes up quickly ; but the operator must not be frightened, but allow it to go on until density has been obtained ; the shadows will always remain clear. Two negatives were passed round, one developed with pyro and one with metol, also prints therefrom.

Mr. Morgan then successfully developed a portrait negative exposed that afternoon at thirty minutes past three (half a second with *f*-11), also a bromide print and lantern slide, the latter being developed with the same solution as the bromide.

Answering a question, Mr. MORGAN said he always used half a grain per ounce of soluble bromide.

Mr. W. E. DEBENHAM said it was a pity that the two negatives shown were not the same density, so that no strict comparison was possible. The same claim of lessening the exposure had been made for all the new developers, and if in this case it could be substantiated, then metol would be the best developer we had.

Mr. EVERITT said that, of the two negatives one was yellow and the other blue ; also, that by printing on gelatino-chloride paper the thinner one was favoured. Platinum would have been better for the pyro print.

The CHAIRMAN remarked that by not giving the same exposure the advantage in this direction was not proved.

Mr. EVERITT suggested test-exposures as between pyro and metol—that is, stepped exposures to a standard light.

Mr. DEBENHAM suggested the reproduction of a negative by a standard light in order to corroborate the other experiments.

Mr. MORGAN said that the pyro negative passed round was exposed and developed in normal time with a normal developer. The metol one was exposed simply one-half the time, and resulted in better gradation and longer scale.

Mr. FRY said that he could not agree with Mr. Morgan on the question of exposure. He liked colour in a negative, and not a blue one. If a pyro negative was under-timed, then a hard result was obtained ; but, with metol and amidol, the negative was thin, and might give a passable print. He thought that a false conclusion had been arrived at.

Mr. DRAGE saw a great advantage in the cleanliness of metol. It could be used four or five times.

Mr. MORGAN had developed eight half-plates in the same two ounces of solution, when the last was the same as the first.

The CHAIRMAN in proposing a vote of thanks to the demonstrator said he liked metol, as it was clean and useful, except for negative work.

This was carried by acclamation, and Mr. Morgan briefly responded.

In answer to a question by Mr. Haddon respecting "Pepperine," introduced some years ago, Mr. BOLAS said particulars would be found in THE BRITISH JOURNAL OF PHOTOGRAPHY, about 1886. He believed it was an alcoholic tincture of pepper.

Hackney Photographic Society.—August 22, Mr. Beckett in the chair.—Mr. Roder showed a print he had toned using carbonate of soda, but it was not clear. Mr. T. H. Smith showed some work done on Nikko paper, with which he was much pleased. Mr. Roofe had used metol, and obtained plenty of density, Mr. NUNN complaining of lack of colour in amidol. Mr. MILLER, of the South London Society, then gave an interesting account of photographic mirrors, finally concluding with a demonstration of how to do it. For reversing work, mirrors are very useful, and for zinc an absolute necessity. Mirror making was best done in the daylight. The glass must be chemically clean, and ought to be optically worked. The bath must be under 60°, and distilled water must be used. The solutions used were ten per cent. solution of white loaf-sugar in distilled water, and to it one-tenth part ordinary alcohol and one-half per cent. nitric acid. Take three ounces of solution, and add four ounces of distilled water, and to this, in turn, seven drachms of reducing solution, made up of ten per cent. of nitrate of silver. Add drop by drop to bath mentioned until precipitate is formed, which redissolve by gradually adding ammonia. Then add three-quarter ounce of ten per cent. freshly made solution of caustic potash. Then add more ammonia as before, and, when cleared, it is ready for use. In twenty minutes glass will be coated, which must be first washed in acid, followed by distilled water, and dried in blotting-paper.

East London Photographic Society.—General Meeting, Mr. Uffendall in the chair.—Mr. BENNETT read a paper *Upon the Desirability of Adapting the Printing Process to the Subject and Quality of the Negative.* The lecturer illustrated his remarks with some prints, showing that what would make a good picture upon one kind of paper, upon another would be an utter failure. He remarked upon the disappearance from the walls of the exhibitions of pictures printed upon the albumenised paper, and said that the impurities and unstapleness of the paper was the reason. He congratulated the present generation of photographers upon the advantage they have over those of the past, inasmuch that, whilst the older generations only had the one process, the present had an almost unlimited choice. He further said that the aim of all should be to portray, as accurately as possible in the finished print, the natural tone of the subject which forms the negative, for, by so striving to this end, we are distinctly upon the threshold of colour photography. In conclusion, he said that the following maxims should not be forgotten :—"Never print from a weak negative upon a paper which is adapted more particularly to one of greater contrasts ;" "Let your print be finished off in such a way as to harmonise with the subject ;" and, lastly, keeping this well in mind, "that colour, like distance, lends enchantment to the view," and only by a careful study of the several points can we attain to anything approaching perfection, and justify our claim (though by many it is disputed) that photography is an art.

Croydon Camera Club.—A whole day devoted to practical photography in the field was spent by a party of the members under the guidance of the President (Mr. H. Maclean, F.G.S.) on August 23, the locality chosen being on the borders of Ashdown Forest. In the course of the day the ruins of Brambletye were visited ; the Medway, which is here little more than a runnel, nevertheless afforded subject matter for several views. The village of Forest Row, containing a number of old timbered, and also some stone-roofed cottages, received due attention. In the after part of the day Mr. Maclean gave a practical demonstration in composition, the subject being *The Wood-workers.* Later, Wych Cross was reached, and members being by this time somewhat satiated with the scenic attractions, a pleasant tramp back through the forest glades and over the golf links to the Brambletye Arms was made.

Birmingham Photographic Society.—August 22, the President (Sir J. B. Stone) in the chair.—The PRESIDENT distributed to the successful competitors the prizes and certificates gained at the last annual exhibition. In the course of a few well-chosen remarks, he said that personally he deprecated the giving of any prizes, from the point of view that it was almost impossible for judges, however skilled, to decide which were the absolutely best pictures, some being superior in technique, some in artistic feeling. Let photography be a useful record, not a mere striving after prizes. The President congratulated the members on the second Warwickshire Survey Exhibition, now being held in the Corporation Art Gallery, and bade them continue with this useful movement.

FORTHCOMING EXHIBITIONS.

COLOUR PRINTING IN HALF TONES.

To the Editor.

SIR,—In your "American Notes and News," p. 543, you state that Kurtz, of New York, has "patented a process of printing half-tones in colours by carrying out the idea of the three primary colours, and using blocks in which the grain runs in lines of different directions." If this is a fact, Mr. Kurtz is making a bold attempt to appropriate a method which I devised and carried out successfully twelve years ago. Nobody seemed to be able to realise the significance of such a result by such a method at that time; but when I exhibited the same reproduction at the Novelties Exhibition in Philadelphia in 1885 it received some notices in the local newspapers, and I remember that one of these notices was reproduced in one or more of the photographic journals.

The specimen referred to—a reproduction of a chromolithograph, accompanied by printed descriptive matter—occupied a conspicuous position by the side of exhibits of my patent half-tone block process and chlorophyl process of orthochromatic photography. Mr. Kurtz had an exhibit of portrait work in the same section, a few feet away, and I have no doubt that he saw and studied this reproduction by a method which he now claims as new and original.

Mr. Kurtz's recent specimens are more remarkable than the one I made in 1881, chiefly because he selected more striking subjects, made larger plates, and printed on enamelled paper, which does not deprive the coloured inks of their gloss and transparency like the soft plate paper universally used for fine printing in 1881.

If this process had been really capable of successful commercial operation on a large scale, the firm with which I was connected would have gone into it ten years ago; but while it is possible to produce wonderfully effective specimen prints, the quality of the work becomes so uneven and generally bad under the present conditions of commercial printing, that it does not give satisfaction even when the printing plates are perfect. A striking proof of this is found in the result of the Kurtz Company's first attempt to illustrate a periodical with reproductions of colour sketches supplied by the publishers for the purpose. In the "Outing" number of *The Christian Union* (New York), June 10, p. 1143, some of Mr. F. Hopkinson Smith's beautiful colour sketches of the scenery of the Bronx River are "reproduced," in a manner that must have surprised the artist, to say the least. I would advise anybody who contemplates undertaking this kind of work to see these results before doing so, and I would also like to know the Editor's opinion of them.—I am, yours, &c., F. E. Ives.

116, *Charing Cross-road, London, W.C., August* 28, 1893.

[The example of the Kurtz Company's process of Coloritype sent by Mr. Ives is not only sufficiently poor to deter any one from undertaking it commercially, but cannot possibly have done justice to the originals. The colours and tones are, to say the least of it, crude and false: for example, green foliage on a river bank being expressed in red where reflected in water, though this may be due to bad printing. Mr. Ives' specimen made twelve years ago is of its kind infinitely better than the more modern example.—Ed.]

PLATINOTYPE TONES ON GELATINE PAPERS.

To the Editor.

Sir,—Some of your readers may be interested in a simple process of obtaining platinotype tones on gelatine papers by means of the ordinary combined bath, as used for Eastman's Solio paper.

I had toned some prints in this bath and put them to wash, when the idea struck me to try an experiment. To the combined bath (eight ounces) I added about thirty to sixty minims of hydrochloric acid, when the mixture became quite milky in appearance. I then put the toned prints into it, with the result that they changed to a platinotype tone, resembling an engraving.

I did not expect this result. Whether the prints so treated would be as permanent as otherwise I cannot say, but for those who like that particular black-and-white tone it may be useful, and gives little trouble.

Perhaps some of your readers who are better up in chemistry than myself could oblige us with the theoretical reasons for this result.

I was not successful in toning untoned prints in this mixture.—I am, yours, &c., W. J. Farmer.

68, *Blackburn-street, Blackburn, August* 24, 1893.

PHOTO-MICROGRAPHY.

To the Editor.

Sir,—Mr. J. Woodworth wants an explanation as to "how an isochromatic plate can correct the difference between the actinic and the visual foci," and, in answer, I beg to say that, at the discussion which took place at the Quekett Club, when I brought forward this subject for the first time, Mr. Haughton Gill said "there was no doubt," I had "obtained a sharp image in the focus of the visual rays, but the reason of this was that these plates (isochromatic) were sensitive to the rays which were active in producing the visual focus, and, therefore, it was not necessary to work with a focus nearer the violet end of the spectrum. The plate did not cause the two foci to become coincident, but only enabled a picture to be taken by the visual rays." Our President (Mr. E. M. Nelson) confirmed that view by saying that "Mr. Gill had no doubt perfectly explained their action, which could not be due to their bringing the chemical and the visual foci together, but was due to the image-forming rays being the active rays where these plates were employed." Similar views were expressed when I brought this subject before the Royal Microscopical Society in answer to Dr. Piffard's communication; and, seeing there was no exception taken to my conclusions at the time of introducing it, and that they have not been traversed by any microscopist since, I am certainly surprised to find that Mr. Andrew Pringle, in his communication to the Photographic Society of Great Britain, treats the question of an ordinary achromatic objective working true to focus as if the results were the joint product of the orthochromatic plates and the yellow screen.

Now, I am certain that the yellow screen has no effect on focus whatever, and the results are due solely to the isochromatic, or, in other words, the orthochromatic, plates—an experiment any one of your readers may try for himself if he possesses a microscope and camera.

Set up in the usual way by placing an image in sharp focus on the focussing screen of the camera, and then place a screen of yellow glass between the light and the object; when, on examining the image again, he will find that it remains as sharp as before. Should he wish to carry the experiment still further by photographing the object, let him take the yellow screen away, and, using an orthochromatic plate, he will find the negative image on the plate comes out on the same plane as the positive image on the focussing screen. This image may not be a good image photographically; it will vary with the correction of the objective, the quality of the lens, and the skill of the operator, but it will always be in the right plane. Now repeat the process with an ordinary photographic plate, and the chances are ten to one that the image on the negatives will be on quite a different plane. I have reserved the one chance because there is one particular correction of an ordinary achromatic lens which will work true to focus on any plate, provided it is confined to low powers on the one hand, and oil immersions on the other.

I am supposing, for the purpose of these experiments, that the lighting is done with the ordinary paraffin lamp, it being possible that with other modes of illumination the results might be somewhat different, although I should not expect them to be so.

The necessity for orthochromatic plates alone is what I have been emphatically asserting in contradiction to Dr. Piffard and others, and I presume all we want is the truth, whatever it be. If I am wrong in my conclusions it is a subject important enough to be worth confuting; but if I am right some acknowledgment is, I think, due to me for having simplified a process which threatened to become a very intricate one indeed, owing to the elaborate precautions to be taken by procuring specially corrected lenses, and placing various coloured screens and ray-filters between the source of light and the object.

Now, I do not deny the value of coloured screens, but, when required at all, they will be equally wanted when even apochromatic lenses are used.

I enclose four prints of part of the proboscis of a blowfly, two taken on orthochromatic plates without yellow screen, and two on Ilford ordinary. They were taken under the same circumstances with regard to lighting and focus, and in each case the image on the former plate comes out sharp, while the latter is fluffy.—I am, yours, &c., T. F. Smith.

185, *Brecknock-road, N.W.*

To the Editor.

Sir,—That microscope objectives not specially corrected for photography must work to focus if used with colour-sensitive plates and yellow screen is such a self-evident fact that I am surprised to see it referred to as a "discovery," and discussed at length in the photographic and microscopical journals. Nor is the observation a new one. I especially emphasised the fact in a verbal communication to the Photographic Society of Philadelphia in April, 1890, when I presented the Society with a series of photo-micrographs made under those conditions. A few months after, in a communication to J. W. Queen & Co.'s *Microscopical Bulletin*, in reply to an inquiry from the Editor, I recommended Mr. Pringle's book on *Practical Photo-micrography*, but disputed Mr. Pringle's assertion that high-class work could only be done with apochromatic or specially corrected objectives, and repeated my assertion that any objective that gave a satisfactory image to the eye would give an equally satisfactory photograph under those conditions. All of my photographs were made with comparatively cheap objectives selected from stock, yet were certainly equal to those made by Mr. Pringle with the costly apochromatics.—I am, yours, &c., F. E. Ives.

116, *Charing Cross-road, London, W.C., August* 28, 1893.

THE PHOTOGRAPHIC CONGRESS.

To the Editor.

Sir,—I shall be glad if you will allow me to reply publicly to the inquiries that are being made concerning the Congress of the Photographic Society and affiliated Societies.

It is finally arranged that this Congress shall be held on October 10, 11, and 12.

In a few days all the arrangements will be completed, and a full programme will be circulated as soon as possible after that.

We shall be happy to send a copy of this programme to any one who, not being a member of this Society or of one of the affiliated Societies, sends a post-card request for it to 50, Great Russell-street, Bloomsbury, W.C.—I am, yours, &c., Chapman Jones,

Hon. Secretary Photographic Society of Great Britain.

Photographic Society of Great Britain, 50, Great Russell-street, Bloomsbury, London, W.C., August 26, 1893.

Exchange Column.

**** *No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance. The full name of the advertiser must in all cases be given for publication, otherwise the Exchanges will not be inserted.*

Backgrounds, one exterior, in flatted oils, 7 ft. 6 in. by 7 ft. 6 in.; one interior, distemper, 7 ft. 6 in. by 7 ft. 6 in.; and one floorground, distemper, 9 ft. by 7 ft. 6 in.; will exchange for quarter-plate camera, lens, &c., or offer.—Address, A. Miny, 13, Taunton-place, St. John's Wood, N.W.

Answers to Correspondents.

**** *All matters intended for the text portion of this* Journal, *including queries and Exchanges, must be addressed to* "The Editor, The British Journal of Photography," 2, *York-street, Covent Garden, London. Inattention to this ensures delay.*

**** *Correspondents are informed that we cannot undertake to answer communications through the post.*

**** *Communications relating to Advertisements and general business affairs should be addressed to Messrs.* Henry Greenwood & Co., 2 *York-street, Covent Garden, London.*

**** *It would be convenient if friends desiring advice respecting apparatus, failures in practice, or other information, would call at the Editorial Office either on Wednesdays from 4 to 6, or Thursdays from 9 to 12 noon, when some one of the Editorial staff will be present.*

Experiment; Spotty; G. H. J.; F. E. G.; and others.—In our next.

Cymro.—We would select that lens by which the ground before and behind the sitter is equally good.

W. Hobbs.—The "No. 4B" of the same maker has the same rapidity as the 3B, and will cover the size plate you require.

W. Hillgear.—The yellowing of the whites indicates sulphur toning. Better change the constituents of the toning bath, and keep up its strength.

Doubtful.—"Permanency" is a vague and indefinite term. Hence, as the length of the engagement was not specified, we fear you have no remedy.

J. G. Henderson (Lewisham).—Norton's cloud shutter is made and sold by Messrs. Brooks & Norton, of 728, Nicollet-avenue, Minneapolis, Minn., U.S.A.

Reproduction.—Any letterpress printer will do the work if you supply him with a process block. Waterlow & Sons, and other firms, will make the blocks for you.

Alf. Lloyd.—For sitters with auburn hair and much freckled, there would be an advantage gained by treating the plates with erythrosine, according to the method mentioned.

J. Astley.—It is evident that the stops have not been made for that lens. You will have to scratch or engrave the true values on them yourself. You quite correctly appreciate the system on which to do so.

R. Stanley.—The spots or pits on the collotype plates can only be avoided by changing the gelatine for another kind that does not pit. The defects complained of arise from the same cause as pits in gelatine dry plates.

S. S.—It by no means follows that because a piece of apparatus is patented the patent itself is valid. If a large proportion of the patents that are sealed annually were contested, they would certainly be proved invalid.

London, W.C., wants some pure zinc plates for etching. Pure zinc, in the form required, is not an article of commerce. It may be had from operative chemists, but then it is in grains or rough lumps. The best zinc plates, as supplied by the dealers in printers' material, are quite pure enough for general photo-etching.

G. Botts.—The advantage of a 15 × 12 lens, when used for 12 × 10 negatives, is that it will cover the plate better when used with a large aperture. On the other hand, it will not, on that size plate, include so wide an angle. But, for groups out of doors, where there is generally plenty of space, the larger lens will be the best to have.

P. C. Hansen says: "I shall feel very much obliged if you can tell me if there is any book published giving the particulars of Fox Talbot's method of working the calotype, and where I could get the book."—All the old manuals on photography give full details of the process. An abstract of it was given in our volume for last year. Hunt's *Photography* gives it very fully.

G. F. J.—Use ordinary water colours; nothing more is required. If you have not yet attempted to colour photographs, you will find it advantageous to get some lessons from a skilful colourist. This correspondent also asks "as to the likeliest of our colonies or possessions where there would be scope for a professional photographer?"—Perhaps some one can supply the desired information.

H. Spence.—Parcels of negatives sent through the post can be insured; but compensation will not be paid in case of injury if the parcel was obviously insecurely packed. We frequently receive negatives, or rather fragments of them, simply placed between two pieces of cardboard. In such cases as this the Post Office authorities could not be expected to recoup the senders for their loss.

S. Tallon.—1. We know of no work in English devoted exclusively to orthochromatic photography. See our own back volumes, and the last edition of Abney's *Instructions*. 2. We do not think there would be any advantage in copying the photograph through blue glass.

A. X. B.—Certainly not. The fact that by waylaying Her Majesty with your camera you secured a couple of good negatives of her as she passed, in no way entitles you to style yourself "Photographer to the Queen" and put up the royal arms over your shop. By using the royal arms, and calling yourself "Photographer by Appointment to Her Majesty," without being entitled to do so, you would incur a heavy penalty.

T. Moore.—To obtain the very best reproductions of fine line engravings—that is, those most closely resembling the originals—we should take the negatives by the wet-collodion process, and print them by the carbon process in a black tisure, or by the platinotype process. If our correspondent is not *au fait* with working collodion, the next best thing to do will be to use dry plates, such as are specially made for negatives for photo-mechanical processes.

Experimentalist.—An Albion press will answer quite well for collotype work, but there is a certain degree of risk, in buying a second-hand one, that the bed may not be perfectly true. If that were the case, the glass plates would be continually breaking. However, it is an easy matter to test the press before purchasing by placing a glass plate upon it of the full size and bringing the platten down upon it with a heavy pressure and seeing the result.

Subscriber.—The strength of the solutions is of no great importance; the stronger they are the quicker they act. The prints are first treated with the lime solution, and then with the acid, till the stains are removed. As you say, the engravings are very fine; we should advise you to place the work in the hands of a professional print restorer. Many valuable engravings have been irretrievably ruined by novices' attempts to clean them. Print-cleaning requires considerable experience.

B. B.—1. The photographs of lightning sent are of a not uncommon kind. 2. The most expensive item for working the collotype process would be the press. One suitable for the purpose might be obtained cheaply second-hand, in which case it would be decidedly worth your while to undertake the work yourself. See back volumes for information on the working of the process. 3. Take the equivalent by weight. 4. Two shillings each for mounted whole-plates is a good price as things go just now.

Alfred H. Saunders writes:—"A customer of mine has sent me some pictures that he has copied from a book which is copyright to be coloured, and he wants to know how he stands under the Act. Is he liable in any way to prosecution if he exhibits these slides in public? He does not accept payment for his services, neither is there any charge for admission."—In reply: If such copies are exhibited in public, he certainly runs the risk of being prosecuted for piracy. Write to the publisher of the book and obtain his permission for exhibiting them, and then all will be right.

Retoucher writes: "Can you give me any information respecting the following? I have been much worried recently through being unable to get any work on our negatives, owing to a greasiness apparently, of the surface of the film, or something which, when the medium is applied, causes it to lose its abrasive quality, and to form a slippery surface, which the pencil will not touch. We work on the film with the Autotype medium and varnish after, as we cannot get sufficient work on the varnish alone. I have been retouching for some years, and have never met with this difficulty before. Our negatives are developed with pyro and ammonia in the ordinary manner, and I can discover no cause for this strange defect. Any information *re* the above will be thankfully received."—We have never met with a difficulty of this kind ourselves, and do not see how it can arise, seeing that a medium is applied to the gelatine surface. Perhaps some reader can assist our correspondent.

Puzzled writes: "1. I have been keeping old hypo baths, the washing water from printing-out paper, and the old toning baths for same (sulpho and gold), and now, when I have filled the receptacles for same, cannot precipitate the silver and gold from them. Will you kindly say what is the best and simplest method to do this, and about how much of the precipitants it takes to the gallon of liquid treated, as the methods in all articles I have seen give no quantities whatever as a guide? 2. Also please to say whether, if any hypo got into the washings from prints, it would make it useless? And, 3, whether a zinc tank is suitable for a hypo bath, as the one I have been using lately seems to have been eaten away to some extent by the soda? Your kind replies will greatly oblige,"—1 and 2. As the residues are mixed together, the best thing to use is the sulphide of potassium. The amount necessary depends upon the quantity of silver in the solutions. The sulphide should be added until it ceases to precipitate more sulpbide of silver. 3. Zinc is quite unsuitable for containing solutions of hyposulphite of soda.

JOURNAL OF PHOTOGRAPHY.

No. 1740. Vol. XL.—SEPTEMBER 8, 1893.

SOME PECULIARITIES OF PERSPECTIVE.

Pending a full disquisition on the subject of perspective promised by one of our contributors, a remarkable paper, recently published in *Nature* over the signature of Arthur L. Haddon, affords an opportunity for a reference to a topic always interesting to photographers. Much has been said by the skilful and the unskilful about "distortion" by wide-angle lenses, which is both misleading and illusory. One of the most important studies undertaken by all students of art, who go through a curriculum—such, for example, as that of South Kensington—to fit them for teachers, or for independent art work, is that of linear perspective by the aid of rule and compass. Further training is given by practice in drawing from solid objects without instrumental aid. The outlines of the objects so drawn must conform to those which would be obtained if the same objects were represented in the first-named manner; hence, the actual rules for one are identical with those for the other. It is not difficult to explain the underlying principle, and it may be said that there is no disagreement whatever ut the correctness of these rules among experts. Some treatises on linear perspective go to the length of showing mathematically the basis of these rules.

A sheet of glass is supposed to be placed before the draughtsman, and he is supposed to use one eye only; further, it is supposed to be rigidly fixed in one spot. Objects of certain given dimensions, at a given distance from the sheet of glass (called the picture plane), and placed at a specified angle to that plane, are to be depicted in outline on paper in such a way that, if transferred to the sheet of glass, they would actually exactly cover the same outlines of the original object. Clearly, if they do so cover the outlines, the drawing is a correct linear representation of those objects as they are apprehended by the eye. Now, we may at once say that the rules of perspective, accurately carried out, will enable such truthfulness of representation to be achieved, and from this it is right to assert that the rules must be correct.

There are some who have argued that, because the eye is not a perfect optical instrument, judged from the narrow standpoint of strict optics, the picture so drawn must be incorrect, through the distortion it will undergo in the eye. The simple reply to such argument is, that the original object is seen by the same eye, and hence its outlines will be distorted in an exactly similar manner. Let any one place, for example, a thin, straight walking-stick some little distance on the other side of a window pane; he will be able to entirely hide it by placing on the window glass a narrow slip of paper of exactly the same proportions, and so with a drawing.

There are, however, two important limitations about this picture transferred to the sheet of glass.

First, it will only cover the outlines of the object when the glass and object are at one fixed distance from the eye, so that at all other distances it is not a correct representation. The same rule holds good with a photograph. It also will only coincide with the outlines of the object when it is held at one fixed distance from the eye.

Secondly, a draughtsman or painter never paints, for pictorial purposes, a view which embraces an angle of over sixty degrees; rarely does he include that extent. If, however, for a particular purpose he desired to include a larger angle, he would employ exactly the same rules of perspective; and then, with the sheet of glass at a fixed place as before, his drawing would coincide with nature, and would be identical in linear perspective with the outlines given in a photograph taken by a suitable wide-angle lens. Therefore, such photograph must also be correct, subject to the same limitations as to distance, as the sheet of glass. So-called "distortion" would be given equally by lens and pencil if the right distances were not made use of. The bad name given, then, to subjects of wide angle taken by the camera is simply owing to the fact that, besides being improperly viewed, such pictures are common in photography, and very rare in paintings or drawings.

There is, however, a further school of disputants, who argue that the received ideas we have attempted to set down as clearly as possible, do not represent all the truth, and that, in certain positions, objects produce effects other than those usually believed in. These theorists do not fairly meet the sheet-of-glass theory, they go round it. one proof given by them being the fact that skilful artists do not adhere to the rules of perspective. These arguments will find singular corroboration in this paper of Mr. Haddon's that we referred to. The original article will be found in *Nature*, p. 402, and a further communication on p. 416 of the current number. The article is entitled, "Compulsory Laws of Error in Drawing," and, of course, some of the disputants we refer to would say that these so-called errors must virtually be truth. The article referring to "phenomena connected with the art in drawing, or depicting form in outline," . . . . "is to prove that error made in such drawing comes under the dominion of natural law, or compulsion, and is not the result of individual misconception of truth. . . . the intelligent and the dull being equally liable to commit the errors in forms." He divides these errors into three kinds:—

(1.) "A general law making us fundamentally incapable of drawing in perspective . . . . perceivable in the form of direct *divergence* of lines parallel in nature, which in perspective should *converge*."

(2.) "Another general law is a natural incapacity to erect a proper perpendicular for an object, unless the same occurs close on the line of direct sight (forward). The deflection occurs in the nature of an inclining of the top of the line towards the central line of sight."

(3.) "The next general law is less distinct, but still abundantly provable on test. A certain line is not drawn with perspective inclination to the *vanishing point* n front of the observer, but *is drawn on a perpendicular*, or, as s evident, in such a manner as would be the true fact of its direction, void of the influence of perspective."

A large number of instances of geometrical figures, and how the errors tend with them in drawing, are given, and finally, Mr. Haddon states, "I have traced them (the errors) clearly in the draughtsmanship of Orientals, and even in the drawing of the greatest painters." We strongly advise all of our readers who take an interest in scientific perspective to read the articles referred to. They give much food for thought, and an exact appreciation of their bearing may enable the reader to see the extent to which they might be made to prop up false theories as to the proper delineation of objects by photographic lenses.

ECONOMY IN WORKING.

Although the possibilities in the way of saving are far less at the present than they were in the days of wet collodion and albumen paper, there is no doubt that a very great deal of unnecessary waste occurs, more especially on the part of amateurs, although professionals cannot be held altogether blameless. Time was when every amateur had his little arrangements for the recovery of the silver from his print cuttings, as well as his spent fixing and toning baths; while the workers of wet collodion carefully collected the developing and intensifying solutions after use for the sake of the unreduced silver they contained. In large establishments the saving thus effected formed a very important item in the year's business, and even on a small or amateur scale we have, in former days, seen handsome "ingots" of silver resulting from the residues of a season's printing.

In those days, however, it must be remembered that the negative plate, when it came from the silver bath, however carefully and closely drained, was rich in the precious metal in the form of soluble nitrate clinging to its surfaces, and, while much of this mingled with the developer, and took part in the formation of the image, yet the greater portion, in most cases, was recoverable with proper precautions. In our modern developing operations there is, of course, no free silver recoverable, and the solutions, except in so far as they may be used again, are not worth saving.

Turning to printing again, in the old days there was the printing bath, a tolerably concentrated solution of silver nitrate, to be dealt with; and those who have had experience in sensitising paper will be aware how the valuable metal can be wasted in the form of drippings, splashings, and drainings, quite independently of that which can be saved from the prints themselves. The actual quantity of silver involved in the formation of the positive image is but an infinitesimal proportion of that used in sensitising, and it has been estimated that seventy or eighty per cent. was recoverable, with proper care, from the dippings, washings, and fixing of prints. Now, however, both in the case of ready-sensitised albumen and gelatine chloride "print-out" papers the quantity of free silver present —that is to say, silver in the soluble form and recoverable from the washing water—is very much less than formerly, so that it is to the cuttings and fixing baths that we must look more particularly for our residues.

Here again, however, we find a difference between the practice of to-day and former times. The system of using cut sizes of printing paper, which has grown so much in popularity during the last few years, is in itself an important economy, since it avoids the necessity for trimming the prints, and thus does away practically with that form of "residue." Thus, in the old days it was customary to cut up a sheet of paper into thirty-two *cartes-de-visite*, although, as was well known, as many as forty could be cut out of the sheet with a little management. Here, then, was at once a practical waste of twenty per cent. in the shape of trimmings.

One other important fact must also be borne in mind in comparing the possible savings of to-day with those of the past, namely, that, both in the case of plates and paper, the greater portion of the waste is incurred by the manufacturer, upon whom falls the chief onus of exercising economy. Our sensitive films, both negative and positive, now come into our hands ready for immediate use and at a minimum cost, since we are not asked to pay for the waste occurring in the process of preparation. Obviously, then, it is not possible to expect as great a return from residues as in the days when the whole process of preparation was performed by the photographer himself.

There are, however, one or two directions in which the users of sensitive photographic films, but especially amateurs, never think of looking with a view of economy. We refer more especially to the treatment of spoilt negatives, not, be it understood, with the intention of using the plates again, but merely as regards the extraction of the silver contained. In the case of a fairly successful amateur, perhaps, the proportion of spoilt negatives would scarcely be great enough to justify any special system for their treatment; but we know from our own experience that waste plates rapidly accumulate as the result of experiments of one kind or another, and that, in the course of time, these give a very good return for the trouble of recovering the metal they contain. The same rule must hold good in large professional establishments, especially where the negatives are only preserved for a stated time.

Most operators, when a plate is seen to be spoilt, at any rate go to the trouble of fixing it, if for no other purpose than to extract the silver from the portions unreduced by the developer. If they do not, they certainly ought to, for the trouble is little, and the fixing bath offers perhaps the easiest method for extracting the haloids and presenting them in an available form for reconversion. But the developed image which is not touched by the hypo still contains a considerable portion of silver; not as much, it is true, as that removed in the unreduced form, but still sufficient to make it well worth systematic collection, the only question being the most convenient way of proceeding.

As we have just said, the fixing bath is the simplest means of presenting the residues in an available form for subsequent treatment, and all that is wanted in order to bring the developed image within its range is to reconvert it into one or other of the haloids, preferably chloride, on account of its ready solubility. The best way of effecting this is with a solution of bichromate of potash, acidified with hydrochloric acid, the strength being quite immaterial, since, after the silver is converted, no harm can be done. The image being bleached with

this solution, the plate is rinsed and passed into the hypo bath, which then dissolves out all the silver. The bichromate solution is to be preferred to any of the metallic bleaching agents, such as cupric chloride, as it leaves the silver free from other metallic contamination.

When the bath is fully charged with silver, it may be precipitated by means of one of the alkaline sulphides, such as potassium sulphide or "liver of sulphur," and, after washing by decantation, the sulphide of silver may be collected and dried ready to be sent to the refiner. In order to convert it to the metallic state for subsequent transformation into nitrate, it will, of course, require to be fused in the furnace with a suitable flux; but, as we imagine few amateurs of the present day will go to the trouble of converting their own residues, we intend to say nothing on that process.

Another method of precipitating the silver, and which reduces it in the metallic state, is by means of metallic copper, iron, or zinc; but this has the disadvantage of contaminating the silver with the baser metal, which is very difficult to separate again. Some strips of copper, iron, or zinc, are placed in the fixing bath and allowed to remain until all the silver has been precipitated as a black powder, which should then be carefully washed and dried.

The treatment of paper residues may be carried out in a similar way by means of the fixing bath. In the case of Solio and similar processes treated in the combined bath, the latter contains all the removed silver as well as any excess of gold not used up in toning; but, when the separate baths are used, the washing water employed before toning will contain all the soluble silver, and should therefore be saved. In order to render this process as convenient as possible, the prints should first of all be soaked for, say, ten minutes, in a minimum quantity of water, time being allowed for the silver contained to be fairly well extracted. This water may then be poured into a jar, and the prints again covered with a similar quantity, which will remove all the silver that is worth saving. A few drops of hydrochloric acid will throw down the metal as chloride, and by the time the next printing operations have to be performed the water may be poured off.

Clippings and trimmings of prints may be burnt, as in the case of albumen paper; but, owing to the smaller quantity of silver they contain, the gelatine and, above all, the barium sulphate used in the preliminary coating, the ash is far bulkier and more impure, and, in fact, is so difficult to treat that it becomes scarcely worth saving. But fortunately the fixing bath is available, and if the trimmings are immersed in the acidified bichromate solution already mentioned, and afterwards in the hypo after it has performed its legitimate duty, the latter will effectually extract the silver without touching the other impurities. Spoilt or over-printed proofs may be subjected to the same treatment for the extraction of the silver, but the gold in toned proofs may be ignored as not worth the trouble of recovery.

The gold toning bath, for use with gelatino-chloride paper, is a much richer source of "residues" than its predecessors for albumen. Not only is it a more concentrated solution, but it is impossible to work it so closely as the albumen bath, and there is consequently always more of the precious metal remaining after use. Add to this that there seems to be no satisfactory means of preserving the bath after it has once been used, and we have cited sufficient reasons for paying considerable attention to the toning bath. The treatment is very simple, and consists in adding to the used bath some crystals of sulphate of iron, which will form a purple-black precipitate, more or less bulky, according to the quantity of gold present. It is not to be supposed, however, that it is all gold, for much of it will consist of basic iron salts; before collecting, the precipitate should therefore be treated with dilute sulphuric acid until it ceases to lose bulk, and, finally, well washed before drying.

In conclusion, we may remark that the principal difficulty with amateurs in saving their residues is in the length of time it requires to get a sufficient quantity to make it worth while sending to the refiner; but, if the necessary collecting jars be set aside in some out-of-the-way corner, the process of collecting is not a difficult one, and may go on uninterruptedly from one end of the season to the other, or, for that matter, from season to season, until one day a nice little "nest egg" will be found.

Low Prices.—One cabinet and two *cartes* for one-and-ninepence! This is the price we saw announced outside a West-end photographer's a few days ago. The establishment is not in a back street, as might be surmised, but one of the principal thoroughfares of a fashionable part of the south-west district. One would imagine that such prices as these should act as a deterrent to many from apprenticing, or "articling," their sons to photography as a profession.

The Forthcoming Exhibition of the Photographic Society of Great Britain.—The last day for sending in exhibits for the forthcoming Exhibition of the Photographic Society of Great Britain is Monday, September 11. Cases should be forwarded by that date to Mr. Goldstein, 7, Great St. Andrew's-street, W.C. Unpacked pictures may, however, be handed in at the Gallery, 5A, Pall Mall East up to nine o'clock on Wednesday, September 13. We understand that there is every promise of a successful Exhibition from the numerical consideration, between three and four hundred pictures having already been received, while rumour has it that the Exhibition is not likely to suffer by comparison with any of its predecessors from an artistic and technical point of view. We wish the Exhibition the success it deserves, and trust that it will be supported by all interested in photographic progress, and in the fortunes of the Society.

Caution to Photographic Tourists Abroad.—It seems that the spy scare is again aroused on the Franco-German frontier. Last week two persons were arrested at Kiel, and are now awaiting their trial, charged with being French spies. Possibly the German authorities had greater reason for their arrest than appears in the telegrams to the daily press. They were travelling, it seems, in a pleasure yacht flying British colours, and, when arrested, had with them photographic apparatus, plates, photographs, sketches, and maps of the district. Now, these things are usually to be found in the possession of every photographic tourist abroad. Whatever may be the outcome of the present arrests, it is pretty certain that great vigilance is being displayed on the frontier; therefore English tourists with cameras in those districts must be particularly careful where they plant them, or they may inadvertently place themselves in an unpleasant position. We repeat the advice we have before given to photographic tourists to the Franco-German districts, namely, to provide themselves with passports from our Foreign Office; and, further, to have them visèd at the consulates of the two countries here in London. The cost and the trouble is but a trifle, while the inconvenience it may avoid might be great.

Fallacies.—Almost every week we are told, by some one whose knowledge of what was done in the past is extremely limited, of the circumscribed resources at the disposal of the older photographers, and how they were to be commiserated. In a paper read at the last meeting of one of the Metropolitan Societies, on the subject of

printing, the author congratulated the present generation of photographers upon the advantage they have over those of the past, who, he said, had only one process, while the present had an almost unlimited choice. Now, it is difficult to see, if we except gelatine paper, what processes are available to the modern worker that were not also available to his older *confrère*. Had we not the platinotype process ten years ago, and the carbon some twenty years before that? Collodio-chloride we have had about as long as carbon; matt surface printing was in a high state of perfection forty years ago—indeed some of the modern formulæ for this class of work are identical with those employed at that period. Printing by development is one of the oldest methods of obtaining prints from negatives. Where, then, with the exception referred to, is the unlimited choice of process which the present worker has over him of twenty years and much longer ago? By the way, in the paper it was recommended to suit the process to the negative. The older workers proceeded differently, they aimed at producing negatives of such quality that they would suit any of the processes then, and now, in vogue.

Aluminium versus Magnesium.—Winter is now approaching, and there is very little doubt but that artificial light will be invoked, as an aid to photography, to a greater extent during the dark days than it ever was before. There are few districts now in London, and most other large cities, where electricity is not as available as gas from the mains. Therefore it may be expected that this is the light that will be adopted by professional photographers. Amateurs who have employed artificial light at night for negatives have hitherto relied upon magnesium; but, at the last meeting of the Photographic Society of Great Britain, Mr. Bolas demonstrated that that metal now had a formidable rival in aluminium, by obtaining a fully exposed negative by the light evolved by the combustion of a grain and a half of the powdered metal in an ordinary flash lamp. Aluminium promises several advantages over magnesium, one of which is the absence, in its combustion, of the irritating smoke evolved by the latter metal—a great gain when working in ordinary rooms—the greater amount of light from a given weight of metal, and economy, aluminium powder costing but about half the price of that of magnesium, and the possibility of its costing still less if the demand for it be increased. Added to this, the powder is not prone to oxidise like magnesium. As at present met with commercially, the powder requires to be freed from some oily matter used in its manufacture. If a demand is created for it for photographic purposes, there is little question that it will be supplied ready for immediate use.

Reversing Mirrors.—Now that mechanical processes are so much to the fore, anything that will aid in the production of suitable negatives for them becomes of increasing interest. At a recent meeting of the Hackney Photographic Society Mr. Miller demonstrated a method of silvering reversing mirrors, the formula for which was given in our last issue. In his paper, Mr. Miller says the glass "ought to be optically worked." We would emphasise this by substituting *must be*, for, unless the surface be optically plane, the mirror would be worthless if good definition be essential, as, of course, it is in all mechanical processes. So important a matter is this, that it may be mentioned that the best mirror may have its good qualities entirely destroyed by the slightest pressure from its mount, which would alter its figure. Therefore, the glass should always be left perfectly free in its setting. The most perfect lens would have its definition quite ruined by being worked with a defective mirror. While on the subject of mirrors, we may add a few words on the preservation of the silvered surface. When out of use, they should be protected as much as possible from the action of the atmosphere, which, particularly in large towns, readily tarnishes the surface. This can, it is true, be cleaned off with a pledget of cotton-wool and a little fine rouge, but it must be borne in mind that constant cleaning wears away the silver coating. Tarnish and even scratches on the surface do not impair definition any more than do dirt and scratches on a lens, they simply cause so much loss of light, and necessarily entail prolonged exposure. It has just been said that the surface of the mirror is easily polished with cotton-wool and rouge, but it should be added that the precaution should be taken that it is perfectly dry before commencing, because, if the silver film be at all damp, it would come away from the glass in flakes. It is a good plan to make the mirror warm a few minutes before repolishing it. With care a mirror can be in constant use for many months, or even years, without resilvering, but by careless use it may be rendered useless in a few weeks.

THE NEW PHOTO-TELESCOPE FOR GREENWICH OBSERVATORY.

So long ago as 1835 the Treasury consented to give to the Greenwich Observatory a large telescope, for want of which the Astronomer-Royal and the astronomical staff had been somewhat crippled in their endeavours to adequately photograph the spectra of the stars.

The construction of the telescope was entrusted to Sir Howard Grubb, F.R.S., and some idea of the perfection aimed at, and happily attained, may be gleaned from the fact that three years were occupied by the Messrs. Chance in turning out perfect castings of the glasses which were to form the object-glass, which is twenty-eight inches in diameter. Precisely how many castings were made before the required perfection was attained we know not, but we understand they were numerous, as the slightest imperfection ensured rejection.

The object-glass was delivered at the observatory early last year, and the final erection has for some time been delayed by the construction of a suitable dome and the requisite fittings. These are now completed, and a few weeks since Sir Howard, along with Mr. Christie, the Astronomer Royal, devoted some time to the final testing, which, as Sir Howard mentioned to us at the time, had been much impeded by want of clearness in the atmosphere. It is gratifying to know that the 4500*l.*, which is the cost of the instrument and its equipment, could not have been better invested, as it is pronounced to be one of rare excellence, and one of which the nation may well be proud.

The talented optician by whom it has been constructed has shown himself to be such a master in regard to high-class objectives, that we can the more readily understand that, although this 28-inch one has been specially made for spectroscopic photography, it is also available, by the alleged reversal of one of the lenses, for visual observation. We have not yet learnt the precise way by which this has been accomplished, although we know that chromatic correction—that is, from the visual to the actinic—can be effected by a slight separation of the components of the object-glass. Concerning this, however, we must wait for further information, which we presume will be forthcoming on an early occasion, probably at the meeting of the British Association.

Comparing the diameter of the object-glass with some others, it will be seen that, while it is not the largest in the world, still it is believed that, owing to the perfection of its construction, it will be little behind any of them—even the best.

The telescope which it has superseded has an aperture of thirteen inches, and, by squaring the respective apertures of the two (784 as against 169), it will be seen what a great light-grasping power has been obtained. The scientific world will look with interest for the revelations that are confidently expected as the result of the work of this instrument.

MAKING READY FOR EXHIBITION.

It is probably well within the memory of most of my readers that "full many a time and oft" prints displayed at various exhibitions, although possessing in themselves many intrinsic merits, have failed to obtain due recognition of their beauties by reason of the incongruous, offensive, or detractive setting in which they were shown.

That a judicious choice of mount and frame very largely modifies the impression which a print gives to the beholder, even the least reflective photographer will, without doubt, allow.

Granted that there exists this modifying power, it immediately follows that an injudicious choice of surrounding must needs exercise a very deleterious influence upon the effect which a picture will produce

upon the artistic sense of the spectator. It must not be forgotten that what is quite good enough for the common herd, may be vastly too bad for the man of exquisite artistic refinement, and of such temperament it is to be presumed most judges, and some of the critics, belong. This being the case, the ordinary exhibitor, if he desires a good place well on the line, and also the contingent chance of a medal —where such guerdons are offered—obviously needs to be superlatively careful not to transgress any of the canons of good taste when selecting a mount and frame for his master-work of the year.

There are many items of advice which might be profitably set down, but to fully exhaust the subject would need a treatise of itself, instead of the few lines by the way, whose first aim is merely to impress upon photographers to give the question of a suitable surround for their prints more attention than they in some cases have been accustomed to bestow.

Here, however, are some few hints. In the first place, it is to be remarked that the greatest offence is usually given by violent incongruities of colour between mount and print.

Colours may harmonise—in the sense that various slight modifications produced by addition or subtraction of related colours in a tint may be termed harmonious differences—or may contrast, as purple does with yellow. Neither of these juxtapositions produces a discord.

But when two rival primary colours are brought into immediate contiguity—say, Antwerp blue and cobalt—a jarring of the eye ensues, analogous to that which is produced upon the ear by the jangling of music out of tune.

What is true of the two above quasi-primary colours is, although not so self-apparent, true of the secondary colours derived from them, and also of the tertiaries, upon which are based the so-called "neutral tints," which, in most instances, they are far from being.

Many people, without effort, instinctively recognise this clashing of shades of colour; but, on the other hand, a considerable proportion are not quite awake to the importance of the subject, while a large residue really cannot distinguish between any of the minor modifications.

To those who are at all in doubt as to the limit of their colour sensitiveness, I would say, select a white Whatman mount (not necessarily a rough-grained one), and for frame employ a plain black reed.

To do this is, to my mind, to eliminate all risk of giving offence. It is, however, to be remarked, that relying upon such a simple *entourage* is sometimes merely to adopt a choice of evils; because, although I personally consider that a print of the highest quality in tone should, as a rule, not only have the juxtaposition of the white mount, but should be enhanced thereby, there certainly exists a preponderating proportion of photographs which need some reinforcement of the high lights, some subduing of the shadows, or some modification in the warmth or coldness of their tone, which cannot be otherwise attained than by the employment of a specially suitable mount and frame.

Thus, if the high lights lack brilliancy, a neutral grey mount will adventitiously brighten them; and if the shadows are unduly heavy, an unusually dark mount will lend an appearance of light to them by force of contrast.

In a similar position may the particular shade of colour employed in the printing process be modified. Thus, cold tones may be caused to look warmer than they really are, or hot tones made to appear cooler; the danger in using mounts where tints are potently warm or cold is that their effect is apt to be so discordant and assertive that it often only succeeds in producing a feeling of disgust. None the less, used with a nice appreciation of *tout ensemble*, the aforesaid are very valuable. Sometimes the power is well seen by the effect produced by the misuse of the expedient under discussion. Thus, I was lately shown a capital portrait which, however, suffered from being printed in a process which had ensured the rendering of the "female face divine" in a sickly brown hue, which was the reverse of pleasing. Pointing this out to my friend, said he, "All right; I'll soon counteract that." Next time I saw the print it had apparently turned green, the appearance being brought about by surrounding it with a brilliant crimson plush mount. This was my friend's notion of how to counteract; in reality it was, of course, an aggravation. Crimson being complimentary to green, an illusory tinge of the latter colour is, as may be demonstrated by experiment, imparted to the print. It is no exaggeration to say that relatively small low-tinted pieces of paper may be so arranged as regards large high-coloured ones, that the beholder shall not be able to say what colours the small pieces are tinted with.

Some people advocate that a mount and frame should possess the negative virtue of being quite unnoticeable; that they should be, whatever else, unobtrusive. There is without doubt much sound sense in this; but what is the definition of unobtrusiveness in the above? That which is very self-assertive in a dwelling-room may look small, mean, even shabby, on the walls of an exhibition.

On the other hand, we occasionally find that the bright and attractive setting, which was well enough in the middle of the shop window, is, when transferred to Pall Mall, or a similar exhibition, slightly too gorgeous and demonstrative.

Anyhow, one's frame should not be too bashful and retiring. Its object, aided by the mount or flat, is, firstly, to differentiate the contained picture from all the others which are fighting for attention; secondly, to strengthen and magnify the picture's beauties. This a wishy-washy, milk-and-water, humble and lowly arrangement, is not calculated to do. Here let me stop to add to the advice I have given to those who think they lack the needful taste and judgment to go as they please in the matter another maxim, viz., *don't stint yourself in margin.* If two prints from the same negative be mounted on boards, of which the area of one is twice that of the other, the one on the larger board will not only present an appearance of greater importance, but will have its pictorial effect considerably fortified. This is sufficiently well known amongst the more experienced that it not infrequently happens, when conditions of exhibitions or of competitions are drawn up, we find a regulation forbidding more than a certain maximum margin.

Of course, besides the self-evident absurdity of unduly applying the principle of wide margins to such an extent that we get the appearance of "a postage-stamp in a ten-acre field," considerations of cost, both of frame and of wall-space, exercise a wholesome check upon any tendency to overdo the matter, in addition to which, apart from any express rule on the subject, a hanging committee, other things approximately equal, would most certainly be inclined to pass over any print which is characterised by a wasteful and ridiculous excess of surround.

HECTOR MACLEAN, F.G.S.

SOAP-BUBBLES IN THE STUDIO.

OF all the beautiful and ingenious toys which have been placed in the hands of children of late years, it must be said that, either on the ground of amusement, or the higher level of education, they are not to be compared with that delightful plaything, the soap-bubble. Present a little girl with one of Mr. Edison's wonderful dolls, which, by virtue of a concealed phonograph, can talk, sing, laugh, or cry in the most natural manner in the world, the chances are that in half an hour you will find her nursing an ancient creature with one eye missing and an internal economy of sawdust. But when do children tire of blowing soap-bubbles?

Professor Boys tells us that there is an ancient Etruscan vase in the Louvre at Paris, on the sides of which children are depicted in the very act of blowing bubbles with a pipe; but, he quaintly adds, there are no means now of telling whose soap they used. Hence it is quite certain that the practice of this delightful art is of great antiquity.

It is small wonder, therefore, that so many photographers should desire to portray some of their more juvenile clients in this way; but the mechanical difficulties are very great, and so far their endeavours have frequently met with failure. To begin with, a soap-bubble itself is not a particularly easy thing to photograph, as many who have tried to do so will acknowledge; it requires very careful lighting, and is apt to burst at the critical moment of exposure; but the latter difficulty arises from the use of an unsuitable soap solution, and may be easily overcome by making up a solution as follows:—

Take three quarters of an ounce of freshly prepared oleate of soda, which can be obtained from any large chemist, and place it in a perfectly clean quart bottle with a pint and a half of distilled water, or clean rain water. When the oleate of soda has dissolved, add half a pint of Price's best glycerine, and shake the bottle up; but the oleate must be allowed to dissolve without heating the solution, as this would spoil it to a great extent for making good bubbles. Castille soap may also be used in place of the oleate of soda, but it does not answer the purpose so well.

Bubbles blown with this solution are so wonderfully strong and elastic that they may be tossed about on the coat-sleeve, or on a flannel-covered tennis racquet, without breaking, and, if the mouthpiece of the pipe be stopped with the tongue to prevent the bubble from contracting, the bubble will remain upon the bowl of the pipe for a sufficient length of time for the photograph to be taken in a satisfactory manner.

If it is desired to show a bubble apparently floating in the air, as in Sir John Millais's well-known painting, this may be accomplished

in the following manner. A piece of horsehair or exceedingly fine wire is bent into a circular loop about the size of a five-shilling piece, with a crosspiece of horsehair or wire arranged in the fashion of the handle of a bucket. If the loop of horsehair is first thoroughly wetted with the soap solution, a bubble brought into contact with it will adhere to the loop, and can be detached from the pipe. The loop and bubble are then suspended in a suitable position by means of a fine silk fibre, which is invisible in the resulting photograph.

A very good substitute for a soap-bubble may be obtained from any glassblower in the form of a thin glass globe, similar to the silvered balls exhibited in the shop windows at Christmas time. This, when cemented to the bowl of a clay pipe, is scarcely to be distinguished in a photograph from a real soap-bubble.

HARRY SMITH, F.I.C.

THE PHOTOGRAPHIC CONGRESS AUXILIARY OF THE WORLD'S COLUMBIAN EXPOSITION.

THE following additional papers were read:—

THE LINE SCREEN PLATES AND THEIR USE.

WHILE I appreciate most highly the honour conferred upon me of preparing a paper to be read before you on the subject, "Fine Line Screen Plates and Their Use," I also fully appreciate that the task is full of difficulty, and that to treat the question properly much more time than I can take would and ought to be required.

The manufacture of screen plates has occupied my attention for the five years past, and necessitated many experiments, and expensive ones, and required large research; yet the field beyond still seems more immense than that already passed over.

The subject is one requiring much thought and study and constant experimenting. Without taking up time, I will at once proceed to my subject, giving, in my own plain way, my impressions and the results obtained by me, being fully aware that same may be the subject of much just criticism.

The object of fine-line screen plates briefly stated—their use being for the production of half-tone relief blocks for typographic printing.

Screen plates are rulings on glass, having opaque lines with transparent spaces, and can be produced by mechanical means, or by mechanical and photographic processes combined. In actual use, according to the character of the work to be reproduced, screen plates may have from 65 to 200 lines to the inch, the most generally useful screen having 130 to 132 lines to the inch.

The screen is for the breaking up of the continuous gradation of light and shade in a photograph into absolute opaque lines and dots, with transparent spaces between.

It is not an easy matter to convey to the uninitiated the exact meaning of the above terms, but it can be easily understood by the examination of a photograph having a continuous gradation from light to shade, and a reproduction from same by the intervention of fine line screen plates. In the latter the picture is exact in facsimile, the impression to the eye is the same as the original picture; but, instead of the gradation of light and shade as described above, it will be found to have an even tint or colour of dark lines and dots, with perfectly white spaces to correspond, to give the effect of the original picture.

It will thus be seen that by the intervention of the screen, as will presently be described, it is possible—

First, To make a half-tone negative in absolute black lines and dots with transparent spaces between to correspond; and, second, from this an engraving with an even surface, that when mounted on a block, type high, is capable of producing the most beautiful impressions known to the typographic art.

To do my subject full justice, some mention must be made of the earlier attempts to produce typographic printing blocks. As long ago as October 29, 1852, Mr. Fox Talbot took out a patent. He used folded gauze to obtain a grain. Later on, December 4, 1872 (twenty years after the above), Walter Woodbury patented the use of "mosquito netting" and "Brussels net," and again in a patent, May 30, 1873, he claimed the use of fine ruled lines. Lastly, Woodbury obtained a patent, October 5, 1883, for the use of fine ruled lines, netting, gauze, dots, or a print from a grained stone.

Of all the above European patents, none seem to have had any practical value, and the first published attempt to obtain relief half-tone blocks by the aid of photography was the patent of Meissenbach in Munich, whose method consisted in imposing a transparent positive of the subject to be engraved, in connexion with a sheet of glass covered with diagonally ruled lines alternating opaque and transparent, and rephotographing this positive and ruled screen together, and reversing the direction of the lines upon the screen by inverting the screen after about one-half of the exposure is completed. This method, with various modifications, as will be explained further on, is in use by a good many engraving firms to the present day.

Looking back with the knowledge and trained eye of the present day, it is amusing to think of the earlier attempts and what ideas were had in regard to the requirements of a fine-line screen plate. Among the first partially successful attempts was to rule a copper plate diagonally one way with fine lines, then from this to pull an impression on fine white enamelled paper and with black ink; then from this to make a negative by the wet or collodion process, having perfectly opaque lines with transparent spaces, the negative so made being used as a screen plate.

It may be said that at this stage the operator's hopes were mountain high, and success seemingly assured, only to be dashed to the ground by unexpected and unforeseen obstacles in the path.

First, The extreme difficulty of obtaining a perfect impression having pure black lines without breaks or flaws; and, 2nd, an unsurmountable obstacle in copying from the impressions that was entirely lost sight of in the anxiety to obtain a perfect ruling, this obstacle being no less than the nature of the lens itself. To explain, the view of the ruled impression, on a *direct* line from the lens, *i.e.*, the centre of the impression, the lines and spaces were in proportion as the original in the resulting negative, but, *receding* from the centre, the spaces were less wide in proportion to the distance from the centre, the result being that from a large ruling a comparatively small screen could be produced of any value. Oh, the hopes dashed to the ground! It is only the enthusiastic workers that can understand studying and toiling, buoyed up by fond hopes and fancies, at the last to find some obstacle, not seen or calculated on, seemingly unsurmountable. Success, though, is a succession of failures, and this was the first real step to success. The next was to coat a perfectly flat or crystal plate glass with an opaque film, then to cut *through* this film lines of various thicknesses and number to the inch, according to the character of the work intended for reproduction. When this was accomplished, success was assured; it can readily be understood that lines so produced were perfect in proportion throughout the whole plate.

As to the nature of the film on the glass plate and its list of failures before perfection, it is out of the province of this paper to explain. Suffice it to say that, the glass plate having been prepared with the film as described, it is placed on a perfectly level bed plate of an engraver's ruling machine and fastened firmly in place.

In the operation of ruling the most extreme care is necessary. When once the machine is set in operation it must be kept going with an even, steady motion until the ruling is complete; any stoppage, even for a short time, will make a difference in the spacing at that particular place that can readily be detected on examination.

The cutting tools are diamond points, made so as to cut through the film, but without cutting or scratching the glass. These tools are made to cut any width of line desired, and are the perfection of workmanship. It can be surmised they are very expensive. This screen plate, placed in front of the sensitive plate in the camera or in connexion with a transparent positive and reversed during the exposure, constituted the first real success in the making of half-tone negatives for the production of half-tone relief blocks.

Screens prepared as described were open to the objection of rapid deterioration, and especially if used in the camera plateholder in front of the sensitive wet plate moist with the nitrate of silver solution of the bath. The solution would get on to the screen, and in a short while would be spotted and useless. Various means were resorted to to overcome this serious difficulty, until at the present time the screens are cemented with a colourless cement to a cover or protecting glass, that ensures permanency to a great degree.

At the present day there are two well-known methods of manufacturing original screen plates. One is to rule or cut through an opaque film prepared on perfectly flat crystal plate glass; another is to prepare a wax ground on the same kind of glass, then to cut lines through this, after which the glass (laid bare in lines) is etched to a certain depth with hydrofluoric acid; this gives ridges or furrows, which, after the glass is cleaned of the remaining wax, are filled with India ink. This gives a very intense black line with clear glass for space.

On a first cursory glance it would appear that plates so prepared would be more permanent or better adapted for the purposes intended, but such is not the case; there are serious difficulties attending their manufacture any way you will, and of the two well-known methods it would be a question to decide between.

The defects as they exist in both methods the manufacturers are, no doubt, endeavouring by all the skill at their command to overcome. It should also be borne in mind that at the present day the rapid advancement of this beautiful art demands a screen plate that only a few short years ago would have been considered a marvellous achievement.

So far this paper has only generally treated on the production of single-line screen plates. The subjects now under consideration will be, the proportion of opaque line to transparent space and the manner of use to give the best results.

The cross-line screen plate, how produced, the proper proportion of opaque line to transparent space—manner of use and why, as a screen, it is the best and most generally used.

The production of screens and the causes leading to it, &c.

In the use of the single-line plates the effect of "lines and dots," "black lines" more or less wide to represent the detail, and "dots" to represent the high lights, as seen in the resulting etching or reproduction, is by far the most truthful and pleasing manner of reproducing with the single line plate.

Experience has taught that the best method to obtain this result is to use two single-line screen plates of exactly same number of lines to inch, but one having the opaque line *three times* the *width* of the *transparent;* the other, the opaque and transparent lines equal but running in the opposite direction.

The use of the screen would be as follows: 1st, a special kit is devised for the camera plateholder—that will hold the screen firmly and at a certain distance in *front* of the sensitive plate; the exposure is given of sufficient length of time to bring up all *detail* in the shadows, and the separation of the screen and sensitive plates should be such that the opaque lines, resulting in the *high lights* of *negative* will be of same width as the black lines of the screen—in other words, the light from the high lights of picture or positive, passing through the narrow openings of screen, *will spread* and make a black line in the negative, as above described, if the screen and sensitive plate are separated proper distance; while in the middle tones the black lines will be *more* or *less* wide, according as the detail is light or dark.

A negative made in the above manner, while giving an exact reproduction, would lack *contrast;* the high lights being represented by very narrow black lines would not be *as light* as they should be; these lines must be *broken up into dots*, and to do this the screen with even lines must be brought into use. After the exposure, as described, the plateholder is taken to the dark room and placed with the back or door to the wall—remove the slide—take out the screen and in its place put in the one having even lines—an exposure now should be given to *simply cross the lights*—no more, or the reproduction will lose in detail and be too light.

The foregoing is the true principle of obtaining a correct reproduction of an original by the use of single-line screens. The elements to secure success being that the operator understands thoroughly the old wet-plate or collodion process of photography, as all negatives for this or any engraving method should be made with wet plates.

In the use of the single-line screens it will be seen there are two exposures, the plateholder must be removed from the camera taken to the dark room and the screens changed; if the special kit holding the screen and sensitive plate is firmly held in place, and the plateholder fits snug on the camera box, there will not be a particle of danger of movement of the sensitive plate already having one exposure, and the results, if properly done, are elegant. Yet the time taken up in making the two exposures is considerable. The risks of getting a perfect negative are nearly doubled from what it would be if one exposure only was given; and in these days of sharp competition, when work must be finished with dispatch, any saving of time is a great boon. Therefore a method devised of obtaining results equally as good, if not better, with *one exposure* was a great advance.

The discovery of the *cross-line* screen plates marked a new era. The results were found to be as a rule far superior, and the chances of failure from the fact of one exposure considerably lessened.

How Produced.

If the glass is covered with a wax ground, the lines cut through this, then etched with hydrofluoric acid as described, then it would be necessary to rule either two plates in the same direction and when brought face to face the lines would cross at right angles, or, after ruling the plate one way diagonally, to turn it about and rule it the other way so the lines would cross at right angles on the same plate, the latter process or method having the disadvantage of being liable in the etching to eat away the corners of the intersection and not fill properly with the ink, most likely in isolated places, thus making the working of the plate somewhat uneven. In the other method, or where the lines are cut through an opaque film, success depends, 1st, on the evenness of the film; 2nd, on its character; if too brittle, ragged edges would be the result; and, 3rd, on the tools employed in cutting the lines; two plates would have to be ruled singly and in the same direction, then brought face to face.

The ruling machine used for the purpose must be as perfect as mechanical ingenuity can devise—any deviation in a line, no matter if a hundredth or one two-hundredth of an inch, can be instantly detected on examination.

The proportion of black line to transparent space in a cross-line screen:—

In reproducing a subject when the reduction is great, or when the light parts are very strong as compared with the shadows, a screen in which the proportion of opaque lines predominate would give the best result; but the most generally useful screen would be prepared as follows: Take two single-line screens ruled exactly alike, diagonally, in same direction, and in which the opaque line is one-half the width of the transparent; bring them together face to face; the lines will then cross at right angles, and the transparent spaces will be equal in area to the opaque lines. This will make the most generally useful screen for all purposes, the manner of adapting the use of the screen to different subjects being well known to the professional negative-maker.

The manner of use or action of the cross-line screen, as will be seen from the foregoing description; the opaque lines cross at right angles, making a *square* transparent opening. To illustrate the working: Put the screen and sensitive plate in the plateholder, separated the proper distance; place in position on the camera, point the lens to a *white card*, and make the exposure. If properly timed, the light passing through the transparent openings of screen will not form square, but round, black dots in the negative, and will *joint solidly* at the edges, leaving the *intersections of the line as a transparent* dot. This white card would then represent the high lights of a picture. It is evident, then, that in the detail these black dots in the negative would be more or less large according to the gradation of light and shade in the picture, while in parts of subject having black without detail there should be no opaque dot whatever.

The reproduction of screens and causes leading to it:—

The nature of screens reproduced by photographic means:—The making of an original screen, not only from the difficulty attending it, but the very expensive outfit required, makes it necessary to charge what would seem to be an exorbitant price for them. Nearly five years ago the writer of this conceived the idea of manufacturing screens, first making an original, then reproducing from it, and at a price within the reach of any good engraver. At that time good workable screens could not be had at any cost, and the number of engravers in the United States making half-tone reproductions could be counted on the fingers of one hand. This seems an exaggeration, but it is literally true.

Look at the half-tone work of to-day and the countless numbers engaged in it; see the beautiful reproductions, artistic in every sense of the word, that are being done with the use of the fine-line screen plates and the half-tone process, and may I not feel a pardonable pride for my share in the advancement of this beautiful art?

The impossibility of obtaining original screen plates, and the great demand created for them as soon as their possibilities once became known, led to formulating the following reproduction process as worked by myself for the last four years:—

First. The original screen plate is made by the method described, of first coating a prepared glass with an opaque film; the lines are cut through this diagonally, one way only, the cut or transparent line one-half the width of the opaque. Whether an original would have eighty or up to two hundred lines to the inch, the relative proportions for practical working should be the same. The original being prepared, the next important step is the selection of the glass for the reproduced screens. It is absolutely necessary that the glass be crystal plate, perfectly flat, and without bubbles or scratches, and best if about one-tenth of an inch in thickness. This is prepared as collodion dry plates. It was not without many failures and discouragements before a suitable method could be formulated, one that would give an intense black line with clear glass for space, and, though finally got, yet it requires the most extreme care, failure will result.

The original screen and sensitive collodion dry plates are placed in absolute contact; one exposure is made; the plate is then turned and another exposure given with the lines crossing at right angles. The plate is then developed, fixed, and intensified, and after washing and drying is ready for sealing to a cover or protecting glass.

In the method just given for reproducing by making two exposures to obtain the cross lines, the cross section, or where the lines cross, is somewhat enlarged, so that the transparent opening is *not* exactly square; and for this reason, provided the lines are *perfectly opaque*, and the openings or spaces transparent, it makes a very much *better working* screen than the original itself, giving more of the effect of a well-shaded photograph, and without a certain harshness peculiar to a reproduction with a screen having the lines cross with sharp angles.

It is a notable fact that, if a screen could be prepared with the transparent openings *round* and in the proper proportions, it would give the most pleasing effect and be much the easiest to work, but such screens could not be made commercially. I succeeded at one time by a process of copying to obtain such a screen, but it was before the days of sealing. I used it as long as I was able to preserve it, but from that day to this I have not had time to make another.

It might be argued that the film of collodion on a collodion dry plate would be some obstruction to the light, but, if clear as it should be, between the lines it will be as transparent as the glass itself, and so thin that it could not possibly be any obstruction.

I could readily enlarge on the subject at hand, but feel that already too much time has been taken and that my paper should come to a conclusion.

I thank you all for this opportunity of explaining principles that generally are very far from being understood, and I trust that in so doing I have not been irksome to you. M. Wolfe,

"COARSE-GRAINED NEGATIVES"—HOW TO PREVENT THEM.

It is an acknowledged fact that there is a difference between the grain of a highly sensitive plate and one of a lower degree of speed, but from experience I have found that this difference need not be so great as is generally supposed, unavoidable.

Extreme care in the manufacturing of the emulsion is necessary to prevent it. Without this great care there may be great sensitiveness, but there will be coarseness. From such plate it is impossible to get a fine-grained negative, but it is possible to get a coarse-grained negative from a fine-grained plate.

After years of observation I have noticed that as a rule photographers make a better class of negatives during the cooler months than through the hot season. The grain of the negative is finer and the general appearance cleaner. The reason may appear obvious. Use ice, some one will say, and all the difficulties will be overcome. The suggestion is good, but it does not fill all requirements. The negative may appear without fault up to the time of putting on rack to dry, and still when you examine it after drying it does not possess the quality you expected to find. The reason is, that during the sultry days of the summer the drying of the negative takes several hours, the gelatine film becomes partly decomposed, allowing the particles of silver bromide to come together, they having an affinity for each other, the sack of gelatine which kept them apart being partially destroyed, forming coarse particles. The negative has then a woolly appearance.

All negatives have the finest grain and appear the cleanest immediately after fixing. What we want is to retain this quality when dry. How shall it be accomplished during the hot season, when everything is warm and the drying so prolonged? My method is as follows:—

I have a small ice box for my developer made like this: [Illustration omitted] in which are the two stock solutions. When I mix the developer, I take enough ice water to bring it to about 60° Fahr. I first rinse out my tray with ice water, then develop the plate: the fixing bath also is kept cool. If the water I wash my negatives with is too warm, I simply rinse with it and allow the negative to soak in cool water in a grooved box about one hour, changing water two or three times. Then I rinse once more and put on rack to dry. Between this point and the time when the negative is perfectly dry, it is liable to injury during the summer months when the atmosphere is 90° or over and often very humid, taking eight to ten hours to dry perfectly, thus changing the density and producing coarse grain. I have seen negatives that were developed, fixed, and washed in the evening, having wet patches on them the next morning. They were taken to another room to perfect the drying. The consequence was, where the drying commenced to be more rapid, there was at once a change of intensity, ruining the whole lot.

It is important, therefore, that the negative should dry as quick as possible, in as cool and clean air as can be had. The best arrangement I have seen for this purpose is now being used by one of the most eminent photographers in this country, Mr. M. J. Steffens, of Chicago. It is a small electric fan, by the use of which the negatives can be dried in half an hour or less. Connexion is made to a sixteen-candle lamp wire.

Just a word more as to another cause of coarseness. It may be produced by using a developer too strong in alkalinity. A strong alkali has the same effect upon the film as less soda with heat. M. A. Seed.

ORTHOCHROMATIC PHOTOGRAPHY AND ITS PRACTICAL APPLICATION.

It is very evident that the prominence given to orthochromatic photography at this World's Congress of Photographers reflects the growing interest in the use of colour-sensitive plates, not only to produce monochromatic results from nature and the production of the artist, but a close realisation of that long-sought desideratum—photographs in the colours of nature.

Since the first intimation by Col. Waterhouse for the use of dye-eosine in collodion to overcome the inability of the collodion process to render other than the blue and violet rays of the spectrum, scientists have worked assiduously to overcome the difficulties that were inherent in the old wet, and the dry-plate process of the present, and to no one are we so much indebted for the present success in orthochromatic photography as to Dr. Hermann Vogel of Berlin. We owe also much to the research of Mallman and Scolik of Vienna, Bothamley of England, and others we might mention, who by their liberal contributions to the literature of orthochromatic photography have done much to aid those who have made it their business to produce commercially the plates for the photographer's use.

The dyes now generally used, either by mixture with the emulsion before coating the glass plate or celluloid film, or dyeing the ordinary gelatine plate afterwards, are eosine, erythrosine, rose bengal and cyanine, the latter we believe but rarely used, owing to the unsaleable character of the plates made with it. To the above may be added axaline, a compound of Dr. Vogel's invention, said to consist of chinoline red and cyanine blue.

Orthochromatic photography has had its greatest advocates in Germany and Austria, in the reproduction of works of art in monochrome. Since the introduction by myself, in 1885, of orthochromatic plates, the use both by the amateur and professional photographer has had a steady growth. The intelligent amateur, as seems to be always the case on the introduction of any improvement in photography, was the first to test its merits, then the professional copyist of art works took hold of them, and their results now vie with the best products of Europe.

The professional photographers of America were the last to take hold of and use the orthochromatic method, and the wonder to me is that they are not more used by them. One reason is, I believe, a want of acquaintance with the orthochromatic plate, and with many the idea prevails that a colour screen must be used under all circumstances; this arises, it seems to me, from an unwillingness on the part of photographers to read the literature provided for them on the subject, which, if read, would make many things plain that they remain in ignorance of, and, as is often the case, lose business for want of the little knowledge so easily acquired.

It is, however, very pleasant for me, as a manufacturer of orthochromatic plates, to say that since 1891 the increased use of these plates has been very large as compared with the time of their introduction in America up to that date.

The use of the colour-sensitive plate may be used under all conditions when a plain bromide plate has previously been employed. Its use is to harmonise contrasts, whether in the dress of the sitter or a view from nature. Greens and yellows are rendered with more detail and colour value, while blues and light reds in drapery are given their proper colour value instead of being rendered lighter in the photograph, as is common on the ordinary gelatine plates.

The Colour Screen—When and How to Use it.

For ordinary landscape work a very light yellow screen is all that is necessary, a dark yellow or one of orange shade would falsify distance. The most suitable place for the colour screen is at the back of the lens board, sliding it in two grooved cleats, and should be placed in position when focussing. A screen of such a tint as this one would require an increased exposure of four to six times, depending on the state of the atmosphere, the yellower the light the shorter the exposure, and towards evening may be dispensed with; the value of a light yellow screen is best shown where the vista is slightly hazy, or where the clouds are included

in the view. Their outlines and forms will be much better rendered in the negative.

Use of Screens in Copying Paintings.

In this class of work the selection of the proper colour screen is of more importance than in landscape work, and the photographer should be provided with two or three, ranging in tint from a moderately strong yellow, medium, and dark orange. Paintings are best photographed in direct sunlight, and by examining the painting through the colour screen it will not be difficult which one of the screens to select. For instance, take a modern French painting, consisting of light and brilliant colours, a yellow screen will answer; but with a German or English painting, containing strong reds and dark blues and green, we would select an orange-colour screen, and correspondingly increase the time of exposure. It may astonish some of you to learn that as much as ten minutes' exposure is given in direct sunlight on paintings that are old or painted in strong colours.

Photography in the Colours of Nature.

The objective point that has been striven after for years seems w near of being accomplished. I do not mean the actual photographing of either objects of nature in colours, but through and by the agency of the orthochromatic plates. By the patient and scientific research of Dr. H. Vogel, of Berlin, and Frederick E. Ives, of Philadelphia, the first as achieved by triplicate negative and a like number of superimposed impressions, reproductions of objects in colour so true to the originals in colour as to be quite a commercial success, and in this country is being carried out by Mr. Kurtz, of New York. Of Mr. Ives' work I have seen a great deal; it differs in result from that of Dr. Vogel's in that the final picture is a triple image—a positive—on glass, viewed through three colour screens in an instrument invented by him, called the heliochromoscope, and the object as viewed is seen in all of nature's brilliant colouring.

Colour Photography (so-called)

Is now achieved by making three negatives of the object on orthochromatic plates through three different colour screens, viz., violet, green, and red. I have here samples of such colour screens. In printing by the collotype, or half-tone block, as in Mr. Kurtz's work, inks in the three primary colours are used, viz., blue, red, and yellow. The proper selection of tints, however, is a very important matter. Reproductions by this method are shown in Mr. Kurtz's exhibit in the gallery, north end of Liberal Arts building.

Developing of Orthochromatic Plate.

The same developer as used for the plain plate may be used for the colour-sensitive plate, except that we find it best to use it slightly diluted; as the colour-sensitive plate more readily takes on density, and the exposure should always be generous, it is necessary in order to get full colour values.

Keeping of Orthochromatic Plates.

A certain amount of doubt as to the keeping qualities of orthochromatic plates has been disseminated in this country. I can only say, with regard to those of my own make, that I have evidence of many cases where they have yielded perfect results from nine months to a year and more after leaving the factory. Plain plates orthochromatised by the bathing process, writers tell us, are not to be depended on over a few weeks. From past experience I am led to believe that plates from a proper orthochromatic emulsion have as good keeping qualities as the plain plates from same emulsion.

In conclusion, I may say that I am firm in the belief that colour-sensitive plates will in time replace the plain bromide plates, as the latter has the old wet-collodion.

John Carbutt.

MEDICAL PHOTOGRAPHY.

I have often wondered that the art of photography is not more generally employed in the interests of the medical profession. Those who teach the various sciences included under the one general term of medicine can not fail to find it a most valuable assistant. This is so clear that I will not linger longer in discussing it; let me rather say that the disfavour with which photographic attempts in medicine have been regarded by the medical profession is directly due to the poor work which has been done. These poor results have been made by photographers who were either ignorant of what the physician's eye would seek for in the picture, or so poorly skilled in the art of selecting and lighting the right kind of subject, that failure was inevitable.

In medical, as indeed in all other kinds of photography, the first step towards success is to know what to take, what not to take, and how to pose and light the subject to be taken. For instance, all portions of the human body that are not too complex in structure, and have decided outlines, with well-marked contrasts of colour, will be good subjects for the camera. Bones, either healthy, diseased, or fractured, and with or without the ligaments belonging to them, photograph well. I may here say that I was once called upon by a professor of obstetrics to make a set of negatives of the various planes and straits of the female pelvis. Enlarged prints from these negatives were then made, and very successfully used for class demonstrations. Being enlarged to rather more than life size, the smaller details could be easily seen, even from the farthest corners of the lecture-room. In doing work of this kind, which is intended to show only certain portions of the bone, and no more, the camera must be directed with *absolute accuracy*; otherwise the student would receive a wrong impression. Photographers ignorant of anatomy will not easily recognise the importance of what I allude to, and they must be prepared to have their early efforts in this direction sharply criticised by their medical clients, who will naturally expect scientific accuracy as the first desideratum. The photographer should always demand the fullest instructions from the medical man as to what the finished photograph is to show, and how much subject is to be included.

As I before hinted, all deformities and diseases that are *striking to the eye* make good photographic subjects. I have succeeded well with children with hydrocephalic heads, or with advanced cases of black gangrene of both feet, and with cases of advanced starvation. But the interior portions of the body are more difficult to photograph satisfactorily, the various organs crowding one another too closely, and being too nearly of one colour, or (what amounts to the same thing) of the same actinic effect upon the film. To produce really effective photographs of diseased abdominal or thoracic organs, I should recommend the stereoscopic camera, and orthochromatic plates, which, at least, give better marked contrasts in the different colour values. The anatomical relations between the different organs will be admirably brought out in the stereoscope, but care must be taken not to separate the lenses of the camera too widely, and thus produce exaggerated perspective.

It is hardly necessary to add that there is no advantage in using the stereoscopic camera for such a thing as a skin eruption on the breast or back; these, and other flat portions of the body could be as well photographed with the single camera.

Enthusiastic medical men, who take up photography with the idea that it is a mechanical sort of thing soon learned, will find their results quite unfit for use or for show, unless they are willing to learn a little of the principles of posing and lighting in photographic portraiture. These principles can best be learned in the portrait gallery itself, though there is no want of excellent text-books that explain the matter. To those ignorant of these things I may give the following example: Supposing the subject to be a man with a large lacerated wound of the left side, and that he was set in a chair with the wounded side toward the window of an ordinary room, the camera being set in front of him; what sort of a photograph would be obtained? The patient's body would be divided into the two portions vertically, the one greatly over-lighted and the other correspondingly under-lighted and black. The delicate and important details in the wound would be "burnt out" by the light, while the whole of the right side would be smudgy and without detail. Far better results would be obtained by so posing such a subject that a soft, even light from the north falls upon the head and body at an angle of, say, forty-five degrees. A properly arranged skylight will make this easy, and judicious exposure and development will give a clear, rotund image of good printing quality.

To photograph a sick or wounded person by the magnesium flashlight would not only increase all the photographic difficulties, but be injuriously exciting to the sufferer.

There is a very extensive and interesting field in medical photography open for microscopists, particularly in the enlarging of microscopic objects for use in class teaching and lectures. I should certainly prefer an illuminant of unvarying power, such as the electric light, for this sort of work, but I cannot here enter into the question as to the desirability of direct *versus* diffused lighting. Different subjects, as I said before, require different treatment; but I can and do advise the use of low-power objectives rather than high ones as giving greater depth of focus or "reach," and being also in other ways easier to work with. The time of exposure and development must be found by experiment. A simple yet effective apparatus may be fitted up as follows:—After taking out the eyepiece end of the microscope, level the body of the instrument, and insert the eyepiece end into a small camera, say, for plates 5×4 inches, and make the connexion light-tight with a bit of black velvet. The body

of the microscope must now be so directed as to come opposite the centre spot of the ground glass of the camera, and stand exactly at right angles to it; or, in other words, the whole photo-micrographic apparatus must be in a right line axially. The slide is now inserted and focussed upon after the lighting, whether reflected or transmitted, has been seen to. A want of sharpness in photo-micrographs is, perhaps, more often owing to improper lighting than to any other cause, except the use of too high-power objectives. It will be found convenient to stretch a thin, strong cord around the large focussing screw of the microscope and carry it back to a spool or similar arrangement set on the board supporting the apparatus at the right of the camera, and within easy reach of the hand. A cheap and efficient sulphate of copper cell can be made with two pieces of plate glass, say, four inches square, and a rubber ring one-eighth of an inch thick. The ring is laid on one glass, and a few drachms of ammonio sulphate of copper solution poured on. The other glass is then laid down, and the two strongly clamped together by two pairs of short laths made of hard wood, connected by screws. In all this class of work I should advise that soft negatives with plenty of detail be aimed at rather than vigorous ones with great contrast. The soft negative is more useful for slide-making and enlarging, besides which it is much easier to intensify a thin negative satisfactorily than to reduce one in which there is too much contrast. I do not like the action of reducers, and avoid them as much as I can.

The peculiar walk of certain forms of nervous disease might be registered if a full battery of cameras with chronometric shutters was at hand. I need hardly say that such apparatus is very expensive, and requires the greatest care and skill to manipulate. Animal locomotion, as it is now termed, is within the range of possibility from the photographic point of view; but, aside from the value of such pictures as triumphs over technical difficulties, it may be doubted whether they are worth the trouble and expense of making from the medical standpoint. I may repeat in closing that suitable subjects suitably lighted should be chosen, and those avoided that offer no chance of success.

ELLERSLIE WALLACE.

ISOCHROMATIC PHOTOGRAPHY.

AMONG the great discoveries and achievements that characterise our present century, and have accomplished results never before dreamed of and formerly deemed impossible, photography holds a prominent place in practical utility and as a helpmate to art and science.

Portraiture has been brought to simplicity, and in the fraction of a second we can secure the features of those who are dear to us. Foreign countries and nations are brought to our sight in pictures produced by the camera; movements of animals, too quick to be distinguished by the human eye, are truly and accurately recorded by the highly sensitive photographic dry plate; the stars are photographed, as well as the minute bacilli and bacteriæ whose multitudes inhabit the drops of water and the cells of animal life, and which in many instances are the causes, heretofore unknown, of diseases.

Since photography has rendered it possible to secure the rays of light to the sensitive plate, it has been the aim of scientists and practical workers to bring it to perfection, and the greatest improvements have been achieved in the preparation of dry plates ready for use and of the utmost sensitiveness. The great *desideratum*, to obtain photographs in natural colours, is now brought in the reach of possibility, as shown by the fine specimens of reproductions which are on exhibition in the photographic department of our great World's Exposition, and the time may not be far distant that portraits and landscapes are photographed in all the beautiful tints and colours as seen in nature. The most important step in this direction was the production of colour-sensitive plates by which one of the shortcomings of photography is corrected, that is, the insensitiveness of the ordinary plates to the yellow, orange, and red colours, which cause these colours to appear much darker, while the blue and violet appear much too light in the ordinary photograph.

The aim of isochromatic or orthochromatic photography is the production of plates equally sensitive to the different rays of the spectrum, so that in the monochrome of the finished picture all the colours are rendered equally correct in their respective values.

This colour sensitiveness is obtained by the addition of certain ingredients, mostly of the eosine group of analine dyes, to the sensitive bromide of silver emulsion, and the plates so prepared are called isochromatic or orthochromatic plates.

A great drawback to the introduction of the isochromatic plates into general use has been the necessity of a colour screen in order to obtain the isochromatic effect. A yellow glass had to be placed before or back of the lens, or a yellow pellide in place of the diaphragm, to filter the light, and to subdue the greater actinic power of the blue and violet rays. The isochromatic effect being increased in the same proportion as a screen of deeper yellow colour is used, it necessarily follows that the required exposure is prolonged in the same ratio and to such a degree that the use of a colour screen for portrait work and instantaneous exposures is out of the question. If the yellow screen is not perfectly even in structure and thickness, and absolutely plain, it will cause distortion of the image by aberration. Change of chemical focus and reflection may also be caused by its use, and therefore it is apparent that plates which produce the most isochromatic effect without the aid of a colour screen are the most valuable. As such plates can now be obtained which combine great rapidity with good colour sensitiveness, and are no more difficult to work than ordinary plates, their advantages should be appreciated by the photographic fraternity.

In portrait photography the blue eyes, auburn hair, are rendered more truthfully; imperfections in the complexion, such as freckles, are less noticeable; and dresses of any colour are photographed correctly, so that ladies need no longer consult the photographer as to what colour of dress to wear when having their pictures taken.

In landscape photography the main advantage of the isochromatic plate is that distant objects are photographed much more distinctly than with the ordinary plates. A slight haziness in the atmosphere is neutralised by the use of isochromatic plates, while an ordinary plate would not produce any satisfactory result under the same circumstances. White clouds in a blue sky can not be photographed except with the isochromatic plates, and how much clouds add to the beauty of a landscape is known by everybody. In sunset scenes the superiority of the isochromatic plates is as apparent as in the autumn landscapes, with their wealth of yellow and orange-tinted foliage.

In seascapes or marine views the horizon is not lost, water and sky being properly rendered.

In commercial photography the instances where isochromatic plates should be used are too numerous to mention. Wood work, which is generally of a yellowish tint, is photographed more perfectly; inscriptions on waggons, railroad cars, samples, floral designs, &c., which may not show at all when photographed with an ordinary plate, are perfectly reproduced.

Now, for the copying of paintings in oil or aquarelle nothing but an isochromatic plate should be used, and its advantage for this class of work is most strikingly apparent. In an old oil painting the lights are generally yellow, while the half tones are of a bluish tint. It is impossible to obtain a good copy of such a painting with an ordinary plate. Plates of full isochromatic effect are necessary for this purpose.

Another advantage of the isochromatic over the ordinary plate is its greater sensitiveness when the light is yellow, as is frequently the case in fall when the sky is cloudless, or in photographing by gaslight.

I have now said enough of the advantages of isochromatic plates, and beg to be excused if I have made statements of facts supposed to be well known; but the isochromatic plate being undoubtedly the plate of the future, it seems to me that its full value should be more generally understood and appreciated.

G. CRAMER.

A WEEK'S TOUR IN THE BORDERLAND.

Now that the excursion season has commenced in good earnest, and the many votaries of the camera are preparing to take their annual holiday, a few words on a district liberally supplied both by nature and by art with a wide and varied choice of subjects for the photographer, may chance to prove not less serviceable than they are timely.

The region referred to comprehends that portion of the Scottish Borders which is included within the shires of Roxburgh and Selkirk.

It is doubtless the case that of the many places of interest in these counties some are already over familiar to most field-workers, by reason of their lying directly in the beaten parts of the tourists; but it is no less true that a large number (including many spots of much historic and artistic interest) are hidden in out-of-the-way corners and unfrequented by-paths whither the mere visitor is of all persons the least likely to find his way.

The following brief sketch of a week's tour in those parts is intended to serve as a daily outline for the itinerant photographer, by showing him how best he may utilise the short time at his disposal.

For his first day's excursion, let him take the train in the early morning to Riccarton Junction. A four miles' walk over the hills will bring him to the famous castle of Hermitage, the ancient seat of the Douglas family. On his way thither he will do well to halt for a few minutes on the Nine-Stane-Rig, where there are still some remains of the circle of standing stones from which the hill takes its name. Here, if song and tradition may be believed, the refractory vassals of the tyrannical Lord Soulis executed summary vengeance on their master in the painfully original manner related in

Leyden's celebrated ballad. This circumstance may serve some as an excuse for perpetuating a rather unpicturesque spot in gelatino-bromide. Having descended from the heights, the tourist will find himself in the valley of the Hermitage Water. By taking a westward course, and following the windings of the stream for his guide, a short walk will bring him to the castle, which stands on a grassy platform on the northern bank.

This massive and venerable pile is comparatively unknown to the general tourist. It is, nevertheless, perhaps the best and most entire example of an early Border castle now existing in Scotland, its only possible rival being that of Caerlaverock in Dumfriesshire. The natural dignity of Hermitage is greatly increased by its lonely situation in the midst of a region singularly bleak, flat, and desolate, and by the bold simplicity of its architecture, which is that of the beginning of the fifteenth century, with some small remnants of earlier work, and a few additions of a later date. The whole forms an excellent subject for the camera, and several plates may be here profitably expended.

If he go expeditiously to work, our photographer should have no difficulty in re-arriving at Riccarton in time to catch the early afternoon train to Hawick. This done, let him walk or drive to Branxholm Castle (the Branksome Hall of Scott's *Marmion*), distant about three miles to the south of the town. On his way thither, just as he begins to ascend the hill that lies at the farther end of Hawick, he will notice an interesting bowl-shaped barrow standing in a garden by the wayside. This memorial of prehistoric times is locally known by the name of the "Mote." With a little trouble a spot may be found whence a satisfactory negative of this curious relic may be obtained. Further on, upon the summit of a little hillock on the left side of the road to Branxholm stands the old peel-tower of Goldielands. The building is of small size, and without pretensions to either architectural or historical interest; but as an example of the most common type of fortified dwelling-house it has some little claim on the attention of the visitor.

Branxholm Castle, though much modernised to adapt it to the purposes of a nineteenth century residence, still retains many features of its original condition. An ancient ivy-clad tower, abutting on the western gable of the more modern portion, remains almost intact. Under ordinary circumstances, the building is not open to the inspection of tourists, but an excellent picture of the exterior may be obtained from the southern bank of the Teviot, near the suspension bridge. Having returned to Hawick, our photographer will probably be inclined to devote the remainder of the evening to rest and refreshment. Should he, however, prefer a pleasant country walk, he will find Harden Hall, a picturesquely situated old mansion, distant about four miles west of the town, well worthy of a visit. He should pass the night at Hawick, and, in the morning, proceed by rail, *viâ* St. Boswell's Junction, to Jedburgh. He may profitably devote the whole forenoon to an examination of the magnificent remains of Jedburgh Abbey. It was founded in the year 1118 by David I. of Scotland, and is a noble example of the Later Norman style of architecture. Many excellent negatives can be obtained here. The western and cloister doors are particularly worthy of the attention of the photographer, and a good general view of the whole extent of the edifice, with a river foreground, may be had from a spot on the banks of the Jed, a little south of the precincts.

In the afternoon the tourist should pay a visit to Ferniehurst Castle, situated a mile and a half south of the town. This interesting building, which has been lately repaired and partially restored, is chiefly of sixteenth century date. Though of less importance than Hermitage, it is not wanting in the elements of the picturesque, and makes a good subject for the photographer.

The remainder of the day may be spent in examining the Watling-street, the ancient Roman road from Northumberland into Scotland. It passes about two miles to the east of the town, whence it may best be reached. At the point where it crosses the Oxnam Water, a Roman station has been discovered in recent years, the remains of which have been partially excavated. The foundations and ground plan of several buildings may be seen within its area. A number of interesting antiquities have been discovered in the vicinity.

The visitor should pursue the Roman way northwards to Bonjedward, where it crosses the Teviot. Here he will get a train back to Jedburgh. In the course of his walk he will, weather permitting, find many favourable opportunities for employing his camera.

The next morning he should proceed by rail to Kelso. He may utilise the short time spent in waiting at Roxburgh Junction by photographing an old building known as Sunlaws Tower, which overhangs the River Teviot beneath the railway embankment. On reaching Kelso he will naturally devote some time to photographing the ruins of the Abbey.

This, another of the monastic foundations of King David I., dating ten years later than the Abbey of Jedburgh, is also a fine specimen of the Norman style. It is, however, much less perfect in its plan, a large portion of the edifice having been demolished. The pedimented porch in the northern wall is of unique character, and its rich details make it a suitable study for the camera.

Having finished his work in the town, our photographer should proceed on foot to the hamlet of Crosshall, which lies within the border of Berwickshire, about six miles northward of Kelso. Here he will find an antique cross, on the shaft of which are sculptured the figures of a knight and a greyhound. Its origin is still a matter of debate among archæologists. Resuming his walk, he will reach Hume Castle, two and a half miles westward of Crosshall. The building is of some celebrity in the annals of Border warfare, and is a prominent object in an otherwise flat landscape. Our photographer should have no difficulty in getting several good negatives here, after which, by taking the southward road, a walk of five miles will bring him back to Kelso.

The next day, leaving Kelso, let him take the train to Melrose, and spend the forenoon in photographing the oft-depicted abbey. By exercising a little judgment, he will be able to obtain a number of pictures of the ruins which shall possess some measure of individuality. Afterwards, passing through Newstead, a quaint village remarkable for the number of its sundials, a five-miles' walk alongside and across the Tweed will bring him to Dryburgh Abbey, beautifully situated in a wooded nook by the waterside. Both here and on the road hither he will meet with many picturesque "bits," which will keep him busy for the best part of the afternoon. From St. Boswell's Junction, a mile distant, he may return by rail to Melrose in time to pay an evening visit to the Eildon Hills.

Next morning, crossing the Tweed to Gattonside, a suburb of Melrose, and taking the eastward road that runs parallel to the river, a walk of an hour and a half will bring him to Smailholm Tower.

This old fortress, situated on the summit of an irregular and rocky hill, is a conspicuous landmark throughout the length and breadth of the shire. It is a good example of its class, in better condition than are the majority of the neighbouring strengths, and, naturally picturesque in its outlines, is still more so by its situation.

The afternoon may be employed in visiting Abbotsford, distant two and a half miles westward of Melrose. Should the visitor desire to photograph the house or grounds, he ought to seek and obtain permission to do so some days beforehand. By neglecting this, he is likely to meet with a refusal.

The last day of the tour should be spent in visiting St. Mary's Loch in Selkirkshire. This may best be done by journeying by rail to Selkirk, and there taking the coach which, at regular intervals, conveys passengers to the loch.

The spot is one of great natural beauty, and a day's ramble in the vicinity will afford the photographer many opportunities for exercising his artistic taste.

He will thus be enabled to add to his already extensive pictorial series a number of views of an interest apart from their historical associations, and to bring to a close, in the very heart of the Borderland, a holiday tour which, should he enjoy favourable weather, cannot fail to prove both pleasant and profitable.

MATTHEW WILSON.

CENTRAL PHOTOGRAPHIC CLUB.

We are happy to be able to announce that the executive of the Central Photographic Club have secured suitable premises at one of the best and most agreeable hotels in central London, namely, Coleman's Hotel (late Ashley's), Henrietta-street, Covent Garden, a building associated with the earlier days of at least two existent flourishing photographic societies. The rooms available for the use of members will include such as give the usual club accommodation of smoking, reading, meeting, and dark rooms, and seem in every way well adapted for the purpose.

Country members visiting town will have the advantage of securing hotel accommodation, as it were, on the Club's own premises, and certain obvious difficulties as to service of refreshments, tariff, &c., will be easily and happily overcome. It is expected that the premises will be available for the use of members in a few days.

In the meanwhile the opening meeting of members and those intending to become members will be held at the Club, Coleman's Hotel, Henrietta-street, Covent Garden, on Wednesday, September 13, at eight o'clock. This will constitute, as it were, the formal opening of the Club, and will give an opportunity for the amendment of the rules, necessitated by the abandonment of some parts of the original scheme, and for other business of a formal nature. Mr. George Mason, of Glasgow, will take the chair. Intending members and others interested will be welcome.

It should be said that the Hon. Secretaries are Messrs. W. Fenton-Jones, 12, King Edward-road, Hackney, and C. H. Oakden, 53, Melbourne-grove, East Dulwich, to whom communications relating to the Club should be addressed.

Our Editorial Table.

SICHEL'S CATALOGUE OF PHOTOGRAPHIC FRAMES, MATERIALS, APPARATUS, &c.

O. SICHEL & Co., 52 Bunhill-row, S.E.

MESSRS. SICHEL'S catalogue appeals largely to professional photographers. In it are given illustrated details as to a large variety of mouldings for photographic frames, all evincing taste in design, mounts, fancy frames, studio cameras (these appear of great elegance

and strength), field cameras, stands, albums, &c. In the section devoted to accessories are many charming things in the way of studio furniture, while there is an extensive assortment of backgrounds, and designs for the backs of cards. Altogether a useful catalogue for the professional photographer, anxious to be up to date.

Catalogue, &c., of the Cantilever Enlarging Apparatus.

W. Hume, 1, Lothian-street, Edinburgh.

Mr. Hume's catalogue is largely devoted to descriptive particulars with illustrations of his well-known Cantilever enlarging apparatus. Some serviceable hints as to lantern manipulation, enlarging, &c., are also included. Other photographic goods, such as cameras, lenses, microscopes, &c., hand cameras also find places in this well-arranged pamphlet (for it is a cut above an ordinary catalogue in point of utility). No lanternist or enlarger should be without it.

The Sandell Films.

R. W. Thomas & Co., Thornton Heath.

The Sandell film just introduced by Messrs. R. W. Thomas & Co., is an application of the principle embodied in the Sandell plates, the films of celluloid having a multiple coating of gelatine emulsion. One by one the principal makers are selecting celluloid as a support for the sensitive medium, and we have no doubt that ere long there will be none left who have not added the coating of cut films to their specialities. Including, of course, among their characteristics the advantages of lightness and portability, the Sandell films also embody the leading features of the Sandell plates, and yield negatives of a similar character. Consequently, what we have before written of the Sandell plates applies with equal force to the films, at any rate in respect of the quality of the results. Celluloid is notoriously more difficult to coat than glass, with an equal certainty of escaping from mechanical defects and irregularities; but, judging from the sample of the Sandell films, Messrs. Thomas appear to have surmounted these obstacles, and to have produced a film which leaves nothing to be desired on the score of technical excellence. It should be said that the manipulation of the films is precisely the same as the multiple coated plates.

News and Notes.

Northern Photographic and Scientific Association.—September 9, Totteridge.

"Cream" (of the World's Fact, Fun, and Fancy) is the title of a new weekly penny paper, which, under the editorship of Mr. Francis George Heath, will shortly appear.

Manchester Amateur Photographic Society.—September 9, Dunham Park. Leader, Mr. Prince. Train, London-road (L. & N.W.), ten minutes past one; Oxford-road, fifteen minutes past one. Fare, 1s. Book to Altrincham.

Mr. R. P. Drage, the late Hon. Sec. of the London and Provincial Photographic Association, has gone on a six months' tour in India, Japan, &c. He takes a large supply of films for photographic work *en route*. Mr. Drage's numerous friends will wish him a pleasant journey and a safe return.

Great efforts are being made by the executive of the Triennial International Photographic Exhibition, to be held in Bristol next December, to render it a worthy successor of former exhibitions held there. Mr. H. A. Hood Daniel, the president of the Bristol and West of England Amateur Photographic Association, and the Hon. Sec., Mr. E. Bligh Bond, are throwing themselves energetically into the work.

The Congress of the Photographic Society of Great Britain, to be held in the rooms of the Society of Arts on October 10 and 11, is expected to be largely attended by provincial photographers then likely to be in London for the Exhibition. We understand that an attractive programme of important papers is in preparation. The proceedings terminate on Thursday, October 12, with a free lantern entertainment in the gallery of the Exhibition at Pall Mall.

Hackney Photographic Society.—September 12, *Failures*. Members will please bring failures for discussion thereon. The Society's Exhibition will be held on October 17 to 19 at Morley Hall, Hackney. There are four open classes —Portraiture, General work, *Pictures previously medalled or awards taken*, Lantern slides. The Exhibition is open first day at half-past seven, when the awards will be made known, and the successive days at twelve midday, to enable City men to get up in dinner hour.

The Seventh Annual Exhibition, under agreement between the Society of Amateur Photographers of New York, the Photographic Society of Philadelphia, and the Boston Camera Club, open to all photographers, will be held by the Society of Amateur Photographers of New York, at the galleries of the American Fine Arts Society, Fifty-seventh-street, near Broadway, New York, from April 16 to 28, 1894. Entry forms can be had by applying to the Committee. Exhibition Committee, T. J. Burton; R. A. B. Dayton; R. L. Bracklow. Address, 113 West Thirty-eighth-street, New York.

Leytonstone Camera Club.—September 9, Essex Dairy Farm (Cattle Studies), by kind permission of Mr. Smyth. Leader, Mr. H. E. Farmer. The Club will proceed by the train leaving Liverpool-street (G.E.R.) at thirty-five minutes past two p.m., calling at Leytonstone fifty-two minutes past two, arriving at Loughton twelve minutes past three. Open Special Evening at Headquarters, eight o'clock. 13, Ordinary Meeting at Headquarters, eight o'clock, for the purpose of Testing and Selecting the Slides to be sent in to the National Slide Competition. It is hoped that every slide-worker will bring six slides (those with connective interest preferred).

"Trade Depression."—A correspondent writes:—"I cannot believe that the photographic trade is depressed, judging by what I see and read in your Journal. When a new thing comes out it is "boomed," and large profits are made; as the number of persons engaged in the trade increases, prices must fall; moreover, there is the fact that at first all the world is purchaser, and after, all those who have not already purchased. Where are Lancaster's 65,000 cameras? Where Dallmeyer's, Ross's, Underwood's, Tylar's—*et hoc genus omne?* Photographic instrument and material makers have one *desideratum* to find—a cheap film. When this is found, a large and hitherto unsuspected market will be opened."

A Photographic Association for Widnes.—On Wednesday, August 30, a well-attended meeting was held at Bedford Chambers, at which it was decided to establish the Widnes Photographic Association. Officials were appointed as follows:—*President:* V. C. Driffield.—*Vice-President:* G. E. Warner.—*Council:* J. S. Sinclair, A. Wareing, W. Priestnall, O. White.—*Hon. Secretary and Treasurer:* George Ray, Bold, near Widnes. The inaugural meeting of the Society will take place on Wednesday, September 13, at Bedford Chambers, when the President, V. C. Driffield, will give a practical demonstration on the *Determination of the Density of Negatives and Bromide Printing.*

The *Joker*, a halfpenny "humorous" sheet, is circularising photographers in the following strain. We question the likelihood of any "benefit" to the photographer arising out of the scheme. "We beg to call your attention to a scheme which, in America, has proved most advantageous to both newspaper proprietors and photographers. In our paper, the *Joker* (which has a circulation of considerably over 100,000 weekly), we shall insert a coupon, six of which will entitle the holder to a free photograph of himself on presenting same to any one of the photographers who join us. The benefit to photographers will be: First, very few people would be contented with one photograph, but will give an order for more, which can be charged for at such rate as the photographer pleases. Second, as the names and addresses of those photographers who act for us will be published weekly, this will prove a splendid advertisement for them, particularly as the mere fact of our selecting a special photographer in a district will in itself be a testimonial for that artist, as we shall only connect our paper with firms of the highest standing. If you care to participate in our scheme, will you kindly write us to that effect?"

Pinholes.—Pinholes in a plate arise from one or other of three causes: (1) Dust specks in the course of manufacture; (2) dust specks during exposure; and (3) dust specks during development. The first-mentioned pinholes, says *Photographic Scraps*, may be at once and definitely distinguished from those resulting from either of the other causes. If they are due to dust in the course of manufacture, the pinholes will be real ones—that is, they will show as specks of *bare glass*. The other *so-called* pinholes will be, on the contrary, only transparent spots where the gelatine is present; but, owing to the presence of dust during exposure, the light has not been able to act, or, during development, the developer could not get at the film under the dust. It will thus be seen that one can tell instantly whether the spots are due to faulty plates or careless development, and we beg those who experience such troubles to kindly look to this point before they write us. The slightest care will save us and them much trouble. There is another class of spots too often described, unfairly, as pinholes, which arise from the presence of minute air bubbles in the developer—such air bubbles are much more frequent during hot weather, and with a stale developer.

Printing Half-tone Blocks.—The secret of success in making half-tone work commercially profitable is to understand the printer, says *Process Work*. Give him the block he can print, and more orders will follow. Printers are now begining to wake up in regard to the printing of process blocks, and, if they do not make a good job of a half-tone block nowadays, it is not for want of trying. In most cases it is the master printer who is to blame, in giving his man unsuitable ink and paper. It is surprising what a difference there is in results between one sample of paper and ink and another. The fundamental rule is, that it is no good trying to print a half-tone block on coarse-grained paper with thin ink. A highly glazed and sized paper is best, and the ink must be tacky and intensely black. It is no good trying to get colour by means of heavy impression. The ink itself must give the colour. It is important, in printing half-tone subjects, to give the block a clean up occasionally with a fine, stiff brush—an old tooth brush does very well—and turpentine or benzole. Speaking of this cleaning up, we well remember a machine-minder describing to us a great find he had made in the way of a fluid for cleaning up half-tone blocks. He had a mixture—it such it could be described—of hydrochloric acid and turpentine. "Cleans 'em up fine, and no mistake," he proudly exclaimed. So it did, and by the end of the job he had cleaned all the picture away, and, when the customer received the job, of course the unfortunate process man got the "wigging."

IMPROVEMENTS IN AND RELATING TO PHOTOGRAPHIC CAMERAS.

No. 18,899. DR. RUDOLF KRÜGENER, Bockenheim, Frankfort-on-the-Main, Germany.—*July* 22, 1893.

MY invention relates to a photographic camera, in which single sensitised sheets are employed. A number of these single sheets are put together on an improved principle to form packets, and in that state are placed in the camera directly, that is to say, without a special case or the like. By reason of the peculiar packing of the single sensitised sheets, extreme simplicity is realised as regards the exchange of such sheets in the camera and the construction of the latter.

Besides the great cheapness and facility of handling resulting from this feature, the improved camera possesses the further advantage that despite the large number of exposures which may be given one after the other, it is very light, and that by virtue of the improved mode of packing and exchange the bulk of the camera may be exceedingly small, which is of great importance for large sizes.

As above stated, the essential feature of my said invention lies in the peculiar packing and exchange of the sensitised sheets. One mode of packing is characterised by the employment of a long strip of paper or the like. This strip is laid together in folds, which are a little larger than the sensitised sheets to be employed. To the lower end of the said folds are pasted small strips, extending across the strip. These transverse strips are bent outwards a little, and, in conjunction with the respective upper fold of the strip, hold the sensitised sheets between two layers of paper. Packed in this manner, a considerable number of sensitised sheets can be put in a very small space of the camera.

The above-described mode of packing and the resulting mode of exchanging the sensitised sheets may be used in cameras of various constructions. In one arrangement the apparatus comprises the camera proper, a magazine, and a chamber for the reception of the sheets which have been exposed. The camera and magazine are separated from each other by a glass plate, against which the sensitised plates bear as they are focussed. The exchange or conveyance of the sheets which have been exposed into the said chamber takes place by conducting the prolonged end of the strip over a roller, and from this roller to the outside through a slot which precludes the passage of light. When pulling this end of the strip, the transverse strip which is foremost at the time will raise the sheet which has been exposed. By the above-mentioned roller and small block, preferably covered with velvet or similar soft material for protecting the coated side of the sheet, the latter is bent, shifted forwards, and finally falls of itself into the chamber. Now the strip is pulled a certain distance further from the camera, the superfluous end being then torn off. By this means the sheet which has been exposed is laid away, and at the same time a new sheet is put ready for a fresh exposure, as by pulling out the strip the following sheet is liberated and placed against the glass plate, which takes place by a small spring plate pressing the whole packing forwards. After the exposure, the fresh sheet is conveyed in the same manner as the preceding sheet into the said chamber, and another new sheet which has not yet been exposed passes into the focus.

In a second arrangement the chamber is provided vertically above the magazine, and separated therefrom by a tongue. In this instance the sheets which have been exposed move straight upwards, are taken from the strip by the said tongue as the strip is pulled further, and pass in this manner into the chamber.

According to a somewhat different mode of packing the sensitised sheets, a number of single strips are used instead of a continuous strip. All the upper ends of these strips are bent round and lie one upon the other, whilst the lower ends are furnished with transverse strips like those used in the first mode of packing. These transverse strips support the sensitive sheets, which are prevented from falling by the upper bent ends of the main strips. Then the entire packet is so placed in one of the apparatus that the upper free ends of the main strips protrude through a slot formed in the wall of the camera. On pulling the foremost upper sheet after the exposure from the camera, taking hold of the end protruding from the latter, the sheet which has been exposed is conducted into the said chamber by a plate or other suitable device, the following sensitised sheet being at the same time put ready for exposure. In order to preclude the passage of the light through the slot after a number of strips have been pulled out, the said slot may be kept closed by any suitable device—for instance, by a plate held in guides and adapted to slide down in proportion as the strips are pulled out, or the said slot is specially covered over by a flap on the outside.

Instead of pasting on to the strips small transverse strips for holding and raising the sensitised sheets, a very narrow width of the latter may be fixed with paste to such strips. When pulling the strip the sheets are finally torn off and drop into the magazine.

Of course my improved method of packing and exchanging sensitised sheets may also be employed with cameras of any construction without departing from the scope of the invention.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

AUGUST 31,—Mr. W. D. Welford in the chair.

It was decided that the monthly lantern nights of the Association should commence in October.

Members were invited to contribute slides for the Lantern Evening of the Photographic Congress, to be held in the Exhibition Gallery of the Photographic Society of Great Britain, 5A Pall Mall East, on Friday, October 13.

"WHAT IS A PINHOLE LENS?"

In reply to the above question from the box, Mr. T. BOLAS remarked that the late Colonel Stuart Wortley took some large photographs with a lens having a very minute stop. This might be the sense in which the term was used.

OPENING OUT THE APERTURE OF A PORTABLE SYMMETRICAL LENS.

Mr. P. EVERITT, alluding to the mount Mr. Haddon had made for him which allowed of the full aperture of the lens being used, said he had taken a negative with the opening *f*-9 (approximately), and the print from it (which he passed round) showed that definition had not been greatly impaired.

Mr. W. E. DEBENHAM thought that with such an aperture there would be less equality of illumination, the corners not being proportionately so well lighted as with the original stop.

Mr. BOLAS said that Messrs. Swift made a type of portable symmetrical in which the mount acted as diaphragm for facility of focussing. He was surprised at the good definition obtainable. The lens with the large opening was not intended for actual use.

Mr. EVERITT pointed out that a portable symmetrical working at *f*-9 could be used for instantaneous work.

Mr. A. MACKIE stated that Mr. Williams, who did a great deal of instantaneous work ten years ago, used a portable symmetrical for the purpose.

The meeting subsequently became a Special General Meeting, called with reference to a consideration of some of the rules.

Hackney Photographic Society.—August 29, Mr. E. Puttock in the chair.—Mr. T. H. SMITH showed some Nikko paper, toned with the sepia bath, but said it was a very tedious process. Mr. BARNES showed a Barnet plate, and asked the cause of markings appearing like fog. Mr. BECKETT thought the plate was not at fault. The HON. SECRETARY said he would get an opinion from the firm. Mr. HENSLER had used the P.O.P. Ilford formula more concentrated, and found it tone quickly and regularly. Mr. FARMER had been advised to use ferrotype plates for squeegeeing. Mr. A. BARKER said old ones were apt to blister. The HON. SECRETARY advised using an enamelled metal plate, such as now sold. A question was asked: "Is quick negative drying advantageous?" Messrs. HENSLER, TUNSTON, and others deprecated it. Dr. ROLAND SMITH read a paper on *Daylight Enlarging*. It was a great advantage to enlarge. No enormous cameras should be necessary. He used a window facing N.-N.E. or N.W., fitting a tight frame to exclude light, and having attached a dull spot to reflect in. Camera slips on to groovings of frame, and two mop-handles are used, on which is placed board to take enlarging paper. A rapid rectilinear lens was advised—not portrait. Eastman's slow bromide paper, with ferrous-oxalate developer, was recommended. He used the same stock for four years, but, after using, placed out (in tubed bottle with film of paraffin) in sun. The HON. SECRETARY preferred amidol, found ferrous oxalate blocked out detail too much.

Liverpool Amateur Photographic Association.—August 31, Mr. P. H. Phillips (the Hon. Treasurer) presiding.—After the election of three new members, Mr. F. Anyon, a member of the Council exhibited twenty-one prints, representing fourteen different printing processes, and clearly explained the method of working each. Instructions were also given for producing the best results. A great deal of useful information was contained in the address, which was very interesting throughout.

Northern Tasmanian Camera Club.—Fifth annual meeting, Mr. R. L. Parker in the chair. The Secretary read the annual report and balance-sheet, which showed that the club was still increasing its membership, and that the new year started with a fair credit. The members continued to make good use of the library, thus gaining much useful information from the various journals subscribed to by the club. The attendance at the monthly meetings during the year was larger than previously, the members evidently taking great interest in the work of the clubs. After four years' services as Secretary, Mr. F. Styant-Browne intimated that, owing to increasing business engagements, he had reluctantly been compelled to resign, and the members that evening would have to elect a successor. The following officers were elected for the ensuing year :—*Patron :* His Excellency Lord Gormanston.—*President :* The Rev. A. H. Champion, M.A.—*Vice-Presidents :* Dr. H. A. Roome, Mr. F. Styant-Browne, Mr. R. C. Kermode.—*Committee :* Messrs. F. Stewart, W. H. Twelvetrees, and C. Nickolls.—*Librarian :* Mr. F. S. Browne.—*Secretary and Treasurer :* Mr. J. Sparrow. The Chairman, on behalf of the members, then presented the retiring Secretary with a purse of sovereigns, intimating that the members wished its expenditure in an optical lantern and accessories, having preferred giving Mr. Browne the choice of procuring the make of lantern he most desired. Mr. Browne thanked the members for their kind appreciation of his services. A hearty vote of thanks was accorded the Chairman for the use of the room during the year; and the first lady was enrolled as a member of the club.

FORTHCOMING EXHIBITIONS.

1893.	
September 20–21.....	*Hove Camera Club. Hon. Secretary, H. Emery, 142, Church-road, Hove, Brighton.
,, 25–Nov. 15	*Photographic Society of Great Britain, 5A, Pall Mall East, S.W. Assistant Secretary, R. Child-Bayley, 50, Great Russell-street, W.C.
October 1–31	*Hamburg. Das Ausstellungs Committé des Amateur Photographen Verein, Schwanenwik, 33, Hamburg.
,, 2–14	Midland Camera Club, Botanical Gardens, Moseley, Birmingham. Hon. Secretary, C. J. Fowler, 4, Woodstock-road, Moseley, Birmingham.
,, 9–Nov. ...	*Photographic Salon, Dudley Gallery, Piccadilly, W. Hon. Secretary of Organizing Committee, A. Maskell, 215, Shaftesbury-avenue, W.C.
,, 17–19	*Hackney Photographic Society, Morley Hall. Hon. Secretary, W. Fenton Jones, 12, King Edward-road, Hackney, N.E.
,, 30, 31	*East London Photographic Society, New Tabernacle, Old-street, E.C. Hon. Secretary, W. R. Gould, 61, Gibraltar-walk, Bethnal Green, E.
November 7–11	*South London Photographic Society. Hon. Secretary, C. H. Oakden, 53, Melbourne-grove, Dulwich, S.E.
,, 20–25.....	*Leytonstone Camera Club. Hon. Secretary, A. E. Bailey, Rose Bank, South-west-road, Leytonstone.
December.....	*Madras. The Hon. Secretary Amateur Photographic Society, Madras.
,, 18–Jan. 22, 1893	*Bristol Triennial International Academy of Arts, Bristol. Hon. Secretary, F. Bligh Bond, 36, Corn-street, Bristol.

* Signifies that there are open classes.

Correspondence.

PHOTO-MICROGRAPHY.

To the Editor.

Sir,—I am very glad to gather from your columns of late that considerable attention is being given to some interesting points in connexion with photo-micrography. Two letters in your issue of to-day evidently allow of, or perhaps call for, some reply from me.

First, my friend Mr. T. F. Smith "goes for me" because I hold that the results under discussion are the result of the use of both colour-correct plate and yellow screen. I hold, and claim to have proved, that the use of a plate more or less abnormally yellow-sensitive is the first step towards the result; the use of a light strong in rays more or less near D is the second step. The yellow light, in plain language, ekes out the effect of the extra relative yellow-sensitiveness of the plate. Mr. Smith does not appear to see the importance of his own words: "I am supposing . . . . that the lighting is done with the ordinary paraffin lamp.' In fact he uses a light which is practically equivalent to my limelight transmitted through a yellow "screen." If Mr. Smith will use a light relatively strong in blue-violet rays, and then another with the yellow rays relatively strong, whatever he may "expect," he will find the effect of the yellow light. My experiments showed that the worst result was got with "white" light and an ordinary plate; a colour-correct plate greatly improved matters, while a colour-correct plate and a yellow light gave the best results of all.

We need not discuss the opening statement of Mr. Ives': "That microscopic objectives not specially corrected for photography must work to focus if used with colour-sensitive plates and yellow screen is such a self-evident fact," &c. The statement seems to me loose, but let it pass. Mr. Ives' chief complaint is that I gave credit for noticing certain facts to Dr. Piffard, whereas Mr. Ives had pointed out the same facts on a previous occasion specified by him. In giving the credit to Dr. Piffard for having lately called attention to the facts in question, I acted according to my lights. I was not aware of Mr. Ives' verbal communication to the Photographic Society of Philadelphia, nor have I seen the transactions of that Society of the time mentioned by Mr. Ives. But I must say that, knowing Mr. Ives' intimate connexion with, and knowledge of, colour-correct photography, I can easily believe that he noticed long ago the effects of orthochromatic methods with uncorrected microscopic objectives. I can only say that I knew nothing of Mr. Ives' work in this direction, and, so far as I remember, I have not said that Dr. Piffard was *the first* to notice the facts alluded to. I know too much of the scientific world to claim priority for myself or for another.

Mr. Ives proceeds to say that on a certain occasion he recommended my book on *Photo-micrography*, and for this I thank him heartily; but he says he disputed my assertion "that high-class work could only be done with apochromatic or specially corrected objectives." Well, I did not then know as much as I do now, and I might have made the assertion; but, after a careful search through my book, I cannot find any such statement. This was *not* kind of Mr. Ives. I have over and over again, almost every time I have written or spoken about photo-micrography, said that very good work *can* be done without apochromatic glasses, and, if I overlooked a statement by Mr. Ives, he has overlooked a dozen by me, as well as disputing what I never asserted. I have said, and I say again, that the highest class of work requires apochromatic glasses; and I believe that all the best work has been produced with these objectives. I cannot say what Mr. Ives calls the highest class of work, nor can I say whether his productions are equal to mine; but, if he will permit me to see some of his work, I will either gladly "own up," or say boldly that I do not call his work the highest class. If Mr. Ives builds on the illustrations to my book, I can understand his position to some extent, even without seeing his work of the *same nature*, for these illustrations were chosen, in my own words (p. 10), "to illustrate various types of subject and varied treatment," and they were not all done with apochromatics. It is not only an opinion, but a fact, that apochromatic objectives represent the highest point of excellence at present attained, both for visual and photographic purposes, and I should be much surprised if any real authority were found to deny it.

I am taking for granted that Mr. Ives is conversant with the best work of such men as E. M. Nelson, Van Heurck, Comber, T. F. Smith, Bousfield, R. Zeiss, and even the "buga" of A. A. Carnell. If he is not, he has still something to learn about high-class photo-micrography.—I am, yours, &c.,

Andrew Prinole.

RETOUCHER'S TROUBLES.

To the Editor.

Sir,—Having experienced the same difficulties as the retoucher in your correspondence column mentions, namely, that of not being able to get sufficient lead on the negative, I can give a remedy which may be of use to my brother artist in photography.

There is one condition of the unvarnished gelatine film suitable for retouching upon, that is, the matt-surface looking film, with a texture like the rose leaf; you can work on such a surface with or without medium. When the surface of the film has a polished appearance, a kind of metallic lustre, there is greater difficulty in getting the lead on. By applying medium, and working with gentle pressure, you can get the lead on. Too much pressure upon the pencil brings the medium off again. A softer pencil enables you to put more lead on the negative. If the varnish is very hard and glassy, first apply the medium with the finger, rub it well in with a circular motion, then bring the finger right down the same part several times, this abrades the surface; then apply the medium again with handkerchief, just a little medium. You will then be able to put sufficient on the negative.—I am, yours, &c.,

A. W. C.

To the Editor.

Sir,—In reply to "Retoucher," while unable to assign a cause for the trouble, I would advise him to go over the negatives lightly with an old silk handkerchief moistened with methylated spirit before applying the medium. I have found this to remove all trace of greasiness from a negative when wishing to apply water colour to it; also to see that the

medium has not, by evaporation or chemical change, become too thick. Hoping that these hints may remove the difficulty,—I am, yours, &c.,

Clare, Suffolk, September 4, 1893. THOS. STOKOE.

MR. W. E. DEBENHAM ON "PHOTOGRAPHIC SOPHISTICATION." A REPLY.

To the EDITOR.

SIR,—After reading Mr. Debenham's criticisms in THE BRITISH JOURNAL OF PHOTOGRAPHY for September 1 on my article on "Optical Truth and Visual Truth," published August 26, I feel somewhat at a loss to reply to him, since it seems to me that I have not succeeded in making the main point of my arguments quite plain. When correcting the proofs, I actually sent back another diagram, and a little additional matter, with the intention of making my point still plainer if possible; but, no doubt because it was too late, my article appeared as it originally stood.

Mr. Debenham wishes to know whether I approve, or not, of Mr. Van der Veyde's apparatus being used for modifying the sizes or proportions of head, arms, waist, and other features of the sitter, "independently of whether they are enlarged or diminished by perspective to suit an ideal, conventional or otherwise."

I at once reply, No. I should call this a most illegitimate use of such an apparatus. I am quite agreed with Mr. Debenham in his remarks made at the Society of Arts on this subject of conventional flatteries. I was not attempting to deal in detail with this aspect of the subject—or second branch of it, as Mr. Debenham calls it—except, perhaps, by implication.

Then, in his fourth paragraph, Mr. Debenham puts forward two cases for my consideration, one being the case of a block of buildings viewed in perspective from a distance of 100 yards, and the other, a case of, say, a model of such building on one-tenth of the scale, viewed from one-tenth of the distance from a corresponding point of view, so that the geometric perspective is exactly the same in both cases. He then challenges me to show why, in the latter case, a rendering of the view by photography is not to be considered true to the visual sense, while the photographic rendering in the first case is to be looked upon as faultless. I can answer this quite agreeably to the theory which I have already put forward, although I must remark that my arguments do not apply quite so strongly to representations of solid geometrically shaped objects showing a vivid perspective, whereby the eye, or mind, is more certainly impressed with the sense of relative distances, and therefore sizes, than it is in the case of objects of uncertain and varied outlines. My explanation of why the above two subjects should be somewhat differently treated lies in the fact that, in the first case, the two eyes of the observer at the distance of 100 yards are practically the same as one eye; whereas in the second case, while the scale of everything, including the distance of the point of view, is reduced to one-tenth, yet the distance between the two eyes remains the same—that is, the distance between the eyes is *ten times as much* in proportion to the scale of the buildings in the second case as in the first. Leaving out any considerations of atmospheric perspective, in the first case the observer can only guage relative distances, and therefore sizes, by means of the effect of geometric perspective, while, in the second case, besides the effect of geometric perspective, he has also the further effect of binocular vision, which, of course, tends to give a greater sense of relief than in the first case.

In the first case, the fact that one end of the buildings is twice as far away as the other may be approximately realised; but, in the second case, it is possible to realise this fact far more completely, and I fully believe that the nearer parts of the buildings in this second case will appear to two-eyed vision relatively smaller than they do in the first case. This is, after all, merely another way of stating the fact, which I find experimentally verified, that one-eyed vision tends to over-estimate the relative sizes of nearer objects, when viewed closely, *as compared with two-eyed vision*. This, of course, is but the correlative of the truth that two-eyed vision of near subjects is apt to under-estimate the relative sizes of nearer objects as compared with the effects of geometric perspective, pure and simple, which are experienced when viewing the same subject with only one eye. But it is just the effects of *two-eyed* vision of near subjects which the painter seeks to transfer to his canvas, and if, in the process, he unconsciously perpetrates something not quite true to the laws of geometric perspective, it need be owing to no desire to conventionalise his subject, but owing to the unavoidable discrepancy between one-eyed and two-eyed vision.

What I assert is, that the perspective of near subjects must be somewhat modified, or "sophisticated," as Mr. Debenham calls it, in order that the plane representation on canvas or paper may give the same sense of relative sizes of parts as are obtained when viewing the original subject with two eyes from the same point of view.

I agree with Mr. Debenham that "no single picture can give binocular effect," but I maintain that it can give something in the nature of an equivalent for it, some compensation for the *absence* of binocular effect.

But I own Mr. Debenham makes a very good point against Mr. Van der Weyde's apparatus, inasmuch as he points out that no reducing of a hand or a foot can take place without a corresponding shrinkage of the part of the background behind against which it is seen. This would be an insuperable objection were the background of such a nature that a modification of its proportions would be of consequence; but in most cases of studio work it would not matter. He then assumes that no diminution of the head could take place without, at the same time, lengthening out the neck. Although I should strongly disapprove of making the head smaller in the first place, I may yet point out that the neck need not be lengthened, seeing that the head, besides being reduced, may also be lowered in position.—I am, yours, &c.

York, September 2, 1893. H. DENNIS TAYLOR.

To the EDITOR.

SIR,—Please allow me to correct some printer's errors, which, in some places, change the meaning of my writing in the article on "Photographical Sophistication," of last week.

In the sixth paragraph the first sentence should read, "My own view is that pictorial representations are generally referred (not preferred) by the spectator," &c.; and, a little farther on, I am made to hold up the book of beauty as eminently responsible for ridiculously small hands and feet, &c. What I wrote was, "the book of beauty or (not of) the pre-photographic period," and I wished to describe the generality of the artistic work of the period, not of the particular work which did not include such striking examples of the conventionalities mentioned as were to be met with elsewhere.

In the fourth paragraph I am made to speak of a "cake or a house," rather an odd conjunction. Whether "cake or" stands for "side of," or what else I do not now remember.

The concluding sentence should read, "Does Mr. Taylor consider that the reduction of heads and waists, the making of the sitter taller and slimmer in the picture, and the photographers' assent to and proposition that this is, in accordance with visual truth, is in itself a truthful proceeding, or would he consider it to come under the censure of the sentence quoted from his article?"—I am, yours, &c., W. E. DEBENHAM.

KEEPING QUALITIES OF FILMS.

To the EDITOR.

SIR,—As there is at present a controversy going on as to the keeping quality of celluloid negative films, facts bearing on the practical solution of the question may be of interest to your readers, and I would like to mention that to-day I gave an exposure to a Thomas's rapid film purchased in January, 1891, and developed a perfect negative in every respect. The film had been knocking about in the slide for over six months.—I am, yours, &c. GEORGE MANSFIELD.

Morristown, Lattin, Naas.

THE PHOTOGRAPHIC SOCIETY'S EXHIBITION.

To the EDITOR.

SIR,—Will you kindly remind your readers that Wednesday, September 13, is the only day for receiving exhibits at the Gallery for the annual Exhibition of the Society, and that they may be sent at any time up to September 11 to our agents. Full particulars can be obtained on application to the Assistant Secretary at the Society's rooms, 50, Great Russell-street, W.C.—I am, yours, &c., CHAPMAN JONES, *Hon. Sec.*

Photographic Society of Great Britain,

50, *Great Russell-street, Bloomsbury, W.C., September* 1, 1893.

Exchange Column.

*** *No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance. The full name of the advertiser must in all cases be given for publication, otherwise the Exchanges will not be inserted.*

Will exchange thirty lantern slides of Germany, plain, for some coloured slides, any subject.—Address, G. MOORE, Buckfastleigh, Devon.

Backgrounds, one exterior and one interior, about 8×8. Will exchange for others. Can send photographs of both.—W. HOBBS, Gold-street Studio, Saffron Walden.

Prize pigeons, ten pure bred silver duo Antwerps and two red chequered Antwerps, will exchange for half-plate camera and lens and three double slides.—Address, WALTER BOX, the Studio, Cannock.

Will exchange whole-plate portable bellows body camera, very light, three double slides, also a tripod stand, in exchange for studio camera and accessories.—Address, F. DAVIS, 8, Zingari-terrace, Forest Gate, Essex.

Wanted Archer Combined quarter-plate camera or half-plate Watson's Acme, McKellen, or similar pattern, any size, in exchange for Marion's 6½. 10s. embossing press.—Address, W. H. HUNTER, 73, Trafalgar-road, Peckham, London, S.E.

Answers to Correspondents.

*** *All matters intended for the text portion of this* JOURNAL, *including queries and Exchanges, must be addressed to* "THE EDITOR, THE BRITISH JOURNAL OF PHOTOGRAPHY," 2, *York-street, Covent Garden, London. Inattention to this ensures delay.*

*** *Correspondents are informed that we cannot undertake to answer communications through the post.*

*** *Communications relating to Advertisements and general business affairs should be addressed to Messrs.* HENRY GREENWOOD & Co., 2 *York-street, Covent Garden, London.*

*** *It would be convenient if friends desiring advice respecting apparatus, failures in practice, or other information, would call at the Editorial Office either on Wednesdays from* 4 *to* 6, *or Thursdays from* 9 *to* 12 *noon, when some one of the Editorial staff will be present.*

G. H. I.—A lens of sixteen inches focus would be required.

F. GARNER.—We do not remember the name of the maker, but the lens is undoubtedly of French origin.

G. BROWN.—This correspondent inquires if we "know anything of the Photographic Apparatus Supply Society?"—Reply: No.

SPOTTY.—1. Yes, occasionally. 2, Yes. 3. Furnish us with particulars as to toning bath, quality of water, and we may be able to help you.

M. E. C. W.—Almost any cabinet lens could, we think, be fitted to your half-plate camera. Write to the principal makers for the diameters of the flanges necessary.

R. WARD.—It is not necessary that the thick glass plates for collotype be bevelled at the edges when they are printed in an Albion press. In the case of the power press—machine printing—they should be.

A. W. ERSKINE.—Possibly the deposit is ferrocyanide of silver. Do you use hypo to follow? If neither of these is the cause, perhaps an acid solution will remove the deposit, which may be due to lime, &c., in the water.

F. E. G.—1. The addition of fresh hypo solution will be necessary when it is seen that the bath is losing rapidity of action. No definite strength can be given. 2. Add sufficient until no further precipitation takes place. 3. We have as yet no further information.

EXPERIMENT.—The reason why the blotting-paper causes the stain could only be ascertained by careful chemical analysis. It must be obvious to you that we hardly have the time to devote to such an operation. Procure two or three samples, and experiment with them as to their suitability.

D. WEBSTER.—We are by no means surprised that you have not improved the appearance of the lens mount. By cleaning it with emery cloth you have cleaned off the lacquer and exposed the bare brass. The only thing that can be done now to improve matters is to get the mount relacquered.

WATCHMAKER.—No rolling press will give the same gloss to gelatino-chloride prints as can be obtained by drying them in contact with glass. Those who desire the extra high gloss do not, as a rule, consider the method of obtaining it too troublesome. The rolling press mentioned is a very good one for the money.

TONY.—So far as we are aware, no one supplies gelatino-bromide emulsion ready for use. Therefore we suspect you will have to prepare it for yourself. It is possible, however, as you only require a little for an experiment, that some dry-plate manufacturer will oblige you with a small quantity, but it will only be as a favour.

TRAVELLER asks: "Would you inform me if, when I go to Australia, I may take any quantity of films for hand-camera use, or will there be any duty for same, and will the Custom House want to see them? If any duty, what is the largest amount I can take without having to pay anything?"—Perhaps some of our readers who have carried films to Australia will supply the desired information.

DRY PLATE.—It is quite out of the question to give in this column such details of the working of the wet-collodion process as would be of any value to one who has no knowledge whatever of it, or has never seen it worked. Our correspondent's best way will be to get one or other of the old manuals of photography. When the rudiments of the process are mastered we shall be pleased to assist our correspondent further.

J. BENNELL.—By shortening the tube of the rapid lens, so that glasses are brought together, it will cover a larger field; but it will have to be worked with smaller stops than before. We should advise you to have a separate mount for the glasses, to be used only when the widest angle is desired. Then they can at any time be returned to the original mount, and thus the commercial value of the instrument will not be impaired.

O. M. O. asks which side of a studio, running north and south, should be glazed, the east side or the west, as only one side can be of glass?—The best side to glaze will depend upon circumstances. If the studio is likely to be used most in the early part of the day, the west side will be the best to glaze, so as to avoid the morning sun. If used most in the afternoon, then the east side had better be glazed, thus avoiding the sun on the side most used in the after part of the day.

A.A.B.—The composition is composed of gelatine and glycerine, with sometimes treacle. The proportions are varied according to the degree of hardness or softness desired and the kind of gelatine employed. It will be better to purchase the composition ready prepared. It may be had of different degrees of hardness. Tubes for moulding rollers are supplied by all dealers in printers' material. Ordinary printing ink of good quality is what is used in printing half-tone blocks.

C. C. SMITH says: "Would you let me know if there are any books published on the process of photogravure, and where they are to be got?"—For a few pence the Assistant Secretary of the Photographic Society of Great Britain, 50, Great Russell-street, will supply you with a copy of the Society's *Journal*, containing a lecture on photogravure by Mr. Denison, which may meet your requirements. Our own back volumes contain a large amount of information on the subject. We do not know of any reliable book on the subject.

S. A. Y.—This correspondent says that "we can purchase almost everything connected with photography cheaper if it is made abroad than we can if it is of home manufacture, and why is this not the case with dry plates?" adding that "it would be a great boon to an amateur if he could buy his plates cheaper."—Quite so. We imagine that it would be an advantage to every one to have his goods, whatever they may be, at a cheaper rate. But the fact remains that foreign plates, quality being equal, are much dearer than English ones; also that probably more English plates are used on the Continent than those of Continental make. We strongly suspect "S. A. Y." will not get cheaper plates from abroad than those manufactured in this country, for some time to come, at least.

R. W. H. says: "I have been much tried by spotting, such as you see on the enclosed photograph. I have tried everything to remedy it, but with no avail. I may say I find it only on the two kinds of mounts enclosed. The mounts came over last year at the time the cholera was about. They were disinfected. Do you think the disinfectant used has anything to do with the spotting?"—Without knowing how the mounts were treated, it is impossible to offer an opinion that would be of any value. We have seen many examples of similar spots on prints the mounts of which had not been disinfected.

T. WILLIAMS says: "I want to convert my bath room into a dark room, but it must be on the 'Box and Cox' system—that is, it must still be a bath room when required as such."—We strongly suspect that bath rooms are frequently extemporised as dark rooms. The usual way is to have a wooden shutter, if the window is large, with a small glazed opening, the shutter being hinged so that it can be open and shut as required. If the window be small, a light wooden frame, either covered with non-actinic paper or glazed, will suffice. This may be secured to the window frame with a couple of "turn buttons," or may be permanently hinged to it. The bath itself is sometimes used as a sink, but it is better to have a proper sink if space will allow.

F. R. F. writes: "A friend of mine has a photographic portrait of Garibaldi, received from him and signed on the mount. It is an albumen print, framed and hung, and is now decidedly yellow and beginning to fade. I pointed this out, and being asked what should be done suggested that the print should be copied, removed from the mount, and a platinotype be substituted for it. I venture to ask you kindly to advise in your 'Answers' column if any better course can be adopted, and whether any method, beyond taking the print from the frame and keeping it from the light, could be employed to prolong the life of the original print."—We should advise the print being copied as it is, an orthochromatised plate being used for the negative. In this way, if the detail has not disappeared, a copy as good, or nearly so, as the original was in its pristine state can be obtained. It is scarcely advisable to remove the print from the mount, as the treatment with water often hastens the fading. Light will have but little action now on the print.

JOURNAL OF PHOTOGRAPHY.

No. 1741. Vol. XL.—SEPTEMBER 15, 1893.

OVER-INTENSIFICATION OF NEGATIVES.

An unusual number of letters having been received during the past and present week from querists who find that they have been over-intensifying their negatives, we take this means of replying to them all.

When a negative has been under-exposed and the action of the developer has been prolonged in the hope of getting the details in the shadows coaxed out, by the time this latter effect is produced, if produced at all, the high lights will have acquired such a degree of density as to require a duration of printing so prolonged as to entirely destroy the delicate shadows. The transition from the highest light to the deepest shadow is too abrupt, and the print resulting is hard.

We have intentionally produced a negative having these characteristics in order to see the effect obtained by the discriminating action of light in imparting density to the weaker parts. This we have done by varnishing the hard negative by a collodion emulsion of chloride of silver and exposing its back to light. The action thus produced is obvious. The thinner portions of the negative permit more light to be transmitted to the sensitive varnish than do the more dense portions, and hence, by the darkening of the former in due proportion, a marked degree of equalising is produced.

We do not here enter into full manipulative details, feeling assured that these will scarcely be required by our readers, more especially as it is scarcely three years since we treated of this special phase of the subject. On that occasion, however, we recommended applying the sensitive coating to the back or glass side of the negative, but we have since found it preferable to coat the film side. Further, we may state that a simpler and not less effective collodio-chloride coating than the one we then gave may be prepared by the three following stock solutions:—

A.	
Nitrate of silver	1 drachm.
Water (distilled)	1 „
B.	
Chloride of calcium	64 grains.
Alcohol	2 ounces.
C.	
Citric acid	64 grains.
Alcohol	2 ounces.

To every two ounces of plain collodion add thirty drops of the A solution, previously mixed with one drachm of alcohol; then one drachm of B solution, gradually shaking well at the same time; lastly, half a drachm of C solution. It is ready for use almost immediately after mixing, and will keep well for a considerable time.

When negatives have been simply made too dense, without being hard, they may be made thinner by one or other of the expedients so often published, such as treatment with a very weak solution of ferridcyanide of potassium, followed by immersion in a solution of hyposulphite of soda, or by treatment with a solution of bichromate of potash, to which has been added very little sulphuric acid. Exceptional care must be taken that this latter mixture is used in a highly dilute form, as its solvent action on the image is so great that, if strong, it will remove it altogether.

It is when a negative has been intensified by bichloride of mercury, with a subsequent treatment with ammonia, that one is most apt to over-intensify, even to such an extent as sometimes to necessitate more than a day's exposure in the printing frame to secure one print. The cure for this may in nearly all cases be readily effected by reimmersing the negative in the mercury solution, by which the dark-brown opaque colour of the image is rendered translucent, and usually of a yellowish colour, that, without any further treatment, serves to convert it into a good printing negative. It should not be forgotten that the action, both of the mercury solution and the ammonia, is a progressive one, and, by attention in watching such progress, either in intensifying or in reducing, the operator who uses his judgment will have complete command of the situation, it being well understood that the solutions employed are sufficiently weak to enable him to have control over their action.

Although we have assumed ammonia as the reagent in intensification, it is well to realise that there are several others, each of which imparts its own colour to the deposit. Amongst these may be mentioned sulphide of ammonium (the most powerful of all), hyposulphite of soda, sulphite of soda, and others.

TESTING MOUNTS AND MOUNTANTS.

The many examples of fading and spotty prints we are continually receiving, with the query as to whether the evil is not due to the mounts, renders it necessary to say something more on the subject than can be said in brief replies in the correspondence column. At the present time it seems that considerable suspicion exists with regard to photographic mounts, and in some instances it is well founded, and in others just the reverse. It is too frequently assumed, if a mounted print fades quickly, while a corresponding one which was kept unmounted does not, that the mount must of necessity be the cause. This is a fallacy, as the fading may be, and in many cases is, really due to the mountant. We have frequently had cases brought under our notice where prints mounted in optical contact with glass have become yellow in a very short time,

while others, kept unmounted, have not suffered. In these cases it is clear, as the mount is a glass plate, that it cannot be the cause of the evil.

There is a very simple way by which photographic mounts may be tested without subjecting them to a chemical analysis. The method is that described by Mr. Foxlee in our ALMANAC for the current year. Briefly, it is this: A light print is made on albumenised paper, toned, fixed, washed, and dried as usual. The mount to be tested is just moistened with distilled water, and over one half of it is laid a sheet of any material that is impervious to water, such as talc, celluloid, or two or three thicknesses of paraffined paper. The print is now laid on face downward, and over that is placed a piece of plain Saxe or Rives or other pure paper. The whole is then fastened together with a paper-fastener or a few stitches of cotton. It is then backed up with several sheets of moistened blotting-paper, and the whole placed between a couple of glass plates under pressure. The object of the glass plates is to prevent evaporation, and so retain the print and mount continually damp. As moisture conduces to fading, particularly at a warm temperature, the print should be kept in a warm place, as our purpose now is to hasten its fading as much as possible.

The print should be examined from day to day. If it fades uniformly all over, the mount may be considered innocuous; but, if that portion of the print which has been kept in contact with it shows spots or signs of fading before that part which is protected from it by the impervious material, it proves that the mount has had a pernicious action. In some bad cases we have seen a marked difference between the two tables of a print, so treated, at the end of a couple of days, or even sooner.

If the mounts are of the dark kind, it is quite possible that the print may become stained by soluble colouring matter diffusing out. But this does not prove that the mount is unfit for its purpose. By long contact with a damp print a mount may produce a stain, yet have no otherwise ill effect on the silver image, as proved by examining it by transmitted light. Instead of employing a light print from a negative, a piece of sensitised paper, exposed to diffused light until it is about as dark as the half-tones of a light print, then toned, fixed, and washed, is preferable, as the change, if any, is more quickly detected on the uniform surface than it is on an image. If photographers who suspect the mounts as being the cause of their prints fading in a brief period were to submit them to the above simple yet reliable test, they would frequently find their suspicions quite unfounded, and that the source of the evil must be sought elsewhere.

The mountant is frequently a fertile cause of fading. The most general mountant is starch, and an excellent one it is, provided the starch is of good quality and the paste is used freshly prepared; but samples of starch, as they are met with in the oil shops, vary much as to their suitability for our present purpose, although they may all be equally good for laundry uses. Some kinds have had a blue colour added to them in the manufacture to give them a fictitious whiteness by disguising their yellowness; others are strongly coloured blue. We are informed that the blue, sometimes used for the purpose, is artificial, ultramarine, which is composed largely of sulphur, and is readily decomposed by acid with an evolution of sulphuretted hydrogen. Gelatine and glue are favourite mountants, but many samples are strongly acid or rapidly become so if kept in dilute solutions. Dextrine is sometimes used, and that, as found in commerce, is almost invariably acid. The various liquid gums and ready-prepared cements, sold by stationers for general adhesive purposes, are sometimes used for mounting purposes; most of them contain an antiseptic, and sometimes that is bichloride of mercury. If cements, such as those enumerated, be employed, the delicately constituted silver image will be jeopardised, particularly if the mount be impure.

The effect of a mountant can be tested in a similar manner to that of mounts, namely, by coating one half of a print with it, and mounting it face downwards on a piece of clean glass, leaving the other portions free, and allowing it to dry. It is then kept damp in a warm place, as in the case of testing mounts, and examined daily. This, it may be mentioned, can scarcely be considered so conclusive a test as in the case with the mounts, as the moisture and warmth favour fermentation and mildew, conditions that do not pertain in a state of dryness. But a deleterious mountant will generally make itself manifest before that sets in—sometimes, even, in a few hours.

BUBBLES.

NOT the bubbles of the Millais picture with which the advertisement hoardings have made the public familiar, or those appearing in some charming photographs to which we have referred several times lately, but such as are formed on gelatine films during development. As more than one correspondent has recently written us complaining of this unwelcome visitation, and its equally undesirable after-effect in the shape of transparent circular spots in the negative, and as, moreover, we have ourselves had some experiences in this direction, it may be worth while to devote a little consideration to the causes of the defect and the remedies for obviating it.

Setting aside for the moment defects in the emulsion which may tend to produce transparent markings in the negatives of the minute form known as pinholes, as well as the larger and more symmetrically defined variety analogous to those produced in development, let us enumerate the commoner causes which produce them. Particles of dust on the film during development not only cause pinholes, but occasionally act as nuclei for air bells, and thus produce large circular transparent spots, due to the retention of the developer from the spaces covered by them. Again, if a quantity of developer insufficient to well cover the plate be employed, or the wetted film be left exposed for a considerable time to the air, air bells appear, with a like subsequent result.

A developer that has been used again and again, especially in hot weather, such as that of the departing summer, rapidly becomes frothy and bubbly, and is therefore a prolific source of failure if means be not employed to stop the growth of air bells. Some operators allege that a preliminary soaking of the plate in water is also favourable to their formation, while others affirm that the action of flowing the developer over the plate should be avoided in preference for the immersion of the plate in the developer.

The nature of the gelatine of the plate is, perhaps, as much responsible for the formation of air-bells as any other cause. If it be of a repellent character, and the developer is above the normal temperature and at all frothy, the conditions are very favourable. On the other hand, we have observed that plates of which the gelatine is of a soft kind, even under such circumstances as those just described, do not prevent the access of the developer to all parts of the film alike.

Such a degree of skill is required for the successful touching-out of transparent holes in negatives, that it is worth while to take a little extra precaution to prevent them. We have not

confirmed the suggestion that preliminary soaking of the plate, its immersion in the developer, or the flowing over of the latter upon it, have anything to do with either fostering or obviating the growth of air bells on the surface; but it is quite certain that the quantity of solution used is of considerable importance. Sufficient of it should always be taken to well flood the plate, which should be left uncovered for as little time as possible. So soon as the solution is in contact with the plate, a broad, clean camel's-hair brush, or a pledget of cotton-wool should be evenly, and not too forcibly, drawn over its surface, so as to disperse any bubbles that may have formed, and to prevent their occurrence by ensuring that the film is uniformly wetted. As a rule it is next to impossible, in the dark room, to see when the bells have formed, so that it is well not to trust to one's eyesight in the matter, but to keep a brush or some cotton-wool handy for constant use. Where an old developer (for which many workers have a fondness) acquires perceptible frothiness, it is worth while running it through a filter paper, which will render it temporarily clear.

These are some of the commoner causes of an aggravating complaint which happens in the course of every-day practice, and a little attention to which will ensure its prevention. We have not spoken of splashes of water, before or after exposure, and other obvious sources of danger, as we take it that due care is always exercised in every well-regulated studio, professional or amateur, so that such are guarded against as a matter of course. We have also assumed that the causes of these transparent markings are not inherent in the plates, which are too often unjustly blamed for them.

"A Sign of the Times."—Among the causes that contributed to their failure, the members of a large firm of printers, wood-engravers, &c., recently "gazetted," are reported to have included the influence of process work, which had operated to oust wood-engraving from its former pride of place.

The New Fixing Material.—We have looked into a large number of English priced catalogues of chemicals, to endeavour to learn the probable cost of thiosinnamine in this country, but so far unsuccessfully. We have, however, come across the price in an English agent's list of a foreign manufacturer's chemicals, and in this (a wholesale list) it was priced at three shillings and sixpence an ounce. But, then, we must remember there are photographers now alive who can remember hypo at a guinea a pound.

A New Thermometer Liquid.—M. P. Chappuis, of the International Bureau of Weights and Measures, has, since 1889, been experimenting with regard to a substitute for alcohol in thermometers for low temperatures, which is found to be very unsatisfactory in many respects and irregular in its action according to the various sources of its supply. So far M. Chappuis has fixed upon toluene which has a much higher boiling point (about 111°), and is of greater fluidity. Its indications are much more trustworthy than those of alcohol.

To Blacken Zinc.—Mr. J. A. Moss, writing in the *Electrical Review*, while stating that Brunswick black (a solution of asphalt) is the best for the purpose, as it forms a resistant varnish, at the same time points out that, when a metallic blackened surface is needed, it may be obtained by pouring a weak solution of copper sulphate over the object, which thereupon becomes coated with a dense deposit of black oxide of copper. This is pulverulent, and requires lacquering to ensure its permanency. For lantern work, diaphragms, &c., it is not possible to imagine a less costly process than the latter.

Developer Stains on Negatives.—There is, we believe, a growing desire with many photographers to revert to the kind of negative having the slight stain producible by pyro development either without sulphite or with a very small portion of that agent, such as was frequent a few years back. We have heard it stated by many operators that the "pretty" negatives yielded by the newer developers are so deceptive in their printing qualities that they are tempted to go back to negatives of pyro-like quality on that very account. This implies that, after all, a slight yellow stain is no disadvantage, but rather the reverse in some cases.

The Meeting of the British Association offers very few themes of interest to photographers; but, in one respect, the lecturers have borrowed a page from photographic experience, in that the optical lantern and photographic representations are being made use of to some considerable extent. We wonder if *Convention* authorities could in return take a leaf out of the Association book? We read that "the local committee has engaged the Theatre Royal for Wednesday night next, when Mr. Wilson Barrett's company will give the new play, *Pharaoh*. It is hoped that members will avail themselves of the invitation extended to them for this entertainment, and that it will induce them to remain in Nottingham and take advantage of the excursions arranged for the following day."

Economical Manufacture of Oxygen.—This subject continues, in chemical circles, to excite much interest, and in the *Chemiker Zeitung* has quite lately been treated by one expert—Kassner, the inventor of a process before described in these pages, and by Le Chatelier in another place. Kassner's improved process makes use of furnace gases; a new process has been patented by Peitz in which, instead of furnace gases, pure carbonic acid is employed. Le Chatelier concludes that calcium plumbate gives up its available oxygen by merely heating at a temperature of 200° higher than that employed in Brin's process in the case of barium peroxide, and that the heated residue absorbs oxygen from the air much more rapidly than the latter substance. He seems not to have read Kassner's explanations of the latter's process, who points out that he has already explained this, but now asserts that his indirect method possesses two great advantages over Le Chatelier's direct method, in that a lower temperature is required, and a consequent saving of fuel and wear of retorts is effected, and that a valuable bye-product, pure carbon dioxide, is also obtained.

M. Kassner's Indirect Method.—The inventor claims a distinct superiority over Brin's process. He first exposes calcium plumbate to the action of moist furnace gases, previously well washed, at a temperature not exceeding 100°. Under these conditions the plumbate rapidly absorbs the carbon dioxide of the furnace gases, with the resulting formation of calcium carbonate—free peroxide of lead. This decomposition is not accompanied by any change of form, the spongy masses preserving their original appearance. They are next transferred to a strongly constructed retort heated to redness, oxygen being then strongly evolved This evolution is facilitated by leading superheated steam over the mass. When most of the available oxygen is given up from the peroxide, carbon dioxide begins to come off, which after a while is collected separately, the gas being perfectly pure. The first outburst of this gas, which is not quite pure, is carried over a further quantity of calcium plumbate, which absorbs it entirely and allows pure oxygen to escape, and so the process is made to continue indefinitely. It seems abundantly evident that the barium process is by no means the only one available, and we can only hail with satisfaction any improvements in the direction of reducing cost, as it must ultimately reduce the already low price of this valuable agent.

AN IMPROVED MICRO-CAMERA.

Now that the microscope is becoming such an adjunct to the camera, we hail with pleasure every appliance that is calculated to develop this union. Hence we have pleasure in giving a brief description of

a micro-camera which appears to us to combine several advantages. We have called it an "Improved" micro-camera. So it is, in respect both of its simplicity of design and construction. The manufacturers are Messrs. Perken, Son, & Rayment, and we incline to the opinion that, of their various productions which warrant them in adopting the trade term "Optimus," this will not be found to be the least worthy.

The one we examined is constructed for micro enlargements on plates $3\frac{1}{4} \times 3\frac{1}{4}$, which, it will be observed, is the English standard for lantern plates, for which adaptation it is intended, in order to exhibit the subjects by projection on a screen. This at once imparts an idea as to the dimensions of the camera proper, which is erected on a baseboard fifty inches in length. The bellows-body is twenty-four inches long, and is attached by one end to a strong wooden front erected a little over two feet from the rear end of the camera, and pierced in the centre with a hole of such dimensions as to permit of the insertion of the eyepiece end of the microscope. But the microscope itself is erected upon an movable baseboard outside the wooden front mentioned, that is to say, it is adjustable as regards its motion to and from the camera, and, when the microscope has once been adjusted to the proper height, it is in accurate centre for ever after. On a second and similar sliding sub-baseboard, made, like the former, to slide axially, is erected any of the various microscopic sub-stage appliances common to the microscope, such as the condenser, which, after being fitted, is, like the optical system, ever afterwards in centre, requiring no further attention than the sliding backwards or forwards. A third sliding platform, similar to the two just spoken of, is intended for the lamp.

A rack extends the whole length of the principal baseboard, and each of the movable platforms mentioned is operated by a pinion ready of access to the photographer, who thus can control the various movements necessary.

The rough adjustment for degree of enlargement is made by sliding in or out the bellows-body, which is under control of one of this firm's patent pinions, capable of being thrown out of gear with the rack for rapid adjustment, and of being geared again when it becomes necessary to focus. This we consider a very handy arrangement, as it saves the long and tedious racking out when extending the bellows to any considerable extent. The fine adjustment of the microscope is done by means of a hand and pulley at the rear end.

The various sliding pieces work smoothly within brass guides at either side of the baseboard. It is made of mahogany, and is finely finished. Although the one we examined is made of dimensions suitable for lantern slides, there is no limit to the size to which it can be made. A great charm lies in the readiness with which work can be resumed at a moment's notice after the instrument has been packed away on the shelf.

CONTINENTAL NOTES AND NEWS.

Monument to Daguerre.—A monument to Daguerre is to be erected in the village of Bry-sur-Marne. The municipality has charge of the matter, and M. G. Rolland, of 2, Rue de Sfax, will receive subscriptions.

Imitation Ground Glass.—The following plan is advocated by Herr Toch, in the *Rundschau* for imparting a very fine grain to glass for focussing purposes. Fix an unexposed gelatine plate, wash, and immerse in a solution of chloride of barium. Then, without washing, treat with a very dilute solution of sulphuric acid, keeping the latter in motion over the plate. A fine precipitate will be formed in the film.

The International Union of Photography.—The second session of the International Union of Photography opened at Geneva on August 21. A large number of members and delegates from photographic societies were present. At the opening *séance*, M. Joseph Macs, president of the Union, took the chair, being supported by Messrs. Janssen, Batault, Pricam, Demole, Luckhardt (Vienna), Warnerke (London), Liesegang (Düsseldorf), Davanne, Audra, Gravier, and Berthaud (Paris), Bucquet, Boisard, Lumière, Puttemans, &c. The second sitting was remarkable for an account, by M. Janssen, of the photographic work of the recent Eclipse Expedition. At another meeting, pictures in "natural colours," according to Lippmann's method, were exhibited by M. Lumière. On the Thursday an animated discussion took place over an attempt to obtain a clear and precise definition of what constituted an amateur. Several excursions and receptions took place during the week, and the proceedings concluded—not with a "werse," as Sam Weller has it, but with a banquet. On the whole, the Union appears to have had an enjoyable time, its doings much resembling those of our own Convention.

Iodine and Glycerine in the Developer.—Professor Lainer states that a drop of tincture of iodine to about each ten c.c. of eikonogen developer imparts excellent softness and gradation to the negative. The addition of glycerine 5: 100 prevents fog, and adds to the keeping properties of the solutions.

Relative Quantities of Silver Haloid and Gelatine in Commercial Gelatine Dry Plates.—MM. Frutiger & Perrot have ascertained the respective weights of silver and gelatine in a dozen kinds of plates. Their method consisted in the elimination of the silver haloids with cyanide, washing the films in running water and then removing them. After being washed in alcohol for two hours the films were allowed to dry spontaneously at the ordinary temperature, placed in a drying stove at 105°, and weighed. When incinerated the gelatine leaves a trifling weight of phosphate and carbonate of lime behind completely free of silver salts. The resulting figures show proportions of silver to gelatine varying from about 1: 2 to 1: 5. The authors, however, are inclined to think that the proportions of silver and gelatine contained in a plate afford no guide as to its qualities.

SOME USEFUL PHOTOGRAPHIC STANDARDS.

[Brixton and Clapham Camera Club.]

Do not think that in this memoir much in the way of novelty will be brought forward in relation to photographic standards. For years English photographers have been, like pelicans, crying in the wilderness for simple standards of measurement, and to their bitter cry dealers have responded but in homœopathic doses, with the loss of years of time between each driblet. One object of the paper is to emphasise old-established demands as to what scientific photographers want, but, so far, have not been successful in obtaining.

A demand constantly exists, and that demand is sometimes expressed at the meetings of photographic societies, for a standard light for common use in photography. Herr von Hefner-Alteneck once read a paper before the Electro-Technical Society of Berlin, describing his amyl-acetate lamp as a photometric standard. His invention next came before the Congress of Electrical Engineers in Paris, soon after that city had been partly lighted by electricity, where the simplicity of the lamp riveted the attention of the late Sir William Siemens, who made it widely known among electrical engineers in London; and, when it subsequently came under the notice of Captain Abney, he read a paper about it before the Photographic Society, setting forth that it was exactly what photographers required. Then it was forgotten for a course of years, until the holding of the International Photographic Congress in Paris at the Exhibition there in 1889, when the amyl-acetate lamp was again recommended for general photographic use.

Still, the mass of photographers have no amyl-acetate lamp. What, then, is this lamp which commercial men are so long in supplying? If you gaze in certain oil shops and ironmongers' shops, little brass lamps will sometimes be seen piled a yard high, and selling at threepence or fourpence each, under the trade name of "benzolene" lamps. They are made for burning light petroleum. These lamps are practically amyl-acetate lamps unstandardised. If good double screws be put to them to raise the wick, if the tube be made to standard size, and some minor conditions receive attention, you have an amyl-acetate lamp. It is largely a question of exactitude in manufacture, and in screening the flame with a diaphragm having a standard aperture. If these modifications were made, and the standard wick used, they might be sold to the photographic public at, say, eighteenpence each, with say, fifty per cent. profit; but, from the experience of the past,

we may have to wait for years before such lamps are readily obtainable. A horizontal piece of platinum wire, supported by a brass rod, indicates the height to which the flame should be adjusted.

Amyl-acetate is burnt in these lamps because of the uniformity of its composition. This liquid is better known, especially to manufacturing confectioners, by the name of pear oil. When the outside of the lamp is not kept clean, or when the wick is turned too high, an overpowering smell of pears prevails. With the best management of the lamp, a faint odour of this kind diffuses, and, after a time, becomes unpleasant. This simple little lamp is exceedingly trustworthy as a standard of light, and would probably have been recommended by scientific experts as the legal standard for testing the illuminating power of coal gas were not its flame a little too yellow. Its tube gets corroded unless made of silver, and Mr. Bothamley has introduced a special method of screening the flame from draughts.

Should this standard ever be used in photography, it is probable that some other hydro-carbon than amyl-acetate will be burnt in the lamp. I think that a more useful standard in photography would be a lamp of the Argand type, giving a light of about ten candles, such, for instance, as Dibdin's Pentane Argand standard lamp. Printing by artificial light could then be done with it, and we should no longer hear the remark at photographic societies, "The exposure should be thirty seconds at one foot distance from the flame of batswing burner," a barbarously vague definition of the amount of light to be employed.

We come now to a standard of light to which small attention has been paid in this country but much in France, namely, Giroud's jet photometer, one of the class of rat-tail photometers. Giroud tests the illuminating power of gas by its own combustion, which, at first sight, seems a strange thing to be able to do. The main principles on which all jet photometers depend are:—1. For the same gas with the same consumption, the height of the flame with the same aperture of the burner is almost directly proportional to the lighting power of the gas. 2. On comparing gases of different qualities burned as a jet, the heights of the flame are in proportion to the illuminating power. Giroud uses a flame 105 millimetres high, which is kept up by thirty-eight litres per hour of the normal gas of Paris, subject to regulation by an excellent rheometer.

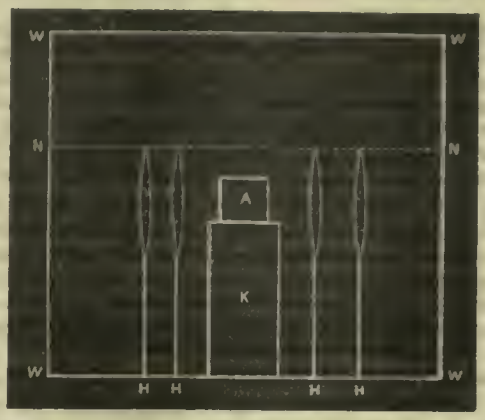
Photographers have all heard of, although few have seen, the sensitometer invented by Mr. J. B. Spurge, one of which is now on the table before you. This instrument has never been on sale in the market, the few that have been made having been constructed by Mr. Spurge's own hands. In calibrating his sensitometer he found the standard candle established by law to be too uncertain to be of any use for the purpose, therefore he employed for the purpose four of Giroud's rat-tail jets.

First, as to the sensitometer itself. It consists, as you see, of a number of holes of different diameters in a plate of hard brass; behind each hole is a little cell, and at the back of the cells is placed the plate to be tested. A standard light is made to shine through the holes for a given time, and the larger the hole the more light does the plate behind it receive. The apertures have to be made with the most scrupulous exactitude, and they have been so well made in the past as to bear with credit measurement under the microscope. In making these sensitometers in large numbers, the holes would have to be made to fit a series of specially constructed Whitworth's gauges, and the construction of these gauges in the first instance, is the only outlay of importance in the way of the commercial introduction of these instruments. The diameters of the apertures were calculated mathematically, so as to be specially useful in scientific research, by Mr. Spurge and by the late C. F. Varley, the Atlantic telegraph electrician.

A few days ago I wrote to Mr. Spurge, telling him that I was going to bring these matters before you to-night, and inviting him to attend. I am glad to say that he is here, and has brought with him his modification of Giroud's photometer.

The following rough diagram will help to show how the appliances are used:—A is the back of the sensitometer, standing upon the wooden platform K. Alongside it are four jets, H H H H, with rat-tail flames, all turned to the height N N, which level is indicated in the instrument by guide wires. Twelve or eighteen inches in front of the flames and the sensitometer is the rectangular board, W W W W, covered with a sheet of pure white Rive paper, which paper is evenly illuminated by the flames, and the light from this extended illuminated surface is that which acts upon the sensitive plate through the circular holes of different sizes in the sensitometer. The whole apparatus is made to fold up neatly into a narrow flat box form, for carriage.

Mr. Spurge adopted the jet photometer as the source of light because he found the standard candle to be so inaccurate and variable that he could not use it for the calibration of his sensitometer. Rat-tail photometers, for their simplicity and accuracy, are in use in nearly all gasworks in this country, but the flame used is long, and more influenced by draughts than the form employed by Giroud. Mr. Spurge gets additional steadiness by using four of the



short flames at once. In Paris it has been found that the maximum error of Giroud's photometer does not exceed one per cent.

Mr. Spurge's sensitometer, because of its accuracy, is much used by Captain Abney, Mr. H. M. Elder, and others in photographic research, and I am glad to have drawn that man of modest merit, Mr. Spurge, out of his too great retirement, to give us some information on sensitometry to-night.

We had to wait many years before opticians began to give us standard diaphragms and standard screws to lens mounts; but at last some opticians at home and abroad moved in the matter, and in time uniformity will be the rule. How long shall we have to wait until the same screws are put upon the fronts of lens mounts, to take flanges put for the purpose upon some of those instantaneous shutters in the market, which are used in front of lens, and at present have to be made to stick on by means of india-rubber bands or other unsatisfactory devices? Then, again, when will all camera screws be made to one gauge, instead of presenting that lack of uniformity of which Mr. Traill Taylor complained at the Camera Club Conference? Captain Abney then hit the right nail on the head by stating that it might be well to form a sort of unofficial trades union among photographers. By common consent, purchasing photographers might do much to direct the channels into which the trade shall flow, and to support those particular dealers who show a desire to meet their requirements.

When standards are wanted, it is obviously necessary that some disinterested public body should specify what the standards are to be, otherwise commercial men have nothing authoritative to guide them. For this reason the photographic Society may well add to the debt of public gratitude by forthwith specifying some more standards, especially a standard Argand lamp of ten or twenty candle power for use in transparency printing and other work, as well as for use as a photographic unit of light. Although I was a foreign member of the Paris Photographic Conference Committee, I do not now agree with the decision of the Conference about the amyl-acetate lamp, except on the ground that any standard of light is better than none. It would be better to have a larger luminous source, useful also for some kinds of practical photographic work. The Photographic Society some time back began to affiliate other Societies, apparently with somewhat vague ideas of what was to come out of that line of action, but directly the united societies begin some work in which the public are strongly interested, plenty of life and energy will cluster about the affiliation movement, and the two representatives of this Club will then tell us whether the affiliation movement is still in existence, what it is doing, and what they are doing on our behalf. W. H. Harrison.

THE EVOLUTION OF ARTISTIC PHOTOGRAPHY.

The art of photography, dissociated from its purely mechanical connexions, has been written about by many able exponents of art subjects, the greater number of whom regret the intractability or limitations of a process that, on the face of it, promised so much and performed so little. This was the keynote of most writers in the earlier days of photography, and has, no doubt, continued its influence to the present time. The dictum of skilled men will always, right or wrong, shape the public mind, and an opinion once established in a

matter of this kind is very difficult to upset, with even the most conclusive proofs to the contrary. I firmly believe scores of pictures now made are equal, and very often superior, to drawings in monochrome by acknowledged artists, and quite as dependent on personal skill as any pencil or brush work can be. It is simply absurd nonsense to limit the production of artistic pictures to any special *materials*, a clever man, or woman either, for the matter of that, will make a picture with *anything that will make a mark*. It is not the manner of producing, but the production itself that has to be judged, and to claim on its own intrinsic merits the position it is to occupy. I am convinced photography is an art in the fullest significance of the term, and not only that, but one that puts to shame a vast amount of hand work to which is arrogated the right of being the only true and legitimate method of representing nature literally and ideally on a plane surface.

"More twaddle about art," I fancy the reader ejaculating; but, twaddle or no twaddle, it is plain to see that a process mechanically perfect, almost from its first inception, and which goes on improving by leaps and bounds in its purely *artistic* character, to which no limit can be put, has considerable claims to the title of art—a claim audacious and wrong, as many declare it to be. Thirty years ago—but it is really longer—quite as perfectly manipulated negatives were produced as at the present time, just as good definition, almost as much softness, and more brilliancy, in fact, as *chemical* productions, just as good in every respect as now. Their number was, however, somewhat limited, and their art qualities, with few exceptions, left much to be desired. Great things were expected, art was to be revolutionised, nothing was too difficult for its comprehensive grasp; sentiment, passion, everything could be represented, in the twinkling of an eye, true to nature and of unimpeachable correctness. Painter-artists would have to take a back seat in the future, to make way for the new procesa. It was soon found that too much was expected, as is generally the case with a new and sensational thing, and from the pinnacle of expectation it fell to be a butt for the gibes and sneers of artists of all degrees. As I write, I have before me a few early photographic portraits, and, most assuredly, as candidates for *artistic* recognition, they deserve the disparagement meted out to the class of which they are specimens. There is no fault to be found with their manipulative qualities, that is as good as the present average, in spite of the difficulties of the process as then carried on; but as pictures, artistic treatment, and so forth, compared with modern work, are as much behind as is the four-year-olds pencilling, with the legend, "Thia is a man," to one of Millais' or Sant's society portraits. Certainly, in the early days, the light of art was hidden under a bushel, and it is assuredly, but gradually, shining forth as the means of production becomes less and less evident and the shadow of mechanism passes away. "Like a photograph" was a term of reproach; "Like a photograph" will be the criticism of approbation. Let time work its magic influence, and, if we remember that lenses, cameras, and plates are but tools; in evidence, *only* to take the place of brushes and pencils, we shall then get on; in fact, we have got on, the thing is accomplished, and only wilful blindness or obstinate partiality can find anything to say disparaging to many photographs now produced. Look at the designs and sketches of dozens of pictures hung at our leading Exhibitions, Royal Academy included; take away the colour, and what could be weaker, poorer, or show less inventive capacity for design than many of them? Thousands of photographs are a long way ahead. There is not much doubt that, if any one of our *best* photographs was copied line for line in chalk, sepia, or any other monochromatic colour, it would stand an excellent chance of being hung at any representative exhibition, *so long as it remained a secret that it was a copy* of a photograph; that damning information being afforded, it would, metaphorically, be pitched into the waste-paper basket as a thing of no account. So much for the influence of process and unfair *prejudice*, for it cannot be called anything else. There is no denying that artists had good reasons for their restrictions *long ago* on the generality of photographs claiming kindred with art. As soon as the process became well known and popular, it was taken up by all classes, educated and uneducated alike, as an easy means of money-making, which it undoubtedly was, and the most awful things were perpetrated in the name of art.

One class, and that was a large one, invariably introduced a curtain, pillar, high-backed chair, and carpet, no matter whether it was an indoor or outdoor background. A wild, stormy sky, with waves beating on a rock-bound shore, a ship foundering, and a lighthouse flashing was considered suitable for a lady in evening dress, sitting on a drawing-room chair, with an elaborate ottoman and Brussels carpet. Thousands of such incongruities were made, and liked—think of it, positively looked on as works of art by the million! Most of the poses (and there was not much variety) were stiff and formal. This style of thing continued until ridicule had its effect, and we then arrived at the second stage of severe simplicity, plain backgrounds, and few or no accessories, an improvement no one can deny. The dress of the time was rather difficult to deal with. Then vignetted heads and busts were introduced, which swept away a lot of trouble and introduced a very pleasing and artistic style of picture, which has continued its popularity to the present time. Vignettes, in some form or another, will in all probability remain with us, whatever changes take place. Then came double printing—the figures and surroundings on separate negatives; but, although some splendid work was done in this way, there was much coarse, incongruous stuff made up by people who borrowed the idea, but had not either the taste or skill to carry it out artistically till this kind of picture was practically smothered.

It really required more art training than that then possessed by the majority of photographers to do it properly, but at the present time I should think it (double printing) might be revived with advantage, for the results are exceedingly attractive when well done. Almost all styles have been produced, and well, too, in isolated instances; but in these remarks I allude to the *general run* of any speciality. It is only seldom now that we see modern work spoiled by the incongruity of indoor foregrounds with outdoor backgrounds, which used to be so common. The chief fault of composition in the present day is crowding a lot of accessories into the picture close round the sitter. A lady, for instance, may be well posed and lighted, seated on an ottoman, with her feet placed amongst a number of flower-pots containing ferns, palms, or other green stuff, suggesting the idea of their being overturned if she changed her position. Whoever saw any in ordinary life so crowded up with greenery in a fashion that would require an acrobatic performance to clear them without damage? Art will never be advanced by such attempts, that is very certain. This going out of the way for the sake of displaying the covering power of the lens—or, in the usual studio slang, breaking up the straight lines—will have to be modified or eliminated for more reasonable means, less ostentation, and more of the character of those associated with every-day home life. Even the expression of the face is frequently assumed for the benefit of the photographer, and seldom or never seen at other times. This, however, is not altogether the fault of the photographer.

Then we get all sorts of eccentricities in lighting, under the impression they are Rembrandtesque—a streak of light down the profile and the top of the head like a fall of snow, whilst the face generally is buried in deep shadow, sometimes in positive blackness, which is neither Rembrandt-like nor anything else but absurd. Vagaries of this description are happily toning down at the present time, although they were plentiful enough not long since. It is curious how the public will take a fancy to some particular kind of lighting, some special effect on an exceptional subject, and forthwith conclude it will suit them individually. The photographer sees £. *s. d.* in it, tries to please the public and outrage common sense at the same time; for, when we have said and done all, we must admit that it is mainly £. *s. d.* that rules the roast. But it is when the inartistic mind attempts to do something startling in the way of picture-making that we are brought face to face with the depths of degradation to which photography is exposed.

Human emotions are not successfully treated by photography, and, except in rare instances, are not likely to be truthfully rendered; the poetical extracts we find attached to many such attempts provide the only poetry of the exhibit. Perfect models are unattainable, and photographers, unlike painters, cannot select the beautiful from many and blend them together in one, whatever their skill may be; and, despite of all this, the advance of artistic photography has been very great of late years, and promises to be greater still in the future. It is by comparison of the best pictures of different decades that the improvement is so marked, is realisable. Adam Salomon was the first to set English photographers thinking. Luckhardt and Angerer showed us what could be done with ordinary dress, as Salomon did with lighting and posing, and from that time dates the artistic revolution of the art. It was soon evident that the most skilful manipulation would not make up for lack of artistic knowledge—a fact that was not so soon realised as one would have expected—but gradually the pictures turned out by different men effectually proved that those who possessed the most artistic knowledge made the most popular work; and at the present time, unless a man can supplement good manipulative skill with artistic treatment, he had better by far give up photography as a source of income. The business of good houses now depends for popularity on the work of the artist rather than that of the photographer pure and simple, for with dry gelatine plates, and the ease with which a perfect chemical image can be produced by almost any one, a merely good photographer is absolutely of no account. But in lighting, and in the treatment of the sitter generally,

is centered the test of competence—a fact of itself that proves the extraordinary improvement that the last few years have made in the practice of photography from an artistic point of view.

EDWARD DUNMORE.

To be continued.)

PHOTOGRAPHIC METASTASIS.—II.

THE sources of error which we must take into account, and against which we must guard in estimating the density-value corresponding to a given exposure-value in a finished normal image—to set aside for the moment all consideration of "neutral," "reversal," and intermediate forms,—are chiefly due to the following causes, enumerating them in the order in which they occur:—

1. *Unequal Coating.*—(*a*) Of one plate as compared to another from the same batch or box, the thinly coated plate being more rapid and giving less density than that which is more thickly coated. (*b*) Of the margin as compared to the centre. Here the preceding observations also apply; the margin being the thinner portion is the most sensitive, but usually receives the least light, when a lens is used. (*c*) From the viscosity of the emulsion. Few plates have the film of uniform thickness even in the centre. I have found commercial plates by the best makers to show inequalities of relief when viewed by the light of the dark-room lamp, reflected from the surface of the film when held at very obtuse angles. In every-day picture-making this defect like many others does not, when present, detract appreciably from the quality of the result; but in the quantitative estimation of the density-value of one flat tint as compared to another the variation is distinctly perceptible. (*d*) Owing to the surface of the (glass) support not being truly plane. Hollows in the glass sufficient to form Newton's rings might, even when superadded to other sources, be inconsiderable, and be left out of account save where such a delicate estimation is claimed that the analysis is expressed to the thousandth of less than the thousandth of an inch.

2. *Unequal Development.*—(*a*) Due to insufficient precision in measuring out the ingredients. (*b*) Caused by inaccuracy in timing the period of immersion. (*c*) Resulting from inequality of temperature, which makes the effect of a minute's immersion at one time different from a minute's immersion at another. (*d*) Arising through the impurity or unequal strength of the chemicals employed, and also from the unequal rate at which some of them volatilise and lose their efficiency.

3. *Unequal Fixing.*—(*a*) Owing to the diversity in the resisting power of different brands of plates. (*b*) Brought about through employing inconstant proportion of the ingredients of the developers. (*c*) Produced by variation in the rapidity with which the density has been developed, little matter from what cause. (*d*) By using a fixing bath of unknown strength, or for uncertain periods.

4. To these causes we may add, while treating of the production of the finished plate—(*a*) Inequality of colour. (*b*) Inequality in washing between development and fixing, some plates and some exposures acquiring more density than others during this interval. (*c*) The very marked inequality in density between equal wet densities when dried at unequal rates.

5. The inaccuracy and untrustworthiness, where minute variations are concerned, of most photometric methods.

To all these sources of error we must add, when dealing with abnormal exposures—(*a*) The printed-out increment in density. (*b*) The greater activity of the fixing reagent.

Nor must we forget when working with the unbacked plates—for backing, though it does not cure, mitigates the evil of halation—that there is in most subjects a certain amount of unequally distributed density, excessive or deficient, which is not directly due to the incident light, but is mainly attributable to the localised reflection of that which has already passed through the film.

Taking, as I have been forced to take, all these considerations into account, I have preferred, in my work of the past five or six years, to make my experiments as exact as possible, but never to trust to the accuracy of any single observation, nor to any reasoned-out estimation of the amount of the error of observation, choosing, under the circumstances, rather to multiply results and take the average of repeated testing, of single, and stripped, and superposed films, by eye, by the time taken to print through, and by photometer. I hold, and I consider myself abundantly justified in my belief, that without the check afforded by the previous determination of the arithmetical series of density-values $0+\cdot5$, $0+1$, $\cdot5+\cdot5$, and $1+0$, corresponding to the geometrical series of exposures, no set of analyses of fractional densities can, *se ipse*, furnish sufficient or sufficiently reliable data to how what is the actual relationship existing for the time being between exposure-value, and density-value, nor to suggest that the connexion is that of common ratio to common difference.

A working hypothesis is, I feel certain, an absolute necessity, because, where unstinted experiment might amply suffice to rebut or confirm the position taken up, the life of man is far too short to admit of the creation of a *luculus ordo* from the chaotic jumble of *disjecta membra*, which must infallibly accrue when a complicated analysis and synthesis are undertaken unadvisedly and without premeditated intent.

Finding that all experimental essays to connect the shorter exposures with their developed densities were utterly untrustworthy, I relinquished the task, and devoted my energies to the graphical representation of both semi-constituents of density, which, commencing with the normal image, I found to be reciprocals one of the other, not only during one complete cycle of revolution (cycle of phases), but for more than one repetition of the same. Whilst in this determination of the connexion between exposure and density-values I chiefly employed the method of superposing the complementary densities—stripped, or on the glass, and allowing for it—and comparing them in a photometer, I took care to check my figures by printing opaque spots through them, and by giving very short exposures, and submitting the action produced to the test of a constant developer.

Accepting the leading statement in my paper of 1888 as correct, the following may fairly be advanced as the line of reasoning naturally suggested to any mathematician cognisant of the elements of photography.

In order to express the density at any instant in terms of the time which has elapsed since the exposure of the film commenced, let e denote the time of exposure requisite to produce the first normal image, and a^4e that required to produce the second normal image; a^4 is chosen for the ratio, in preference to a single letter, merely to simplify the subsequent formulæ; a thus depends upon the accelerator employed. If d represent numerically the maximum density of the image, we can tabulate the corresponding values of t and D (time from commencement of exposure and density) as follows, adding for convenience a third column giving log t.

t	D	log t
e	d	log e
ae	$\frac{d}{2}$	log e + log a
a^2e	o	log e + 2 log a
a^3e	$\frac{d}{2}$	log e + 3 log a
a^4e	d	log e + 4 log a
a^5e	$\frac{d}{2}$	log e + 5 log a
a^6e	o	log e + 6 log a
a^7e	$\frac{d}{2}$	log e + 7 log a

Comparing the second and third columns of this table, we see that log t increases uniformly as the density of either semi-constituent varies from normal to neutral, from neutral to reversal, from reversal to second neutral, from second neutral to second normal, and so on. The density is a continuous function of the time. Hence we must come to some decision as to its mode of variation at intermediate points. As the density rises and falls, always repeating the same cycle of changes, the simplest hypothesis we can make is that of simple harmonic variation. This clearly coincides with the known results of observation at the four points in each cycle which are of greatest importance, and it is the law obeyed by almost all periodic phenomena in nature, *e.g.*, the rise and fall of the tides, the vibration of elastic bodies, the motion of the particles of every medium that transmits waves, whether air, or water, or ether, and the swing of the pendulum. Its sufficiency can only be demonstrated by experimentally determining the density at points intermediate to those given in the table. This, as stated in THE BRITISH JOURNAL OF PHOTOGRAPHY for January 13 and November 16, 1888, in the paragraph preceding my leading conclusions, I did for several points after the first normal image and intermediate to the four critical points of each cycle, as also for a series of points between the first mean and greatest densities. The values given by these experiments coincide with those required by the law to the closest degree of accuracy which we can reliably measure. But, even in default of such experimental verification, we still know that this hypothesis satisfies all the known facts, is the simplest assumption

which will do so, and has been found to be the law of multitudes of similar natural phenomena.

Owing to the periodicity of the circular function, the table can now be written thus:—

t	D	log t
e	$\frac{d}{2}(1+\sin\frac{\pi}{2})$	log e
e a	$\frac{d}{2}(1+\sin 2\frac{\pi}{2})$	log e + log a
e a^2	$\frac{d}{2}(1+\sin 3\frac{\pi}{2})$	log e + log a
e a^3	$\frac{d}{2}(1+\sin 4\frac{\pi}{2})$	log e + log a
e a^4	$\frac{d}{2}(1+\sin 5\frac{\pi}{2})$	log e + log a
e a^5	$\frac{d}{2}(1+\sin 6\frac{\pi}{2})$	log e + log a
e a^6	$\frac{d}{2}(1+\sin 7\frac{\pi}{2})$	log e + log a
e a^7	$\frac{d}{2}(1+\sin 8\frac{\pi}{2})$	log e + log a
e a^n	$\frac{d}{2}(1+\sin\overline{n+1}\frac{\pi}{2})$	log e × n log a

Hence we have D and t expressed in terms of a variable parameter, n, the elimination of which will at once give the relation between them.

Taking the general entries in columns 2 and 3, we have:—

$$D=\frac{d}{2}(1+\sin\overline{n+1}\frac{\pi}{2}) \quad (1)$$

$$\log t = \log e + n \log a \quad (2)$$

From (2)

$$n=\frac{\log\frac{t}{e}}{\log a} \quad (3)$$

Substituting from (3) in (1) we get:

$$D=\frac{d}{2}\left\{1+\sin\frac{\log\frac{at}{e}}{\log a}\frac{\pi}{2}\right\} \quad (4)$$

This formula gives the density, D, at any instant in terms of the time, t, which has elapsed since the beginning of the exposure.

The data from which the foregoing formula has been deduced are as follows:—

I. The laws expressed in 'C' and 'D' of my original paper.

II. The successive maximum densities (or contrasts between zero and unity) are equally intense. *This applies with the same force to either semi-constituent.*

III. No account is taken of the continuous degradation or fogging of the film.

The provisional law based on these data, and applicable under the limitations stated, is, in brief:—

"The density is a simple harmonic function of the logarithm of the time from the instant of exposure."

Although resulting from a consideration of densities brought out by immersions of considerable duration, the foregoing law is put forward as specially applying, not so much to the density actually produced as to the total conjoint energy or power to produce density of light of a given intensity when superadded to a developer of known potency acting upon a film of silver bromide suspended in gelatine, the contact of the exposed plate with the chemical multiplier or divisor being assumed to be instantaneous. The primary object of all the experiments from which the law was deduced was the obtaining, in the first place, such information regarding the qualitative and quantitative individual influence of the separate ingredients of a standard developer as would admit of the assigning to each an absolute and comparative value, with the ultimate view of arriving at some definite conclusion as to the precise nature of those physical and chemical properties of the silver salt in question which constitute its sensitiveness, properties to which Messrs. Hurter & Driffield have assigned the symbols "*k*," "*a*," and "*e*" in their mathematical formula:—

$$\text{"}D=\gamma\log_e\left[O-O-(O1)\beta^k(1-a)\frac{It}{e}\right],\text{"}$$

a formula which, with our present knowledge of "*k*," "*a*," and "*e*," I consider to be pathetically simple. It is, nevertheless, extremely mathematical and scientific in appearance, and to mathematicians who know little of photography, and to photographers who know little of mathematics, it is most satisfactory. Only it won't work out, because it means *nothing* as yet. When it means *anything*, it will be found to be wrong.

HUGH BREBNER.

THE PHOTOGRAPHIC CONGRESS AUXILIARY OF THE WORLD'S COLUMBIAN EXPOSITION.

THE following additional papers were read:—

PHOTOGRAPHY AS APPLIED TO SURGERY.

THE service which photography is capable of rendering the surgeon covers a wide and important field. By this means minutely accurate delineations of the work in progress can be secured in a few seconds' time, which will subsequently reproduce all the surface features of a case at a glance, and that, too, more perfectly than an elaborate description.

In surgical cases intended for publication the photograph is an invaluable adjuvant, either for direct processes of reproduction or as an accurate basis for a careful drawing, which will in this way be enabled to preserve the life and individuality of the subject, often lost in drawings hurriedly made and then finished from memory.

A further and possibly a still more important field for photography in surgical operating room is one which has been for the first time brought into use in the gynecological room of the John Hopkins Hospital of Baltimore, Maryland. That is, an effort by this means to crystallise a sufficient number of important steps during an operation from the commencement to completion, so that, by producing the photographs in the same order, a fairly accurate conception of the operative procedure may be obtained, and in any event the pictures will afford a basis for a vivid lecture, when given before students for instruction.

The effect of the photograph is much enhanced when the negative is converted into a positive on glass in the shape of a lantern slide, and the operation reproduced upon a screen of sufficient size, in lifelike proportions, by the aid of calcium or electric light, as an illuminant. The contrast of lights and shadows and the stereoscopic appearance in this field are superior to the best prints, and leave nothing to be desired in the realistic effect. While photography possesses these manifold advantages and holds for itself a wide field of utility never before occupied, it does not supplant the more painstaking drawing direct from the specimen or subject. By means of the drawing, always more or less diagrammatic, those features are emphasised to which the surgeon wishes to draw the attention, and the drawing is for this reason more quickly self-explanatory. In addition to this, photography becomes difficult, if not impossible, as soon as the field of operation lies deep in the body, either in the abdomen or vagina. The lack of actinic power in red blood also often interferes with the success of a negative taken during the progress of an operation, the deep red spots showing as unsightly black blotches in the positive. Moving objects, to be sure, cannot well be photographed, unless the illumination is great enough to allow an instantaneous exposure to be made.

In this way the movements of respiration transmitted to the abdomen and pelvic floor may be a serious disadvantage. Sometimes, however, it is advantageous to photograph the motion of a part. Motion may, for example, be registered in this way: If a patient's chest is heaving during an exposure of several seconds, the outline will be a blurred one, while the other parts are sharp, thus demonstrating the motion. A photograph of the contour of the abdomen from sternum to pubis shows a hazy outline due to the transmitted respiratory movements. If, however, the lower abdomen is filled with a myoma large enough to reach the anterior wall, this part is splinted and remains quiescent on the tumour, showing a sharp outline in the picture, while the rest of the abdomen above has a faint, hazy outline, thus demonstrating the presence of the tumour to the eye.

The conditions necessary for making a good photograph are but few: A good illumination of the subject and the employment of prepared plates of a sufficient degree of sensitiveness, so as to make an impression quickly, without delaying the operator in his work. None of the pictures thus made in the gynecological operating room (and we have made about eight hundred and fifty in the past year) delay the work longer than three seconds, and generally less time is consumed.

A good instrument, lens, and shutter are necessities. The camera proper must be arranged with considerable movement or adjustment of the front carrying the lens, so as to bring properly into the centre of the plate that particular part which is the principal object of interest in the picture. A vertical swing back is also a *desideratum*. The camera should be strong and well made, and equipped with an abundance of plate-

holders. The use of lenses of different focal length is of assistance to the photographic operator, but two lengths are all that are made use of in our work.

The best size of plate is that known as 5 × 7 in the list of photographic sizes, which is a convenient one for those prints to mount in our reference albums. Should a larger size be desired, they can readily be enlarged. With this size a good rectilinear lens of ten inches back focus, classed in the price-lists to cover the next larger size of plate, say, 6½ × 8½.

This will enable the photographic operator to use his lens without small diaphragms, as the object on the ground glass will be of sufficient size without moving too near to the subject, thus avoiding distortion and irregularity in the sharpness of the field. The use of small apertures to secure uniformly sharp focus of the image considerably lengthens the time for necessary exposure of the plate. For photographing specimens a lens of shorter focal length is necessary, as it will be found that to get an image of the desired size, when the foregoing described lens is employed, the length of the bellows of the standard cameras is insufficient; so I would suggest that one of about five or even four and one half inches back focus be added to the photographic outfit.

As a stand or support for the camera, I urge that the conventional tripod be altogether discarded, because of its liability to slide and slip about in a very erratic way, and a table, with such suitable attachments as I will hereafter describe, be substituted. This table had better be one rather high in proportion to its size, square on the top, but made strongly, so that there may be no vibration. It should be about four feet high, and on the top about thirty by twenty-four inches square, with a shelf placed about midway between the top and the floor; this will make the same more rigid, and, besides, give an opportunity of a greater range of adjustment for the attachments as you may want to place them. As a general support for the camera, have made two pieces, or rather angles, made of boards about eight inches wide and one inch thick, the shape of a letter L; these two are placed one against the other, one having a slot about two-thirds its length, and in the other a nut to work on a thumb-screw, to enable you to slide one on the other, and secure them in any position in which they may be adjusted. You now have the two angles fastened together something in the shape of a very straight up-and-down letter Z. On the upper horizontal part of this you have placed a second board, same width and length, and hinged to it at one end, while at the other you place a long wooden screw, so by this means you can elevate and depress that end. On this part the camera is now placed, and it can be tipped to a great angle from a horizontal line, depending upon the length of the screw. The lower part of this is then placed on the table and secured by a screw on which it can revolve. The great advantage of this arrangement is that the camera, when desired, can be placed in a position of being plumb, level, and square.

We find very often that we wish to place the camera in vertical position—that of pointing down upon a subject. To enable this to be done, have two pieces of board, one about two feet six inches long and the other about eighteen inches, fastened together so as to form a right angle, as before mentioned, only that the shorter part is fastened to the table at its edge, and the other longer part is to have a long slot running almost from the top to the bottom, through which the tripod screw will pass and allow you to slide the camera up and down in a vertical position, and secure it at any point. Have now a frame of such suitable size, and capable of holding a sheet of plate glass, supported by slender legs, so as not to obstruct the light, about ten inches high. On this table we place the specimens to be photographed.

The advantages of this method of photographing specimens are apparent. In the first place, they will lie in any position in which they are placed. Again, the background being at a distance from the plane of support gives the specimen the appearance in the picture of hanging in space without visible support, and securing thus a stereoscopic effect not otherwise obtainable. In some cases the specimens are placed in a dish of a shallow nature, and floated or submerged in water, then the dish placed on the plate-glass stand, and so the photograph is made, the floating out of all the delicate velamentous adhesions. When the flow of blood is such as to interfere with the photographic work, a generous flow of water from the "irrigator" will not oppose the work of the camera.

A record of all negatives made during the operations and the nature of the subject is kept in a book in the operating room, with date and the patient's hospital number. By referring to the album, in which all the prints are mounted in the order taken, the cases are recalled with definiteness which descriptions and drawing cannot attain.

A. S. Murray.

POSING AND ILLUMINATION.

The subject of posing and illumination in the photographic studio is more nearly related to the artistic than to the scientific part of photography, and therefore there will naturally be a wider diversity of thought and opinion on this subject than might be expected concerning the more scientific, and therefore more exact, branches of our profession, such as are practised more particularly by the dark-room worker or the printer, although there can be no doubt that each of these is successful in accordance with his knowledge of art principles and his ability to apply them in his work.

The successful photographer may well claim to be an artist, for the highest product of his genius must be the exquisite flower of the combination of the purest and most cultivated taste and the highest skill.

The artist, however, they say, is born, not made. Nature must first have endowed him with gifts that would have constituted him an authoritative connoiseur in all art matters without having studied either line or rule. The endowment of artistic taste, however, does not carry with it the ability of mechanical expression; taste is of the intellect, inward; mechanical expression is of study and practice, outward.

Taste is God-given; it may be improved by cultivation, but cannot be acquired by study.

Manual skill is only acquired by long and generally painful exertion, and only retained by constant practice.

The artist, therefore, in whatever line (whether as the musician who charms and enraptures us with heavenly sounds, or the painter who enchants us with harmonious colours, or the photographer who delights us with beautiful effects of light and shade), is one who has been impelled to acquire the manual dexterity or skill to give outward expression to the beautiful in sound, or colour, or light, whose origin is from within.

All photographers may not be artists in the highest sense, because art is inherent, not acquired; but that which a man has may be improved by study and observation of the works of artists who have made for themselves a name and reputation as such.

All photographers may and should be students, eager to find out for themselves every means that may enhance the beauty or value of their work.

At no time in the history of art has the study of art principles in the beauty of form, colour, and shade been so easy or the opportunities so numerous as at the present time, the near ending of the century.

Posing and illumination under the photographer's skylight or in the painter's studio must be governed by the same rules, and these rules or laws have so frequently been published in photographers' journals, and have been so frequently commented on by eminent photographers for the instruction of their fellow-workers, that it appears unnecessary on this occasion to occupy time by any detailed discussion thereof. I would, however, remind you that you have the works of H. P. Robinson, of Edward L. Wilson, and many other eminent authorities, equally accessible, and I would strongly recommend the study of the same and the application of their ideas in your daily work in your studios.

The time is now past when any photographer poses and illuminates any subject without study and consideration.

It is not the rule now to seat your subject carelessly before the camera and fire away, considering that any outcome must be a likeness, and therefore good enough. The light now furnishes the modelling, and the lens cuts it in; therefore the handling of the light and the use of the lens must receive the study and practice that are necessary to the skilful use of the pencil and the brush.

If the artist photographer has any appreciation of the line of beauty, he will easily understand that, in posing his subject under the skylight, he should develop, or bring into prominence, the curve, rather than the angle, and that the centre of gravity should fall within the base.

He should understand that symmetry and proportion must characterise his work, whether of the one or of the many—the single figure or the group.

He must understand that, in composition, lines must have supporting lines when not perpendicular, and that a picture is unsatisfactory that carries no idea of firmness and support.

The artist, having these elementary principles constantly in mind, will practically make a study of each face and form that comes under his studio light; viewing the subject or model from every direction, and by every method of illumination; studying the face by front, three-quarters, or profile view, both toward and from the light; and also by the various arrangements of the light, such as broad Rembrandt or shadow lighting, or by any recognised method of lighting that the studio will admit of, that may impart character, form, or piquancy to a face or figure that may, perhaps, lack one or all of these graces when in repose, while

abundantly interesting when animated by conversation or engaged in the common affairs of life.

Every face will present some one view that will be more pleasing or interesting than any other. The long, thin face may, perhaps, be more pleasing from the front; the broad face may look better at the three-quarter view; one view may suppress an angle and develop a colour, while an inconsidered pose might bring out the reverse.

The tilting of the head to one side or the other, the raising of the chin or the reverse, may give piquancy to this one, and picturesque effect to the other.

In this manner he will decide on that view that gives the most pleasing outline, and that method of illumination that gives boldness and brilliancy where features are small or insipid, or that tones down the harshness of a too rugged face without losing altogether its characteristic quality, for it is well to keep in mind that an indication of character adds as much to a portrait as does action or life to a pose, avoiding always the commonplace. Tameness in expression, pose, or lighting, is contemptible, and will rob even the finest execution of every charm; at the same time an evident straining for effect in pose or lighting is objectionable to any refined taste, and should be avoided as strenuously as the other extreme, however true it may be, that the daring innovator may sometimes produce charming effects that may not come strictly within the approval of a too-cultivated taste.

In my opinion, a resort to ultra effects is only justifiable in cases where the face and form of the subject are not amenable to ordinary methods, and when it may be desirable or profitable to experiment.

When posing a single figure, in either full or three-quarters, certain accessories may be used with good effect, but care should be exercised in making the model the central point of attention; everything should be subservient to the portrait.

The three-quarter length will always be better without accessories, unless in a sitting or leaning position, in which case the proper support will necessarily be provided.

Groups of two or more require the exercise of common sense, and a knowledge of the capabilities of light and lenses. In form, the group should be as symmetrical as may be, with dark complexions and dresses placed next the light; and, in large groups, more attention should be given to the general than to individual effect.

The best photographic light is received from two windows—a top window or skylight joined to a side window, which shall reach to within three feet of the floor of the studio.

The dimension of the skylight should not be less than ten feet square, if space permits, but preferably larger if convenient, the pitch of the upper light only enough to easily and safely carry the snow and ice of winter, and shed the rain of summer without leakage.

The quality of the top light is softness and delicacy of detail, but with two heavy shadows beneath projection.

The quality of the side light is vigorous harshness, with abrupt lateral shadows.

The one corrects the other to any extent desired, so that, having a top and side light properly shaded with movable curtains, every description of face may be so lighted as to make prominent all the good points, and to lessen, or entirely suppress, all that is not desirable.

By a proper arrangement of the top and side light we can give boldness and prominence to small or weak features. We can by similar means soften and refine coarse and rugged faces.

By seating the model facing the light, and at a suitable distance therefrom, it is possible to remove, to a great extent, the appearances of age; the wrinkles and crow's-feet are lighted up, but cast no shadows.

In fact, it is possible to change the shape of the face of any subject to a great extent by judicious management of the light.

Having a good light, use all of it that may be used with advantage, according to the method of lighting adopted for that particular subject.

Many photographers shade their lights down closely and give long exposures; but the preponderance of opinion among artists of recognised ability is in favour of using all the light the model will bear, and make shorter exposures comparatively, thus obtaining bolder modelling, finer gradations, and more brilliant effects, while not losing the softness that is characteristic of all really first-class work.

I have stated that time of exposure has much to do with the quality of the negative; it is also very true that the character of the dry plate has an important bearing on the resulting negative. I have always found that thinly coated plates invariably had a tendency to make negatives whose printing quality tended to contrast because of the fact that the shadows were always thinner than they looked. Such plates require longer exposure, and the subjects should be more evenly lighted than when plates of a thicker coating, although of even sensitiveness, are used.

The effect of the lighting of the subject will not be the same on the sensitive plate as it is on the retina of the operator's eye; therefore the photographer by closely observing the action of the lens will learn to see photographically, or to understand the precise effect on the sensitive plate of any method of illumination he may employ for his subject.

Also, he must understand that the time of exposure will greatly modify the effect he may be desirous of obtaining.

The subject should be posed well out under the light, and generally at a proper distance from the background to get what is called atmospheric effect. Then, if the whole figure or head is well lighted, a proper exposure will give the effect of daylight illumination, while a short exposure will produce the effect of artificial lighting.

By daylight illumination I mean that the figure or head will be fully lighted with soft modellings and easy gradations from high light to transparent shadows, while by artificial illumination the lights are chalky or flatted, and the gradations are abrupt to heavy shadows. I therefore consider that it is safer to err on the side of over-exposure than to under-expose, although I have known eminent photographers to lean constantly to the short exposure for picturesque effects.

Picturesque effect of pose and light should be aimed for in all photographic portraiture, and a thorough knowledge of the peculiarities of light and lens should be acquired by the artist, so that his judgment may ever readily arrive at the proper methods of arrangement of the light and the exposure for lens to produce the effects desired for any face or figure with as little delay and hesitation as possible.

This promptness of decision will secure the confidence of the sitter and facilitate matters in a large measure, the natural result being more patrons, enlarged business, and increased profits. That such may be the good fortune of all who have listened to my views on the subject under discussion is the sincere wish of your friend and fellow-labourer.

E. M. Estabrooke.

Our Editorial Table.

Messrs. York & Son, 87, Lancaster-road, Notting Hill, London, have issued their 24th Annual Supplemental Catalogue of lantern slides and lecture sets, which contains many valuable additions. Amongst these we find fifty and sixty views respectively of Chicago city and the Exposition; similar numbers of Athens and the Piræus, cities of North Italy, the Canary Islands and Madeira, Ceylon and tea-culture, with many others of both an instructive and amusing character.

Accompanying this is a twelve-page Catalogue of the titles of the sets issued by this firm. Some idea can be formed of the enormous numbers kept in stock when we say that one line alone in this double-column index frequently represents several hundred slides.

The New Roller-slide Films of the Eastman Company.

Some time since, the Eastman Photographic Materials Company (Limited), having discovered that there were imperfections in their original rollable films which militated against their keeping, reconstructed their formulæ and method of manufacture, recalling what had been previously issued. We have recently made trial of their new and improved film, and are much pleased with it. While so sensitive as to permit of snap-shots being made with it even under unfavourable conditions, it develops with great brilliance and cleanness, giving negatives of excellent printing quality, with entire freedom from imperfections. The Company is to be congratulated upon now turning out films of such excellent quality. We have also received samples of this Company's new "Nikko" paper, upon which we expect to be in a position soon to report.

STANLEY SHOW, 1893.

Stanley Photographic Competitions will take place in connexion with the Seventeenth Annual Exhibition of Cycles, their accessories, machinery and tools, photographic apparatus and pictures, held by the above Club, at the Royal Agricultural Hall, Islington, London, N., from November 17 to 25 inclusive. Twenty medals (five gold) are offered for competition under certain rules and conditions in the following classes:—(*a*) Champion; (*b*) Landscape; (*c*) Lantern slides; (*d*) Portraiture; (*e*) Hand-camera work; (*f*) Beginners; (*g*) cycling, and (*h*) Special society prize. Address all communications respecting this exhibition to Walter D. Welford, Manager Photographic Section, Stanley Show Office, 57 and 58, Chancery-lane, London, W.C.

News and Notes.

MANCHESTER PHOTOGRAPHIC SOCIETY.—September 16, Worsley (Ramble).

NORTHERN PHOTOGRAPHIC AND SCIENTIFIC ASSOCIATION.—September 16, Hadley Wood.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.—September 18, Demonstration. Lantern-slide making by Mr. H. E. Farmer.

PHOTOGRAPHIC CLUB.—September 20, *Dark-room Appliances.* The annual wind-up outing to Hampstead Heath will take place on Saturday, September 30.

HACKNEY PHOTOGRAPHIC SOCIETY.—September 16, Excursion to Kew (by Boat). Hand Camera Day. Meet at Old Swan Pier at two o'clock; tea at Richmond, and return by train. 19, Members' Lantern Night.

THE Newcastle-on-Tyne and Northern Counties' Photographic Association and Hexham Photographic Society's joint outdoor meeting will take place on Thursday, September 21, 1893, to Bardon Mill and Staward, under the leadership of Mr. J. P. Gibson. Train leaves Newcastle for Bardon Mill Station at twenty minutes past ten.

LEYTONSTONE CAMERA CLUB.—September 16, Radlett and Aldenham. Leader, Mr. A. E. Bailey. The Club will proceed by the train leaving Moorgate-street, Midland Railway, at nineteen minutes past two p.m., arriving at Radlett at twelve minutes past three (take single tickets, return from Watford, L. & N. W. R.). Open Social Evening at Head-quarters at eight o'clock.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.—September 14, Members' Night. 21, *Paget Lantern Plates*, demonstration by Mr. S. H. Fry. 28, *Film Working*, by Mr. W. H. Barnes. 30, Outing, "Bull and Bush," Hampstead; tea at six o'clock. October 5, *Unconventional Printing Methods*, by Mr. S. H. Fry. 12, Affiliated Societies' Meeting, 5A, Pall Mall. 19, Lantern Night, by Mr. T. C. Hepworth, on *A Recent Trip to the Lake District.* 26, *Aluminium Flash Light*, by Mr. T. Bolas.

AT the recently opened Bristol Industrial Exhibition, Messrs. Epstein & Co., of 33, Broad-street, have a large exhibit of picture mouldings in great variety. Some 1200 patterns of German moulding are shown; also a large collection of chromos, oleos, etchings, and many specialities for photographers. Messrs. Epstein's business was established in 1878, and its growth has been such that it has necessitated enlargements of the premises more than once. Other sections of the business are devoted to the restoration of engravings, paintings, mount cutting, &c. From the illustrated sample sheet we observe that great taste is displayed in the choice of mouldings, &c., while the price-list includes particulars of all requisites in framing and mounting.

THE Capetown Photographic Society opened a very successful exhibition on August 17. Amongst the principal exhibits were a number of beautiful carbon enlargements, as well as some fine large direct prints of views taken in Italy, shown by Mr. T. E. Fuller, M.L.A. Mr. G. Lindup lent some valuable oil paintings. The Cape Royal Observatory, through the president of the club, lent amongst other exhibits a Dallmeyer's rapid rectilinear lens to cover a 34×34 inch plate. This cost no less than 100*l.*, and has been in use a number of years at the Observatory, no less than 3000 stellar photographs having been taken with it. Some interesting spectroscopic apparatus was also contributed from the same source. Amongst the loan photographs were also specimens of the series of "Artists at Home," being platinotype portraits of most prominent English Academicians taken in their own studies. These were the work of Mr. Ralph W. Robinson (of the firm of H. P. Robinson & Son), besides English rural scenes by the same photographer, and a set of views of Windsor Castle during Jubilee year, principally interiors, taken by special permission by Mr. William Brooks. A number of microscopes, graphoscopes, magazine stereoscopes, lanternscopes, and other scientific instruments were also exhibited; as well as a swarm of bees lent by Mr. Gracie, the structure of the bees being illustrated by a number of micro-photo lantern slides, the work of Mr. A. J. Fuller.

CONGRESS OF THE PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN AND AFFILIATED SOCIETIES, 1893.—This Congress is arranged to take place on October 10, 11, and 12. All who are interested in the progress of photography are invited to be present, and take part in the discussions. It is expected that, by the kindness of M. L. Lumière, some of M. Lippmann's latest specimens of photography in colours will be on view at one of the meetings. It is necessary that, for the lantern display, admission shall be by ticket only, and a limited number of tickets will be sent to every member of the Society for themselves and their friends. Members of affiliated Societies should apply to their respective Secretaries for these tickets, or for any further information. Programme:—Tuesday, October 10, at eight p.m., at the Gallery, 5A, Pall Mall East: The presentation of the medals awarded at the Exhibition; the President's annual address; a paper on *The Action of Light on Bacteria and Fungi*, by Professor H. Marshall Ward, M.A., F.R.S. Wednesday, October 11, at three p.m., at the Theatre of the Society of Arts, John-street, Adelphi, the following papers will be read: *The Present Position of Photomicrography*, by Andrew Pringle, F.R.M.S.; *On a Process of Photo-mechanical Printing in Natural Colours*, by W. Weissenberger, of St. Petersburg; a paper by Mr. Emil von Höegh, of Berlin; *Photography in Compartments*, by Hector Maclean, F.G.S. At eight p.m., at the Theatre of the Society of Arts, John-street, Adelphi, the following papers will be read: *On Exposure and Chemical Action*, by Captain W. de W. Abney, C.B., F.R.S.; *The Recent Solar Eclipse*, by Captain Hills, R.E.; a paper by Dr. A. Miethe. Thursday, October 12, at three p.m., at the Theatre of the Society of Arts, John-street, Adelphi, a demonstration of collotype printing will be given by Messrs. T. Bolas and W. E. Debenham; the following papers will be read: *The Measure and Numeration of the Stops of Photographic Lenses*, by Dr. P. Rudolph; a paper by Mr. Arthur W. Clayden, M.A. At eight p.m., at the Gallery, 5A, Pall Mall East, a special lantern display.

,, 22 ...	Croydon Microscopical	Public Hall, George-street, Croydon.
,, 22 ...	Holborn	
,, 22 ...	Maidstone	"The Palace," Maidstone.
,, 22 ...	West London	Chiswick School of Art, Chiswick.
,, 23 ...	Hull	71, Prospect-street, Hull.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

SEPTEMBER 7,—Mr. A. Haddon in the chair.

The greater part of the evening was occupied in discussion of matters arising out of the recent alteration of the rules.

VITRIFIABLE POWDER FOR ENAMELLING.

The CHAIRMAN asked if gelatine, loaded with vitrifiable powders, could be obtained?

Mr. T. BOLAS thought not, but the loading was easily done. Tissue prepared with the vitrifiable colour did not keep well, the fluxes making the tissue insoluble, so that it was better to prepare it, the bichromate being added to the mixture.

The CHAIRMAN said it had been recommended to have as much powder as gelatine.

Mr. T. BOLAS said the brown and purple colours were very cheap.

Mr. R. Beckett exhibited a plate which had been exposed on a copy of a group, put away, and forgotten, and then exposed on a portrait. On development the original exposure came out as a positive.

In reply to a request for an explanation, several were made attempting to account for the phenomena on the ground of over-exposure, reversal, &c.; but, as no particulars of the exposure were forthcoming, nothing definite was arrived at.

Mr. Beckett also exhibited several negatives fogged in the same place, and also the slide on which they were taken.

The fog was variously suggested to be due to emanations from the slide, the paper wrappings, &c.

North Middlesex Photographic Society.—On Monday, September 11, Mr. BIRT ACRES treated the members to what he called a "talk" on *Halation, its Cause and Cure.* In opening his subject he said that the halation caused by the reflection of light from the back of the plate was only a small part of that with which photographers had to contend, the greater portion being caused either by (1) the actual spreading of the light rays beyond the edge of, say, the window in an interior view; (2) the luminosity of the air, which was much more manifest to the lens and plate than to the human eye; or (3) the photographing of the atoms of dust floating in the air. Halation of this kind could never be wholly avoided, and, in fact, it would not be proper that it should be, for some of this luminosity was necessary to give a natural result; but this effect was much exaggerated in the negative, and the most successful way he knew of overcoming it in the print was to first take a somewhat faint print on silver paper and fix it, then wax it, or in some way render it translucent, and fix this transparent print on to the back of the negative in the printing frame, and print through it far enough to correct the excessive opacity of the halation-stricken negative. To avoid that halation caused by reflection from

the glass, Mr. Acres recommended backing the plate with Bates's black, which was very effective, was easily applied, and could be easily removed by a sponge dipped in benzine. He thought this method of backing was more free from objectionable features than any other he had seen recommended. A most interesting discussion followed, or rather was sandwiched in with the lecture, which was much appreciated. The voting on the pictures taken at the Strand-on-the-Green outing resulted in Mr. Gregory's being declared best, Messrs. Pither and Spencer tying for the Hatfield competition. The next meeting will be held on the 25th inst., when Mr. Thomas Bedding will read a paper on *Stereoscopic Photography*. Visitors are welcome.

Hackney Photographic Society.—September 5, Mr. Robert Beckett presiding.—The Hon. Secretary presented the Society with Cassell's Academy books. Some of Mr. Powell's plate-backing was distributed, Messrs. Beckett and Smith promising to give in report on same. The negative shown last meeting by Mr. Barnes was explained to have been caused by light, the plate being not to blame. A question was asked by Mr. ROBERTS, how to remedy a film which had been put wrong way in developer? The CHAIRMAN said, if this had been discovered soon, by turning right way and giving prolonged development it might have been cured. In answer to question as to how many gelatino-chloride prints could be toned at once, the HON. SECRETARY advised just enough to cover dish, about two in half-plate. Mr. T. H. SMITH thought six or eight in whole-plate dish. A question of weight and measures was then debated on. The CHAIRMAN said doubt was in many minds at present, so they preferred to say "parts," as avoirdupois and apothecaries' weights seemed to be a rock on which opinions were divided. Mr. PUTTOCK asked what is best amount of developer to use for half-plate? The HON. SECRETARY said he would use at least three ounces; it was a great mistake to be economical. Mr. Gosling showed some stereoscopic work done with his home-made contrivance. Mr. Barnes showed some Isle of Wight views. Mr. Puttock showed a much over-exposed plate. Mr. S. BECKETT advised intensifying. Mr. Avent showed a print executed by the Automatic Printing Machine Company on bromide rapid paper. Prints were automatically exposed and cut off at rate of sixty per minute. The print shown of Captain Abney was very good.

South London Photographic Society.—September 4, Mr. Mark Boxall in the chair.—By the courtesy of Mr. Powell, samples of his caramel and sienna anti-halation backing were distributed among the members for trial. Mr. L. E. MORGAN then gave a demonstration of the working of the new developers—amidol, metol, and glycin. The latter, he said, did not, by reason of the slowness of its action, lend itself to demonstration. It was strongly recommended for reproductions, photo-micrography, &c. Negatives of varying exposures were passed round to show its capabilities in that respect. Amidol, he stated, he was partial to on account of its simplicity. He used a single solution, the formula of which was given by the manufacturers, and proceeeded to develop some negatives, bromide paper, and lantern slides with it. Some plates were also developed with metol. At the next meeting, on the 18th inst., Mr. H. E. Farmer will give a demonstration of the making of lantern slides.

Brixton and Clapham Camera Club.—September 6, Dr. J. Reynolds, F.R.G.S. (President), in the chair.—A member of the Committee of Instruction was present for the purpose of affording assistance to members requiring it. At the conclusion of the formal business, Mr. W. H. HARRISON read a paper on *Some Useful Photographic Standards*. The substance of this paper appears in another column. Mr. SPURGE, who was present as a visitor, then gave a very full description of the theory and practical use of his sensitometer and standard light for use in connexion therewith. Next meeting, September 19, Mr. F. W. Levett on *Carbon Printing*.

Leeds Camera Club.—A satisfactory inaugural meeting of the above Club was held in the Central Market Auction Rooms, 34, New Market-street, Leeds, on Wednesday last, September 6, 1893, at eight o'clock. After a resolution being made that a club be formed, the above title was adopted. It was agreed that for the present the subscription be 2*s.* 6*d.* per annum, with a further call of 1*s.* per member if necessary. A committee of five members was formed to draw up a code of rules to be submitted at the next general meeting to be held at the same address on Thursday, September 14, at eight o'clock. It is urgent that all intending members will be present at this meeting, as the business to be brought forward will be the election of officers for the year and the adoption of rules.

Leeds Photographic Society.—September 7, Mr. J. H. Walker (President) in the chair.—Major Darwin's paper on *Lens-testing at Kew*, kindly lent by the Photographic Society of Great Britain, was read by Mr. WASHINGTON TEASDALE, F.R.A.S., one of the respected founders of this Society, who made many useful remarks and explanations, rendering some of the technicalities simpler and more interesting and instructive. A discussion followed, in which the following gentlemen took part:—Messrs. J. H. Walker, A. A. Pearson, S. A. Warburton, G. H. Rodwell, and others. A number of very fine slides were afterwards thrown on the screen, contributed by Messrs. Washington Teasdale, Godfrey Bingley, and J. H. Walker.

Lewes Photographic Society.—Annual General Meeting. The President (Mr. J. Tunks) occupied the chair.—The Council presented a report in which they regretted that the year just ended had not been altogether satisfactory with regard to the number of members. Several new societies had been formed in the neighbourhood, and this had had the effect of taking some of their outlying members, who had taken advantage of the facilitie soffered nearer home. During the year two new members had joined, four had resigned, two had left the town, and two had been struck off on account of the treasurer being unable to obtain their subscription. There were now thirty-one members on the books. The meetings had been fairly well attended. The exhibition of lantern slides and members' work, which was held in March, though not successful financially, brought together a good selection of pictures and slides, and two enjoyable evenings were spent. The committee trusted that the meetings which would be arranged for the coming season would attract better attendances than in the past, and also that all working members would endeavour to send in slides for the competition which had been announced, and for which a prize would be given. They desired to thank the press, local, and photographic, for their kind notices, and those who had sent free copies of their journals for the use of the Society. The Hon. Secretary and Treasurer reported that the total receipts for the year had been 8*l.* 12*s.* 5*d.*, including the balance of 1*l.* 3*s.* 5*d.* from last year; and that the expenditure had been 6*l.* 12*s.* 2*d.*, leaving a balance in hand of 2*l.* 0*s.* 3*d.* Mr. Curtis proposed the adoption of the accounts, and expressed the opinion that they were very satisfactory. He did not think they could consider the loss on the exhibition unsatisfactory, when they took into account the fact that they had two very pleasant evenings. Mr. Carpenter seconded, and the motion was carried. The following officers were then elected for the ensuing year:—*President:* Councillor Wightman.—*Vice-President:* Mr. J. Tunks.—*Committee:* Mr. E. J. Bedford, Mr. W. J. Young, Mr. G. Carpenter, Mr. T. H. Lyell, and Mr. C. A. Wells.—*Hon. Secretary and Treasurer:* Mr. H. B. Constable. A vote of thanks was accorded to Mr. Curtis for auditing the accounts. Mr. Constable announced that it was intended to hold a special lantern-slide competition, in which it was hoped all working members would take part. A Watkins' exposure meter would be given for the best set of four slides from negatives taken at any time, but which had never received an award in any competition.

Sheffield Photographic Society.—September 5, Mr. J. W. Charlesworth in the chair.—Messrs. Brooks and Loxley were elected as auditors, after which the photographic exchange was effected, and the prints of the last exchange criticised in the usual manner.

FORTHCOMING EXHIBITIONS.

1893.	
September 20–21.....	*Hove Camera Club. Hon. Secretary, H. Emery, 142, Church-road, Hove, Brighton.
,, 25–Nov. 15	*Photographic Society of Great Britain, 5A, Pall Mall East, S.W. Assistant Secretary, R. Child-Bayley, 50, Great Russell-street, W.C.
October 1–31	*Hamburg. Das Ausstellungs Committé des Amateur Photographen Verein, Schwanenwik, 33, Hamburg.
,, 2–14	Midland Camera Club, Botanical Gardens, Moseley, Birmingham. Hon. Secretary, C. J. Fowler, 4, Woodstock-road, Moseley, Birmingham.
,, 9–Nov. ...	*Photographic Salon, Dudley Gallery, Piccadilly, W. Hon. Secretary of Organizing Committee, A. Maskell, 215, Shaftesbury-avenue, W.C.
,, 17–19	*Hackney Photographic Society, Morley Hall. Hon. Secretary, W. Fenton Jones, 12, King Edward-road, Hackney, N.E.
,, 30, 31	*East London Photographic Society, New Tabernacle, Old-street, E.C. Hon. Secretary, W. R. Gould, 61, Gibraltar-walk, Bethnal Green, E.
November 7–11	*South London Photographic Society. Hon. Secretary, C. H. Oakden, 53, Melbourne-grove, Dulwich, S.E.
,, 20–25.....	*Leytonstone Camera Club. Hon. Secretary, A. E. Bailey, Rose Bank, South-west-road, Leytonstone.
December.....	*Madras. The Hon. Secretary Amateur Photographic Society, Madras.
,, 18–Jan. 22, 1893	*Bristol Triennial International Academy of Arts, Bristol. Hon. Secretary, F. Bligh Bond, 36, Corn-street, Bristol.

PROFESSIONAL *VERSUS* AMATEUR.

To the EDITOR.

SIR,—I have heen much interested in reading the correspondence between amateurs and professionals in the late numbers of your JOURNAL, as well as the great amount being written on the amateur and the professional in all classes of journals and newspapers. If the amateurs have so greatly injured the business of the professional as it is claimed they have, I shonld be a just target for the ire of this injured class in America, for it has been my aim for the last ten years to create as many amateurs as possible, and, in America at least, directly and indirectly, I must stand answerable to professionals for influencing several thousands at least of the innocent public to amuse themselves in this luring pastime, unaware that they were acting the part of the boy who was amused at seeing the stones which he threw in the pond create waves, until begged by an injured frog to desist from the amusement in the language of the adage, "for what is fun to you is death to us." And I feel satisfied from quite an extensive acquaintance with the public who have taken up with photography as a pastime, that, while the amateur amusement does not mean (financial) death to the professional, the stones have

hit hard in many cases. Amateurs, and manufacturers of and dealers in the apparatus and materials used by them, should not feel surprised to find the professionals resent this encroachment, and attempt to prohibit, if such was possible; but this cannot be done, and it is unfortunate that at least some of each side will indulge in writing letters that can only tend to do harm.

I felt much regret at seeing Mr. W. J. Stillman's letter of July 4, for, from what I have known of Mr. Stillman and his work, it does not do justice to his temperament and intelligence; and, as he practically accuses the professional of having done nothing worthy of mention either in Europe or America towards that which has "made outdoor photography a practical affair," I feel an answer should be made. I shall, however, only speak for America, yet I have confidence that much could be said for Europe with equal truth.

By making "outdoor photography a practical affair," I presume Mr. Stillman means adapting it to be used by the masses; for photography as practised by some of the best workers is not the result of the apparatus, plate, or paper-maker. Nor do I understand Mr. Stillman to mean the men who first conceived the idea of a sensitive plate without the silver bath. The knowledge of making a dry plate lay unused too many years to give to its discovers (if such gradual gathering of knowledge could be called a discovery) the credit of the dry plate of to-day.

I hardly think I would be accused of immodesty in America if I should lay claim to having contributed a fair share, for one individual, towards making "outdoor photography a practical affair," not only in cameras and apparatus, but in other branches as well, and I have the honour of having once been in the rank and file as a professional. I entered this "rank and file" not as an amateur, but in the studio, and my first experience was in preparing the plates for tintypes.

During my six years' service as a professional I managed to keep myself poor experimenting; in fact, the apparatus which the present Company bearing my name was organized to manufacture in 1880 was invented in the spare hours I found after using the "baby-charmer," or beseeching my adult sitter to "look naturally about here, and think of something pleasant." I make bold, Mr. Editor, to ask you to allow the use of sufficient of your valuable space to copy one of my early visions. I do so hesitatingly, for the quantity of what is termed in America as youthful "gush" in this article has always made a colour approaching the "non-actinic" to hover around my cheeks even when I read it to myself alone.

Photography—What is its Limit?

Did you ever stop, brother photographer, to think of the unspeakable joy and astonishment the present position of photography would cause Daguerre and his co-workers, were they, like Rip Van Winkle, to suddenly awake from their long sleep and behold, with wondering eyes, into what the results of their humble toil had so rapidly developed? Hardly can we mention any branch of industry, art, or science, in which this, their offspring, does not play a part, and, in some, a most useful and important one.

As an assistant to the artist, it is of unlimited value, giving him, if properly handled, a "bit" or landscape which would require hours to sketch. It is a silent detective to the counterfeiter's skilful hand, and leaves with us an undeniable copy of the face of the outlawed criminal, who, having once visited the precincts of the photographic official, cannot say, on his compulsory return, "I now receive my initiation to the walls of justice."

The great discoverers could now cross their legs, peruse the pages of at least a dozen different photographic journals, in almost every language on the globe, all ("well, mostly all") devoted to the advancement of our fascinating art. Surprised, most undoubtedly, would all be who witnessed the birth of this child, born of genius, and with the most promising traits of character, but, alas, under circumstances so unfavourable and enemies so plentiful.

So much worth was not to be crushed by its foes, nor destroyed by the unfertile surroundings; but, like the hardy acorn, it sent its vigorous shoot up, up, until it now stands like a noble tree, swaying its numerous branches, thrusting aside its tottering enemies, and demanding its rights and freedom. Not yet has it attained the ponderous dimensions of the full grown oak; but each year it sinks deeper its roots, adds and extends its branches, until every interested watcher is ready to exclaim, "Where, oh, where are thy boundaries?"

Again, my brother, did you ever pause to think of the marvellous changes which are destined to be wrought in a much shorter time than that which has elapsed since the death of our photographic forefathers? Ah, yes! how surprised, indeed, would we be upon waking, should any of us be so unfortunate as to make an acquaintance with that hunchback, partake of the mysterious draught, and, as did Rip, succumb to the unnatural sleep. Methinks, should the hale old sleeper inquire for "my hobby," the wet-plate picture, all would be wrapped in mystery, except, perhaps, some old veteran might make answer, "It has been dead these twenty years a most."

Dry plate would then run riot. The tourist, the artist, or the solace-seeking maiden would, instead of the *now* popular sketch-book and pencil, have the *then* popular camera and dry plate (or some more modern and convenient device), all, doubtless, of the *ever* "popular" American Optical Company's best. These, with the perfect, the simple, the rapid, the reliable plates, would form an important part of the personal property of all lovers of Dame Nature.

Readers, do I not hear you say, "What over-enthusiastic disciple is this? Should he live to be as old as Methuselah, he will never see his prophecies fulfilled." Why not, I pray thee? In reply, I can most seriously say that, even at the present day, no very difficult obstacles present themselves which would prevent all my predictions being carried out to the letter. Dry plates and emulsions can now be obtained which certainly are nearly all we could ask for. The greatest difficulty lies in getting practical photographers to carefully test what the manufacturers claim for them.

One year ago I was a most bitter and obstinate enemy to the dry plate in any form, fully believing it to be on a par with "perpetual motion," &c.; but, happily, one leisure day, I determined to give it another and a more thorough trial. Carefully I set about it, and so satisfactory were the results that I feel as though too much cannot be said in favour of the cause.

I believe there is an excellent chance for those who would make themselves familiar with dry-plate work, to do a good and legitimate business in developing and printing negatives for amateurs, if they would do it at a reasonable rate and strive to give the finest results. There are hundreds of ladies and gentlemen in every city in the United States who, upon starting for a week's ramble among the mountains or at the seashore, would be delighted at the idea of taking with them a camera and plates were there not so much experience and work required before the pictures are completed. Any one familiar with the development of a dry plate knows how much more it is under his control than the wet, and a list of exposures under different lights could easily be given, so that even the inexperienced could proceed with comparative surety of success.

But, says the landscape photographer, should all this come to pass, our business is gone, for then "every man would be his own photographer."

In my humble opinion such would not be the case. It would no more injure your trade, or lower your profession, than does the fact that almost every schoolboy or girl sketches and paints make "every man his own artist," or decreases the sales of the professional artist, but instead thereof it cultivates a taste and creates a desire for his works.

And yet has all this writing shown the limits of photography? No. And the answer to the question heading this article no man can give, at least not in the year 1880.

In conclusion, let me add an urgent request to all my finger-stained brethren of this dusky art, to give this "future" process an early and careful trial. Follow strictly in the smallest detail the directions, for often a very slight variation makes a marvellous difference in the results. T. H. Blair.

The above article was written in 1879 for the *Photographic Mosaics*, but received too late for publication, and was published in the *Philadelphia Photographer*, 1880.

When we consider how near this prophecy has been fulfilled in every way, and how much further the art has advanced than what was considered a very sanguine prediction, one does not feel that much risk of being called visionary is assumed by saying that Leon Vidal's able article on "Present and Future Possibilities of Photography," in the July 25th issue of your Journal, and read before the world's Congress at Chicago, puts the subject "mildly."

Enough of myself, except to acknowledge that professionals have given me valuable assistance many times in various branches of my work, and there are improvements which, by being brought out by a corporation bearing my name, are credited as the result of my brain exclusively, which emanated from suggestions made by professional friends, and I no doubt present a very ungrateful picture, engaged as I am in the business of creating amateurs whom some would stigmatise as the intentional enemies of these benefactors; but I feel sure they bear me no ill will, and I rely on the good sense of human nature generally to take the right view of my position. I could formulate a lengthy list of professionals in America who have contributed much to the present state of things in photography, and in mentioning those that I do it is possible that I may go beyond what Mr. Stillman intended to cover, as it is difficult to realise where the advantages of modern photography to the masses ceases.

Were not the greater part of the early dry-plate makers professionals? What was the occupation of John Carbutt or G. Cramer? D. W. C. Hoover, the manufacturer of glossy bromide paper since 1889, and the first to make it at least practically and commercially, was a professional and constant experimentalist; he also is the inventor and designer of the Hoover patent printing machine, which, by using the glossy bromide paper, will print from one negative 300 prints per hour, which can scarcely be detected from amongst albumen prints. But why name individuals, for I am sure to leave out many? I must not, however, pass the name of Mr. Frank Rowell, of Boston, large in stature and heart, and always ready to lend a hand or impart knowledge to any and every one if only to help on the art which he so much loved.

As far as my knowledge extends, and circumstances have made it necessary for me to make exhaustive research in this direction, Mr. Rowell, was the first to practically coat celluloid, and thus make a flexible celluloid film. This article, as cut sheet film, he has been selling since 1887. He was the first to introduce and work in America successfully the beautiful carbon process, for which a gold medal was granted to his firm at the Centennial Philadelphia, 1876, and many of the processes which are constantly being brought out at the present time as new discoveries are old to this indefatigable experimentalist, and his portfolio of samples and dates show the results.

He is, and has been for acores of years, a professional. Like many others of the real inventors and discoverers of the world's most useful appliances of the day, he did not possess the capital or the business ability to secure or use others' capital to put his discoveries before the world in the most energetic manner, and thus get the credit for their efforts; but the desire for improvement existed, and the hard work to discover it was done nevertheless, which is the question at issue at present. The willingness of these workers to fully impart to others the results of their efforts, tells whether they were interested for the sake of their art or science or not.

I trust I will not be misunderstood as having any small regard for the great benefit the amateur has rendered, or the long list of scientific men who have done so much for photography. Far from it—and I have them, and my amateur friends also, to thank for many suggestions and much assistance. Neither do I fear that my business interests will suffer on account of my arguments in favour of the professional. I rely on the desire of human nature generally to see fair play for my security in this direction.

Regarding the discussion, there is, as a matter of course, no way in a modern civilised nation to stop such a tendency as the public now have to photograph; but remedies for such abuses as exist will appear, and their appearance can be much hastened by the professionals themselves. It is only fair for the amateur—and I believe but few would object—to pay reasonably for any bother or expense either in time or money he may cause the professional; but the great army of amateurs know nothing about the grievances of the professionals, which exist, at least in print, and it is only rational to suppose it would have no influence on them if they did know.

Human nature remains about the same after it has become the possessor of a camera, and it will accept information free, and use free dark rooms when no charge is asked, the same as it (professional photographers included) would accept free advice or privileges in other amusements or pursuits.

My advice to professionals, if any care to accept it, is, make yourself as useful to the amateur as possible, and charge him as much for this service as conscience tells you is fair, or, I might say, as much as he will pay and feel content; but, above all things, be good-natured.

Injustices are doubtless practised by both sides in cases, but illogical letter-writing will not right the wrongs. If an injured class exists, the professionals are doubtless the class. The amateur should therefore be the more willing to bear with the outbursts of those who at least feel that their pockets are the emptier for the universal desire to photograph.
—I am, yours, &c., T. H. Blair.

September 9, 1893.

"PHOTOGRAPHICAL SOPHISTICATION."

To the Editor.

Sir,—I am permitted to send you the accompanying letter, received some time ago, and which I have no doubt will be read with great interest during the present controversy, in your columns, on "Photographic Sophistication."—I am, yours, &c., Henry Van der Weyde.

182, *Regent-street, W., September* 9, 1893.

"*Lauriston, Bromley, Kent, May* 8, 1893.

"Dear Mr. Van der Weyde,—I have to thank you for sending me a copy of the *Journal of the Society of Arts* containing a report of your lecture. I have read it with much interest. Your invention opens up afresh the often-debated question whether it is permissible to alter a photograph with a view to its improvement in a pictorial or artistic sense. The question has, at least, two aspects—one scientific, the other commercial. Regarded from the scientific standpoint, no one will deny that a photograph, as ordinarily taken, is true, or nearly so, in an optical sense, and that in very many instances it is vigorous optical truth that is wanted, and that gives a photograph its greatest value.

"But it seems to me that while, as a rule, it would be intolerable to tamper with the optical truth or approximate truth of a normal photograph, yet there are cases, and it is these you doubtless have in view, in which an alteration such as will bring the photographic representation more in accord with the mental impression of rightness is not merely permissible, but necessary, in order to satisfy the just requirements of pictorial art.

"The mental impression, as distinguished from the optical impression, is a compromise between the image imprinted on the retina and the ideal image imprinted on the memory and derived from knowledge of the actual form of the thing seen, and every familiar object is regarded under the influence of these dual impressions, which go to make, so to say, a composite image. Pictorial art recognises this complication, and makes due concession to the preconceived ideal.

"'Retouching' exists; it is a step in this direction. You ask that a further step should be taken. I cannot see why it may not, provided it be taken, as you distinctly say you intend it should be, with judgment, both as to the occasion and to the extent.

"From the other point of view much more may be said in favour of your proposals, because there can be no question that they provide means at once simple and effective for, in a large measure, satisfying the almost universal desire for a little harmless flattery in the matter of 'fine little hands, fine little feet.' I am, yours, &c.,

"J. W. Swan."

To the Editor.

Sir,—I am pleased to find that Mr. H. Dennis Taylor's communication in your last issue so much reduces the difference between us, and that, for the most part, we are agreed. Mr. Taylor's condemnation of photographic flattery is, indeed, couched in stronger terms than those I have employed. He calls the diminution of heads, waists, &c. (otherwise than as they may have been enlarged by perspective) a "most illegitimate use" of the apparatus. Mr. Van der Weyde, on the other hand, puts forth the proposition that sitters were right in complaining of waists, &c., coming out too large, and shows how he diminishes them in accordance with the sitters' ideal. If Mr. Taylor, in his first article, had made it clear that this was the kind of flattery by which the method might, as he said, "in some hands, be prostituted," I should not have thought it necessary to reply.

It is not, however, the sophistication itself that I object to so much, as to the proposition that the sitter who desires it is to be told that this sophistication is in accordance with truth—visual, optical, or truth of any other kind—if truth, indeed, itself, is capable of such variations. For verbal flattery of this sort I don't think Mr. Taylor's language at all too strong.

Mr. Taylor says that I assume that diminution of the head could not take place without lengthening the neck. I did not intend to assume anything more than that that was what was done in the examples shown. I am curious, nevertheless, to see how Mr. Taylor could practically overcome the objection in the way he says, by lowering the head, without introducing some other distortion.

With regard to the reduction of near portions by as much as they may have been enlarged by perspective, I have said that, in view of the circumstance that painters have accustomed the public eye to representations of this kind, there is something to be said in its favour; but how is the photographer to recognise the exact amount, and be supplied with sophisticators of various powers for every change of pose? The probability is that he would employ one powerful enough, and, perhaps, twice or three times as powerful, as would give hand and figure in the proportion actually existing at an equal distance. So that the hand was small enough, a little or a good deal of flattery in the direction of the conventional ideal would easily be accepted.

The actual amount of enlargement due to perspective is much less than is, I believe, popularly supposed. If a single figure is taken at a distance of over twenty feet, the enlargement of any part due to perspective is very slight; and, as for heads, I have photographed the same sitter at distances of four and a half feet, twelve feet, and eighteen feet, using lenses of such foci as to make the images all of one size, and when all three were projected by the lantern on to a screen the only one in a large audience who ventured to say which was the near pose chose the wrong one. It is quite possible that the convention among painters for disregarding the rules of perspective when rendering single figures—rules which they would not disregard in other subjects—may die out, and then, when the public has become accustomed to see the facts as they really present themselves, complaints of photographic perspective will cease.—I am, yours, &c., W. E. Debenham.

September 11, 1893.

PHOTO-MICROGRAPHY.

To the Editor.

Sir,—The fact that ordinary microscope objectives work to focus on yellow sensitive plates exposed through the yellow screen was not to me a "discovery" in the popular sense of the term. Having occasion to make some photo-micrographs, and knowing that my objectives were not corrected for photography, I concluded that, in order to use them to the best advantage, I must make the photographs with those light rays for which the objectives were corrected, and at once proceeded to do so by employing yellow-sensitive plates and yellow light. I feel that it would have been stupid of me to do otherwise, especially after having had twelve years' practical experience with colour-sensitive plates and selective colour screens.

I did afterwards *discover* that even the apochromatic objectives gave better results with yellow-sensitive plates and a colour screen than without, and proved this to be due in part to the fact that they are not corrected to give perfect definition with the ultra-violet rays, to which ordinary gelatine-bromide plates are still very sensitive.

It is not a question with me whether an objective is "apochromatic" or only "achromatic," but how good an image will it give to the eye? In low-power objectives I know that there are some achromatics that have a flatter field and greater resolving power than the Zeiss apochromatics of the same focal length, that, with moderate amplifications (say, ×30 with a one-inch objective), they define details so minute that it is only just possible to see them with the naked eye in the photographs, and that such objectives are, therefore, everything considered, *better* for high-class photo-micrography in low powers than any apochromatics

now on the market. In high powers, I have it on good authority, that an achromatic objective has been made that resolves amphipleura pellucida with ordinary white cloud and mirror illumination, which is certainly more than some of the apochromatic objectives of the same angular aperture will do; and it seems to me to follow that one achromatic objective may be *better* for high-class photo-micrography than another apochromatic objective, even in high powers, if properly used. I venture to think that even the "real authorities" may be able to see the force of this argument.

Mr. Pringle says I have overlooked a dozen statements made by him, besides disputing what he never asserted. If so, I have made a mistake of a kind which I do not know that I ever made before. Unfortunately, most of my references are locked up at my home some thousands of miles away. Perhaps Mr. Pringle did make such a statement in one of his contributions to the photographic or microscopical journals, if not in his book?

My photographs and negatives are also locked up in Philadelphia, but, if Mr. Pringle has access to back volumes of some of the American photographic and microscopical journals, he may find some references to them as follows:—*Photographic Times*, New York, April 25, 1890, page 206; the *Beacon*, Chicago, May, 1890, page 117; the *Microscopical Bulletin*, Philadelphia, April, 1890, page 11; the *Microscope*, New Jersey, August, 1890, page 251. Other notices appeared in Philadelphia newspapers and in other microscopical and photographic journals, and in subsequent issues of some of the same journals, but I have not got the references with me. It is, perhaps, significant that the definition and brilliancy of the photographs was such as to lead an old expert like Dr. Nicol to mistake them for aristotypes, although in reality only ordinary albumen silver prints. My subjects ranged from the proboscis, ×30, to various bacteria and the secondary structure of diatoms, ×1000. I have seen nothing better of any similar subjects, but did not attempt anything requiring a higher resolving power than 1 : 30 N. A. With such a power I obtained brilliant and crisp photographs of the "beads" on surirella gemma, and photographs of bacteria that were, and I believe are still, used to advertise the merits of the objectives. One of the latter was reproduced as a frontispiece in the *Microscopical Bulletin*, and three Philadelphia bacteriologists, who had already done something in high-power photo-micrography, soon after applied to me for practical instructions in this work. I also received many letters asking for advice, and it is really quite possible that my recommendation of Mr. Pringle's book may have increased its sale in America, although I suspect Mr. Pringle of sarcasm in his reference to the subject.

Nobody knows better than I do that a very few subjects may be found in which colour value plays such an important part that an apochromatic objective, other things being equal, would give a perceptibly better representation of the object than is possible in a photograph made with an achromatic objective, provided that the photograph with the achromatic was made by the joint action of all the visible spectrum rays, in proportion to their power to excite vision. Such subjects are so extremely rare in microscopical preparations that I do not remember ever to have seen one among the many examples of "high-class photo-micrography" that have come under my notice. I am not even sure that any of the "real authorities" have ever realised the conditions which I have specified in making the photographs.

I have no doubt that the most remarkable photo-micrographs of difficult subjects that have yet been made with apochromatic objectives can be equalled in quality with achromatic objectives of equal angular aperture, and I fear that, if Mr. Pringle is going to insist upon his distinction between "high-class" and "highest-class" photo-micrography, he may have to admit that none of the latter kind has yet been produced.

I am sorry that my letter has been taken as a "complaint." It was not so intended. I am not at all sure that my observation was properly recorded in the proceedings of the Philadelphia Photographic Society, and it is not a surprising fact that Mr. Pringle overlooked a note published in an American microscopical journal. I know of far more important original observations recorded in scientific and technical journals of considerable importance which have escaped fruitful notice for a much longer time.—I am, yours, &c., F. E. Ives.

116, *Charing Cross-road, W.C., London, September* 11, 1893.

To the Editor.

Sir,—I do not think, after all, there is very much difference of opinion between my friend Mr. Pringle and myself, that a light from the paraffin lamp without yellow screen is about equivalent to the limelight transmitted through a yellow screen. I took it for granted, however, that microscopists who could afford to work with limelight would also supply themselves with apochromatic lenses, as there can be no question, outside that of expense, on which side the advantage lies, and operators who have once accustomed themselves to the beauty of image produced by the apochromatics will never be content to work with anything less perfect except as a matter of experiment.

Of course we often read of ordinary achromatics being made better in every way than the apochromatics; but, as these wonders never take place at any distance nearer than America, we on this side are not able to compare results.

Mr. Pringle says: "My experiments showed that the worst result was got with white light and an ordinary plate. A colour-correct plate greatly improved matters, while a colour-correct plate and yellow light gave the best results of all." Now, what I want to know is (not at present having the appliances to perform the experiment myself), does the inferior result produced by limelight without screen and colour-correct plates refer to the quality of the photographic image or to the focus only? for, as I understand it, the question does not so much turn on the former as on the latter. My own experience when working with achromatic lenses and ordinary plates has been that the image formed by the violet end of the spectrum is just as sharp—if you can only catch it—as the visual, and the question I ask is this: When working with white light and colour-correct plates, is the image formed on the visual plane, on the actinic plane, on an intermediate plane, or is it only a wishy-washy image formed on the visual plane? An answer to this by Mr. Pringle (for which I am sure we shall all feel indebted) will greatly narrow the grounds of dispute.

Lest I should be considered captious in taking certain objections to the experiments made by Dr. Pifford, I would say it was not so much to the use of the yellow screen I took exception as to the assertion that the results were even then unsatisfactory, and that certain further corrections of the lenses were necessary to produce the desired result. Having myself worked out the matter somewhat exhaustively by experimenting with lenses of all sorts of corrections, my experience was entirely different, and I see no reason yet for altering my opinion. The conclusion I have come to is that any lens, no matter what the correction, will produce as good an image on colour-correct plates photographically as it can produce visually. I do not deny that a certain yellowness of the light may be necessary; but that does not vitiate my argument.—I am, yours, &c., T. F. Smith.

185, *Brecknock-road.*

RETOUCHERS' TROUBLES.

To the Editor.

Sir,—The primary cause of this particular trouble *may* lie in the use of pyro-*sulphite* developer; any radical change in the developing agent may, however, considerably alter the general character of the negatives; therefore I would suggest after development, which should be full and carried, if anything, to excess, a bath of—

Potassium ferridcyanide	10 to 20 grains.
Hypo	1 ounce.
Water	20 ounces.

The first-named being usually kept in saturated solution and added to the hypo bath. The above acts, of course, as a reducer and *cleanser*, and leaves the film in as perfect a state as can be desired, ample washing, carefully going over the film with wet wool, should follow the application of the above, and, when dry, the negative *should not* be faulty in the respect your correspondent complains of; but, if still obstinate, I would, before drying the negatives, immerse for five minutes in a weak bath of glycerine and water, say, one to fifty.—I am, yours, &c. J. Pike.

September 9, 1893.

Exchange Column.

*** *No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance. The full name of the advertiser must in all cases be given for publication, otherwise the Exchanges will not be inserted.*

Will exchange a stereoscopic camera and pair of lenses and three slides for decent half-plate camera and slides without lens.—Address, Charles Harris, 3, Pentyre-terrace, Plymouth.

Will exchange 8 <5 rapid rectilinear lens by Taylor & Hobson, and quarter-plate portrait lens by Lerebour & Secretan, for enlarging apparatus to 12×10. Address, J. H. Newman, 41, Truro-road, Wood Green, N.

Will exchange Watson & Sons' ten-guinea biunial lantern and blow-through jets (only used eight times) for good detective or hand camera carrying twelve plates, or half-plate camera and outfit (double extension bellows).—Address, Alfred H. Saunders Mount Pleasant, Brierley Hill.

The following are the classes at the Hackney Photographic Society's Exhibition next month:—Members' work: Class A, for any picture not previously exhibited for competition; Class B, for best picture taken in hand-camera (enlargement permitted); Class C, for any picture taken at a club outing since the last Exhibition; Class D, for set of six slides (not previously exhibited), still life excluded. In Classes A, B, and C, a Gold Championship Medal will be given for the best picture, by the *President*, Mr. F. Houghton. Open classes—entries in these classes may be priced for sale at the option of the exhibitor: Class E, for any picture not previously having received an award; Class F, for portraiture and genre (professional class—no restriction); Class G, for pictures which have previously received awards; Class H, for six lantern slides not having previously received award.

Answers to Correspondents.

*** *All matters intended for the text portion of this* JOURNAL, *including queries and Exchanges, must be addressed to* "THE EDITOR, THE BRITISH JOURNAL OF PHOTOGRAPHY," 2, *York-street, Covent Garden, London. Inattention to this ensures delay.*

*** *Correspondents are informed that we cannot undertake to answer communications through the post.*

*** *Communications relating to Advertisements and general business affairs should be addressed to Messrs.* HENRY GREENWOOD & CO., 2 *York-street, Covent Garden, London.*

*** *It would be convenient if friends desiring advice respecting apparatus, failures in practice, or other information, would call at the Editorial Office either on Wednesdays from* 4 *to* 6, *or Thursdays from* 9 *to* 12 *noon, when some one of the Editorial staff will be present.*

PHOTOGRAPHS REGISTERED:

John Horsburgh & Son, Edinburgh.—*Photograph of Right Hon. Sir Stuart Knill.*

Henry John Cherrington, Swinton.—*Two photographs of the Fitzwilliam Family.*

ASK.—Make the silver bath stronger.

G. J. P.—We do not know of such an ink.

SPOTTY, Wasp, Operator, and others. In our next.

A. A. CARNELL.—We do not think the pictures are of any commercial value.

H. H. CROUCHER.—We will try the lens towards the close of the present week

DENSE.—Bleach the negative with bichloride of copper, and dissolve off with hyposulphite.

A. LASCELLES (Napier).—Thanks for the cutting; we shall be pleased to see the photographs.

FRANCIS.—It is possible that oxgall on the surface of the prints may have the effect yon name.

PENCILLER.—Your communication is in the nature of an advertisement, and therefore cannot be published in the text columns.

J. REYNOLDS.—We believe that Messrs. Negretti & Zambra, Holborn-viaduct, can supply you with silvered plates for Daguerreotype.

SUBSCRIBER.—Burton's book, published by Messrs. Marion & Co., Soho-square, may meet your wishes, but you do not specify the process.

G. COWELL.—Bromide enlargements turning yellow at the end of a few months is not the fault of the process but of the one who did the work.

PYRO says: "Can you give me the address of the English agency for the Edison Phonograph?"—Write to Colonel Gouraud, Menlo Park, Norwood, S.E.

H. H. B.—You seem to have proceeded quite accurately; but we cannot suggest any better means for ascertaining the precise adjustment as regards the chemical and visual foci than by making a few trials.

W. SIMS.—Unless the ancient print can be got quite flat—say by pressure between glass plates—there is no way of preventing the creases showing in the reproduction. Can you not have it mounted on cardboard, or strained on linen?

LENS.—Suppose the lens be nine inches equivalent focus, to copy the same size with it the camera must extend eighteen inches. It matters not whether the original be *carte*, cabinet, or any other size, the conditions are the same.

J. TILFOR says:—"Can you inform me where I can obtain a suitable gas stove for warming a dark room? Hitherto I have not required one, but shall be shortly moving into a house where I think one will be wanted."—Perhaps some of our professional readers can supply the desired information.

C. R. B.—The Continental firm named, we know, will supply their apparatus without their name upon it; but, if you were afterwards to put your name on it, and sell it as purporting to be of your own manufacture, you would infringe the Trade Marks Act, and consequently become liable to a penalty. However, the thing is done daily.

AGENT.—We do not know the "longest discount" the two houses referred to allow to the trade. If, as you say, you are a shipping agent, why not write to the firms direct, as in the ordinary course of business? Writing to us as you do rather inclines us to doubt your *bona fides* as a shipping agent or being connected with the trade at all.

D. MCANDREW.—In protecting the proposed studio from lightning, the conductor should not be connected with the gas or water pipes, but taken direct to the earth, into which it should enter three or four feet. Connect it with the building as described in the second proposition. The thick electric-light cable will answer very well for the conductor.

J. K. TULLOCH.—Our opinion is that the object-glass of a cheap French achromatic telescope of twelve inches focus will serve your special purpose. Such can be purchased unmounted for about half-a-crown. Being small in diameter, it will scarcely require a diaphragm to cover such a size as that mentioned, although such may be employed with advantage.

GRAVER.—What is known as the steel facing of copper plates is iron deposited on the plate in a very hard form. It is not, as you seem to imagine, a separate steel plate. When renewal of the steel is spoken of, it simply means dissolving off the iron coating when it has become worn through with dilute sulphuric acid, and then depositing a fresh one, as in the first instance.

W. T.—As the canvasser only worked on commission, we do not think you can proceed criminally against him for the defalcations; he can be sued in the County Court. Had he been a paid servant, or paid by commission and salary, the case would have been different. As, however, there is an attested and stamped agreement, a solicitor had better be consulted before any action is taken.

B. JOSLIN complains that some plates he recently bought in a country town, while away on his holiday, all show a blue metallic-like appearance round the edges after development. He says that he has used the same brand of plates for some months now and has not seen the like before? The plates were old—evidently been in stock for a long time. The appearance is very common with plates that have been made for a long time. However, some plates keep much better than others.

CLARENCE asks where he can obtain a copy of the "new Copyright Act," which was recently passed?—No new Copyright Bill has been recently passed, or, indeed, has one been promoted. Several different Bills on the subject have been introduced during the past few years, but they have all suffered in the slaughter of the innocents at the end of the session. Unfortunately there is very little prospect of copyright law receiving attention in Parliament for a long time to come.

SNAP-SHOT.—Although you may be working the camera, shutter, and lens under precisely the same conditions, so far as they are concerned, and with the same brand of plates, there is yet one factor that has not been taken into account, namely, the light. It should be borne in mind that the light at Brighton a month ago is very different from what it is in London at the present time. The difference is quite sufficient to fully account for the under-exposure, even if all the other conditions are identical.

S. J. writes: "I have a Doulton's stoneware sink, but am continually breaking measures, dishes, and plates with it. Is there any other material that I can use instead of these sinks, as I am going to fit up a new dark room?"—Sinks lined with lead answer very well; so do wooden ones, provided there is always some water kept in them. A wooden frame at the bottom of the stoneware sink will prevent a great deal of breakage. A piece of "expanding" lattice work, which may be purchased at most timber yards, answers the purpose well, and it is very inexpensive.

E. J. DAVISON.—We do not attribute any fault to the mounts themselves, but it is well known that all bronze printing on mounts produces such tiny spots as we observe in one of them, and, if in mounting the bronze card were laid on the top of the others, it would convey the same defect. What mountant is used? This may be the source of the trouble as regards the yellowness in certain parts. The lubricant also may have acted on the cracked parts. We confess to not being able to give any definite information that can help you to any great extent. We have shown the prints to several persons of experience, and fail to glean anything definite.

RAPHAEL.—From the sketch the studio appears to be very ill constructed for photographic purposes, except, perhaps, for copying. But this may be due to the space at command at the time it was built. All the light appears to come from the front as it is now arranged, and what has to be done is to convert the front light into a side one. This can easily be done by altering the position of the background, and working across the room instead of lengthwise. Although by this modification the length will be curtailed, twenty-five feet will be long enough for general purposes. With this single alteration, a studio, except for length, will be obtained that will be admirable for portraiture.

THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC, 1894.

EDITED BY J. TRAILL TAYLOR.

We have commenced the preparation of the ALMANAC *for* 1894, *and shall be happy to include amongst its contributors all those valued friends who, in former years, have made it the vehicle of their experiences in the progress of practical photography. We shall also be pleased to receive contributions from more recent recruits to the art.*

We should be glad if intending contributors would favour us with their articles as soon as possible, in order that any possibility of their having to be excluded on account of late arrival may be averted.

CONTENTS.

THE BRITISH
JOURNAL OF PHOTOGRAPHY.

No. 1742. Vol. XL.—SEPTEMBER 22, 1893.

FINDERS AND COGNATE SUBJECTS.

We have heard complaints of some of the cheaper classes of hand cameras that the finders attached to them are only so in name, that they do not afford an adequate idea of the amount of subject that is actually impressed upon the sensitive plate; and, what is worse, that the centre of the one does not coincide with that of the other. Photographs have been seen by us in which all their bad qualities have been attributed to the finder.

The most pronounced of these defects has been the convergence of the perpendiculars, owing to the camera having been pointed upwards in order to get in the desired amount of subject. The finder does not always afford an opportunity of detecting this imperfect levelling of the camera. It is of minor consequence that the camera is not held level as from side to side, as the imperfection arising therefrom is remedied in trimming the print at the expense of a slight diminution of its size when cutting it square; but no trimming can rectify the effect of longitudinal mal-levelling when buildings are included in the view. In this case the operator should not trust to his finder, but rather to his own ability to hold the camera level, or, better still, to a small spirit level which may be placed alongside of the finder.

We have seen many photographs of otherwise real excellence obtained by hand cameras, their beauty being marred only by the defect spoken of, viz., convergence of their perpendiculars, and to those who uttered lamentations over this we have invariably recommended the adoption of the remedy we pointed out, with some fulness, in a chapter in our Almanac for 1890, which treats on the curing of distortion already existing in negatives, and which no one has ever known to fail. At the risk of repeating what many already know, but which, unfortunately, many seem *not* to know, we repeat in a few words the directions given, which are to make a transparency from the offending negative by superposition in a printing frame, and, having erected it in front of a plate of opal glass, make a copy of it by means of a camera having a swing back, and in doing so focus as sharply as possible with the largest aperture of the lens, and swing back the ground glass until the convergence of the building is seen to be neutralised, and the vertical lines rendered parallel. Now insert the smallest stop, so as to ensure top and bottom being equally sharp, and expose. The negative which results from this treatment will be rectilinear, and in every respect perfect, so far as drawing is concerned.

We have long thought that there is very much room for improvement in the lenses of finders. The great majority of these is formed of a double convex lens of short focus, with a stop or diaphragm outside. Now, if this lens is used without a stop, in order to secure the maximum of illumination on the small ground-glass pane usually left exposed to light from above and around, the image is exceedingly hazy owing to the imperfection of construction and use of the lens; while, if it be stopped so as to obtain a greater degree of sharpness, a shade of one kind or other must be erected around the screen to shield it from the light.

With a view to ascertain the best form of lenses for finders, we got a plano-convex of short focus (one of a class employed in the eyepieces of telescopes and microscopes), and tried it, convex side out, without any diaphragm. The image given was very bright in the centre, but fell off rapidly towards the margin. This, we may state, is not a *very* bad fault, for, if the centre be sharp and luminous, the object of a finder in a non-focussing hand camera has been attained. Still, and aiming at a greater degree of perfection, it was desirable that equal sharpness as that in the centre should extend to the sides; so we had the system entirely reconstructed, by adapting a powerful plano-convex front, convex side out, as before, with a double convex, having an immense excess of negative aberration mounted a little behind. This flattened the field, and gave an image on the finder screen which we have never seen even approached for luminousness. In optical parlance, it gives an intensity little over *f*-1. The whole combination may, from this description, be designated a Petzval; but the principle is carried to an extent far beyond what this philosopher aimed at, for here a visible image only is aimed at, and further, although from the large aperture there is a residuum of aberration, yet is such not appreciated, on account of the smallness of the image and the fact of its being viewed by the unaided eye, and not through a magnifier. Further, there need be no nicety aimed at in securing perfect achromatism, although, by the way, the front of ours happens to be an achromatic, because the coincidence of the visual with the actinic foci is not of the slightest consequence in this case, and even slight fringes of colour do not interfere materially in the image shown by a finder. The question of cost of construction need not, therefore, be an interfering element in the substitution of a finder possessing immeasurable advantages over that now so generally employed.

We are not, in these remarks, losing sight of the still superior advantages of hand cameras of a double nature in which two lenses identical in every respect are employed, one for focussing and the other for photographing with, now being supplied by several firms; or those of an ingenious American inventor shown at the Derby Convention, in which the ground glass was on the top, *à la* Sutton, the sensitive plate at the back, and the lens and diagonal mirror so adapted to each other, as by pressing a button at the supreme moment

to ensure the light being instantly deflected from the focussing screen above to the sensitive plate at the back, a form of focussing finder camera we now very seldom see, but to the resuscitation of which it might be worth while to devote attention.

CAMERA STUDIES.

It will be interesting, in view of the immediate approach of the annual Exhibition of the Photographic Society, to watch what effect has been produced upon the character and quality of camera productions by an exceptionally favourable season for outdoor work. Never within recollection, we should think, has there been such an almost uninterrupted spell of "photographic weather," reaching from the late winter right through the spring and summer, and still promising to extend well into the autumn.

It goes without saying that there will be, at any rate, an abundance of "snap-shot" or hand-camera pictures of small size, for these form the majority of the total work executed; but there will also be a higher class of the same kind of work of larger size—studies, in fact, in contradistinction to mere landscape—that promises to be the fashionable style of the near future.

This is not to be wondered at when we consider the peculiar advantages that modern dry plates offer for this class of work in the first place, and also, except in a few favoured districts, the scarcity of really good landscape subjects. It is not every amateur who can afford either the time or the money, except for a few brief days in the summer, to travel far afield in the practice of his hobby, and the majority of such, pent up in our large centres, have to look entirely to occasional half-day excursions, or shorter rambles nearer home, for their pictorial studies. Under such circumstances, it is not to be expected that scenery of the grandly picturesque type falls to the lot of the average amateur, though in some favoured localities it may be so, while in others there is no lack within reasonable distance of subjects of a milder type of beauty, which to many perhaps yield equal or even greater pleasure. In this respect, perhaps, London, much as it is decried by some, stands unsurpassed by any other town or city in the extent or variety of the work to be found within easy reach; but the case is very different with some of the great northern and midland centres.

Objects of antiquarian and archæological interest are plentiful everywhere, and suffice to engage the attention of one class of workers, but to the majority they are as "*caviare* to the general." Such subjects are seldom beautiful, and consequently fail to satisfy any but those who make a special study of the subjects. Architecture, on the other hand, may be both interesting and beautiful, and forms a favourite branch of work with almost every class of photographer, amateur or professional; but it is only a branch, and scarcely suffices to form the staple. We have known individuals who have laid themselves out to make collections of the cathedrals, abbeys, castles, or ancestral halls of England, and suchlike; but these are almost invariably found to be individuals who make a special study of architecture, archæology, or take an historical interest in the class of subjects depicted. We are acquainted with another amateur who, *faut de mieux*, devoted his spare time to photographing the churches and chapels in his town, independent of any beauty or interest they might possess, simply that he might have them complete. We can only consider him, as the Americans would say, a "crank" in search of an object in life.

The picturesque in either landscape or architecture is, in fact, very thinly and unevenly scattered about the country, but the class of subjects which we have termed camera studies may be found almost anywhere in our streets, at our very doors, on the river, in the country lanes and fields, anywhere, in fact, where life, human or animal, exists coincidently with the camera and the capacity for using it. But it is upon the capacity for properly using the camera that everything hinges. The idea that all that is required to make a picture is to point the camera at a life scene, and "press the button," has been responsible for the production of an inestimable amount of rubbish in the past few years. Too many of the users, or "abusers," of the hand camera labour under the impression that what is "true to nature" must be right—that, in fact, *realism* constitutes *art*. Rather should they endeavour to convince themselves that the real *ars celare artem* consists in softening down that realism, and depriving it of the excessive truth that renders it vulgar or even repulsive. To illustrate what we mean, let us try and imagine what would be the effect produced if such a picture, say, as Luke Fildes' *The Casuals* had been rendered from nature by means of photography.

This is merely one view of the question, but we may refer to another, namely, the utter disregard in so many instances of the capabilities and requirements of photography, both optically and chemically; or, to put it in another way, the ignorance displayed by the users of the tools they are handling. Thus we have seen an amateur snap-shottist calmly "potting away" in a crowded railway station, where the only light came through the smoke-begrimed glass roof, and where several seconds' exposure with the quickest lens and plate would at least have been necessary. Then, again, how often do we see such curiosities in a group as, perhaps, a toddling infant in the foreground appearing a giant in comparison with a full-grown man a few feet further away. But such things are too common to need pointing out to those who are willing to guard against them.

But, after all, it is not only the "artist" that is to blame for the lack of proper subject. We fear, in a great many cases, the subjects themselves have greatly changed for the worse, and, in fact, do not present themselves to the true artist in the manner he would like to render them. How seldom, in fact, do we see any really satisfactory renderings of rural scenes, such as hay-making, harvesting, gleaning, and a hundred others. As a matter of fact, the introduction of machinery has practically done away with such scenes as we are wont to see them depicted, and, in place of the half-dozen mowers in picturesque *déshabillé*, and the bevy of country lasses in broad straw hats or sun bonnets, and many-coloured gowns and kerchiefs, tossing the hay, one man, with horse and machine, does pretty well all the work. The same may be said of harvest operations generally, and it is only when the gleaners have taken possession of the field that much chance arises for pictorial rendering. But here even the Arcadian simplicity of dress and manners that we naturally associate with gleaning seems to have almost disappeared, for the majority of the women and girls engaged are got up in the fashions of Paris of three or four seasons back, while, instead of listening to the pipes of some shepherd swain, they fill the air with their invocations to "Daisy"—a nice enough name if properly pronounced—to give her answer at once.

Things are fortunately not so bad all the country over, but

it is only too true that within range of the larger agricultural towns rusticity is rapidly disappearing, and the fashions and manners of the East End and St. Giles taking its place. Therefore, when we come across any camera renderings of such subjects as we have suggested, let us give them all the credit that is their due as artistic productions.

VARNISHING AND RETOUCHING.

The interest taken, by courteous correspondents, in the query of a brother photographer in retouching difficulties, leads us to suppose that some further hints on the points at issue will not be deemed superfluous. The particular difficulty first mentioned — inability to get the pencil to bite upon a film treated in the usual manner with medium—does not appear to be solved yet; but, from the data given, the most probable solution would be that some accident had happened to the retouching medium, or that it had been tampered with.

The first point that attracts attention in the correspondence is the perpetuation of the common error as to the function of a "medium" applied to a varnished, in speaking of it as "abrading" the surface. The action of abrasion does not come into play with the usual mode of applying medium, but the term is justly applied when powdered pumice-stone and chalk is used, and partially so when powdered resin is employed. There is a growing tendency to use medium as against abrading substances, and perhaps equally good results may be obtained with either method. But there is one disadvantage of the medium plan that seems to be quite ignored in any retouching discussion, and that is, the great liability it has to cause the collection of dust and dirt, not only upon the retouched surface, but upon the space covered with medium outside the worked-upon surface. When a negative is in constant use for printing, it may not be noticed for a while, but if it be left in the frame for a few days—often if only for a single day—it has a tendency to collect particles of fluff or dust from frame or pad that, eventually, seriously interferes with the delicacy of the work. With abraded surfaces, this tendency to collect, by adhesion, does not exist, and the negatives are the better in consequence after long usage. The tendency of the method of the roughened surface to gather fine particles does not appear to be nearly so great.

All these difficulties are, however, completely avoided by varnishing the negative after being worked upon, and all that are held in estimation should be so varnished. When this is done upon retouching, executed upon the medium-treated film, little difficulty arises. When the work has been done upon the varnish itself, treated of course by medium or abrader, very considerable difficulty will be experienced. Unless great care be exercised the operator will be astonished on looking at his negative after varnishing to find a bare negative without a trace of retouching, the second varnishing has softened the first, the surface of which, with the work upon it, has been floated away by the hot liquid. To avoid this trouble several points have to be considered. The varnish when applied the second time must on no account be too hot or too thick; and it is necessary to choose a suitable one, as there is considerable difference in the resisting powers of varnish surfaces in this respect. It does not seem to make much difference to the dissolving power of the second coating whether the first be a day or a month old; and what forms the most troublous feature in the case is the fact that a dozen retouched negatives may be revarnished without the slightest sign of mishap, while the very next may be hopelessly lost so far as the retouching is concerned.

As regards the surfaces of the unvarnished negatives, they vary considerably according to the make of plate; some give a surface almost like glass, others a beautifully matt surface, well described by one correspondent a rose-leaf surface. The latter will take delicate retouching without any preparation, while the pencil will glide from the former as though greasy.

A negative which has been passed through a reducing solution likewise exhibits a glossy surface, while one that has been intensified with mercury presents just the opposite effect—perfectly matt, and capable of receiving and retaining heavy pencil strokes.

We will conclude our remarks by referring to another point which we do not remember having ever seen referred to. The power of the pencil to bite or grip is not governed wholly by the medium made use of, it depends to a considerable extent upon the surface to which it is applied. For example, a case was brought before our notice which ran parallel to that of our correspondent, except that the difficulty was experienced upon a film varnished before retouching. Good work could not be done, though the same pencil and the same medium were made use of by the same hand. Nothing appeared to enable the retoucher to get enough of lead on his surface, though many different "mediums" were tried, and the pencils were also varied. Ultimately it was discovered that the varnish in use had been thinned down with spirits far too severely, the coating it gave being very slight. There was, consequently, no bed, as it were, for the pencil to grip into, and it would slide along instead of parting with sufficient of its surface to make a defined mark. The varnish was changed, and all went right at once. It is just possible that this may explain the difficulty that first led to the correspondence, though the letter inferentially leads to the supposition that the film, and not the varnish, formed the medium substratum.

Preparing Plaques for Enamels.—At the meeting of the London and Provincial Photographic Association on September 28, Mr. A. Haddon will demonstate the preparation of plaques for vitro-enamel work. We understand that the process is both a simple and an inexpensive one. As visitors to the Association will be welcome, we trust a goodly attendance will result, as the subject, which will, no doubt, be treated in Mr. Haddon's usual lucid style, is one that should be instrumental in reviving interest in enamel work.

The Photographic Society's Exhibition.—We understand that, for the Exhibition of the Photographic Society of Great Britain, which opens on Monday next, more pictures have been sent in than was the case last year. Moreover, the roll of exhibitors will be found to contain the names of all the prominent photographers then represented. In view of the strenuous opposition since organized, this is a very gratifying circumstance. The Exhibition will be preceded by the customary *conversazione* at the Gallery, Pall Mall, on Saturday evening next, when the President will receive the Society's guests. The Exhibition will remain open a week longer than last year.

Studio Roofs.—The roofs of most studios have had an unusually trying time of it during the past exceptionally hot summer. If examined now, it will be found in many cases that the putty has cracked

badly or otherwise left the glass, and, as a consequence, the autumnal rains may, and often will, cause inconvenience and damage within. Therefore now, while the roof is still dry, is the best time to have it seen to and repainted. But is ordinary lead paint the best for the purpose? We ask this question, as we were recently told by an old hand that the outside of his studio had not a coat of paint for years, and was still perfectly watertight. At the close of each summer he had the sash bars carefully "painted" with ordinary gas tar, to which a little tallow had been added, remarking that with paint the heat frequently caused it to blister, and also the putty to crack. With tar, however, he told us the case was different, the heat caused the tar to soften, and, if excessive, to run slightly, and thus fill up any cracks, if any occurred, in the putty, and also bond it tightly to the glass. There is a certain degree of novelty in this system of treating the outside of photographic studios which may prove useful with those—and they are not a few—with leaky roofs in a chronic form.

Enamelled Ironware in Photography.—With the exception, perhaps, of dishes for the developing solution of platinotypes, and occasionally for washing prints, this ware seems to be but little employed by or known to photographers. But many articles are made in it which will answer their purpose better than any other, because, while totally unaffected by the majority of the substances employed in the art, they will stand almost any amount of heat. Funnels, jugs, mugs, and ladles, to say nothing of the handy little saucepans to be seen everywhere, will all find a handy use in the photographic laboratory. Most are aware of the result usually met with in dealing with glass funnels and measures with hot solutions, but with enamelled ware any of the vessels can, of course, be put direct on the gas or other stove whenever necessary, a very great convenience in making solutions where heat is necessary. We were recently shown some enamelled iron spouted-measures of a variety of sizes, graduated in black figures on the inside, and we do not remember having seen anything like them in any of the photographic warehouses. As they were all graduated according to the metric system, we assume they were of foreign manufacture. These measures should be specially useful in compounding percentage solutions. It is quite possible that they may also be had according to the English system. The subject may be worth the attention of some of our enterprising dealers.

A Secession Exhibition.—There are open just now in Munich two fine-art Exhibitions. For several years past the Artists' Society there (we are not quite sure of its exact title) have held an annual Exhibition, and the reason that a second one is being held this year is very similar to that which has brought about two photographic exhibitions in the metropolis at the same time. For some time past, it appears, there has been a certain amount of friction between what may be termed the old school of artists and the new school, the impressionists, and that culminated last year in the latter seceding from the general body of the Society, and forming themselves into a new one. They are now possessed of a fine permanent building, and have their first Exhibition open under the title of the Secession Exhibition. We are informed that the Original Society's Exhibition at the Glass Palace numbers between two and three thousand works, and the new one, though not numbering anything like that, yet makes a very good show, so far as numbers are concerned; but the attendance is limited, and the remarks by many of the visitors on some of the pictures is anything but complimentary. Evidently, although Munich may be considered a hotbed of art, a large proportion of its inhabitants are not yet educated up to the "impressionist" school, for we are told but very few of the works are sold, while at the other Exhibition a very large proportion of them are. It is also said that the impressionist style of painting has been there extolled by the newspapers, precisely as has been impressionist photography in England.

The Influence of Light on Silver Prints. — There seems to be a very common opinion with the lay public that the more photographs are exposed to the light the more rapidly they will fade. The same opinion is also shared by some photographers. Only a few days ago we were in the company of several photographers, when the fugitiveness of photographs was under consideration. One said he had had some ordinary silver prints that had been in a shop window fully exposed to the light for over two years, and they showed no signs of fading as yet. Another remarked that his showcase contained some prints that had been in it for a very similar period, and, although exposed to a direct south aspect, they too showed no signs of deterioration. Now, does light *per se* conduce to the fading of the silver image. It is tolerably well known that, when some silver prints are exposed for a lengthened period to a strong light, they become changed, turning much darker, not only in the shadows but in the lights as well. Such prints are frequently to be seen at railway stations where they have been long exposed. But the action of light in this case is not a fading one, but a general darkening one all over the paper, so that the image, instead of becoming weaker, is actually strengthened. Exposure of silver prints to the ordinary condition of a showcase is a trying ordeal, but is it not climatic influence that works the mischief and not the light? Moisture and heat combined have a most destructive action on the silver image conditions always found in the usual showcase. The subject is an interesting one.

A Photographic Spy Scare.—Reference was made in a recent issue to the spy scare, in which photography figures conspicuously, on the Continent. There appears to be also, if we are correctly informed, a photographic spy scare here in England on our seacoast, particularly at fashionable watering-places. The terror is the hand camera, or, at least, as such it is looked upon by many ladies, who cannot feel at their ease either when taking their morning bathe, or in returning from the machine, or, indeed, in several other enjoyable pastimes, for fear of being, as they often are, waylaid by the hand-camera man, or, as we heard him characterised, "cad." Of course, every one is now quite familiar with the hand camera, and it is exceedingly unpleasant, under any circumstances, for ladies to be aware that they have been "snap-shotted," and know not to what purpose the picture may be hereafter applied. Especially is this the case when their portraits are obtained under such conditions as those referred to. Only a few days ago we were told by three young ladies that, while they were sitting, and being in a *négligé* way, reading an amusing book in a secluded spot on the sea-coast, with no idea that any one else was in the neighbourhood, they were startled by a couple of sharp clicks, and, "on looking up, saw two fellows with hand cameras, who then went away laughing." The ladies were naturally very annoyed, and were in a state of some anxiety as to what purpose the photographs would be put. This sort of behaviour will certainly tend to bring photography into disrepute, and amateurs to be considered a disreputable class. However, if ladies knew much of this class of work by these individuals, they would take comfort from the fact that all but a very small percentage of the plates exposed are abject failures.

VARIATIONS IN THE METOL DEVELOPER.

I NOTICED a remark a week or two back in the JOURNAL to the effect that many of those who have adopted metol are tiring of the "pretty" negatives obtained by its means, and are beginning to yearn for the printing quality formerly associated with the slightly yellow colour of a pyro-developed film. While I can fully sympathise with such a feeling where it exists, and I have at times had a touch of it myself during the past few months, I must urge in fairness that I scarcely think that metol is itself to blame.

It is a good many years since the fallacy of "pretty" negatives, as distinguished from good printers, was pointed out; but it must be borne in mind that the former are not necessarily bad or unsatisfactory printers, though too frequently, especially in the early days of the pyro-sulphite developer, they have proved to be so. A negative may possess clearness of shadow and delicacy of gradation together with freedom from stain, and these qualities may certainly establish for it a claim to the title of pretty; but, in the absence of the necessary vigour, it will never make a good print. On the other hand, vigour, accompanied

by correct gradation, softness, absence of colour, and just the faintest signs of really clear glass in the deepest shadows, combine to constitute a perfect printing negative, and such a one will, at the same time, be beautiful to look upon to a far greater degree than the other. In fact, there is prettiness *and* prettiness.

A considerable outcry was raised against the use of sulphite on its first introduction, on the ground that, by preventing or removing the yellow tint of the image, the latter was robbed of its printing qualities. That many of the earlier negatives produced with the aid of sulphite, and also many of those obtained at the present day with metol, and others of the new developers, were, and are, inferior in printing value to many of those developed with pyro cannot, perhaps, be denied; but that that result is due to the mere absence of yellow or other stain is an absurd contention. If such were true, it would only be necessary to stain the over-clear or pretty image, or to print it through tinted glass or other medium in order to give it the printing strength it lacked. That such is not the case any practical printer is aware, for though, under some circumstances, such treatment may *slightly* improve the print, the difference is so very slight that many experienced workers deny its existence at all.

As a practical test, I would ask any one who pins his faith to the coloured pyro image to take such a negative, of good printing quality, and to remove from a portion of it, by means of an acid clearing solution, the stain to which it is supposed to owe its quality; or, better, perhaps, to cut the negative into halves, and treat one with the clearing solution. If the two portions are then printed so as to get the best possible result from each, I venture to predict that the cleared half will certainly not prove *inferior* to the other, though, in point of rapidity in printing, and very likely in other respects, it will prove superior. Again, if a good negative of the colourless kind—that is to say, one of perfect printing quality—whether developed with pyro and sulphite or any of the newer developers, be stained with a decoction of coffee or other suitable solution, or be printed through a coloured medium, the only difference in result will be that the stained portion will take a longer time to print. I have carefully tried this experiment in a variety of ways, and, except in the matter of rapidity, have failed to find any advantage in a coloured film over one of the perfectly black and white kind.

But here, I think, is the point. We hear the objectors to sulphite and metol, &c., complain that they do not like the blue-coloured image. Nor do I; but it is not necessary to get a blue image, at least with metol; I have had less experience with amidol, so refrain from speaking of that. If the image is of a blue or "steely" tint, it is pretty certain that something is wrong, and also that the negative will not print satisfactorily. When all is right, the image should be a rich neutral black or grey, whether metol or pyro-sulphite is used, and I dare say the result is the same with any of the others properly used. With an image of that colour it is possible to combine perfectly "prettiness," quality, and rapidity in printing.

Why, then, do we hear complaints against metol? The explanation is, I think, to be found in under-exposure and a want of acquaintance with the peculiarities of the developer, and some of the more enthusiastic of the earlier workers with, as well as the introducers of, amidol and metol, are partly to blame for this result. Thus we have been told that with these substances the exposure can be reduced to one-half or one-third; I can only say that I have worked constantly—almost every day—with metol for several months now, and, so far as comparative exposure is concerned, I find I can get as good a printing negative out of a given exposure with pyro as with either amidol or metol.

Metol without restrainer is, as all know, a very rapid developer; but this rapidity of action has been miscalled energy of another kind, and it has been assumed that, because the development is rapid, the exposure may be curtailed, which, so far as my experience is concerned and that of others I am acquainted with, is not the case. Metol seems to have a marvellous power not only of rapid development, but of searching out faint detail and developing it almost as rapidly as the more powerfully illuminated portion of the picture; but it has no power of building up or intensifying the image first produced. It exhausts itself in one supreme effort, and further prolongation of its action can only result in fog.

Then on applying an unrestrained solution of metol, with sulphite and alkali, to a nominally exposed plate, the image will flash up in a few seconds, the faintest details being little behind the highest lights, and, if the plate be of good quality and the developer of suitable strength, probably a good printing negative may result. The operator concludes from this behaviour that either a shorter exposure will suffice or that a weaker developer can be used, and then the trouble commences. The action of the unrestrained solution is so utterly different from that of pyro that he goes on reducing his exposure and weakening his solution, with a constantly increasing poverty of result, although there is still almost the same rapidity of action and the same marvellous searching out of detail. As a consequence of this latter power, it follows that any "light-fog" that may be inherent in the film, or any excessive action of light during development, are brought out with greater facility and shew with greater prominence than if pyro were used, and any continuation of development in the attempt to get density only leads to deeper and stronger veiling of the shadows.

But if, instead of reducing exposures or diluting the solution, a proper portion of bromide be added to the developer, an entirely different result is obtained. The development becomes much slower, not only in starting, but also in its progress—becomes, in fact, very similar to pyro development. The abnormal searching out of detail is less apparent, since the bromide necessarily acts more powerfully upon the most feebly illuminated portions of the image, and these are consequently held back while the rest of the image is gaining in density; but, if the action of the restrained developer be continued long enough, the feeblest details obtainable with an unrestrained solution and a similar exposure will also be produced, though the general character of the image will be altogether different. Vigour and density will be obtained in abundance; indeed, if the action be continued long enough to get out the last details, the danger will be lest too much density be obtained.

It is not that the addition of bromide confers any intensifying power upon the solution, for, if a plate be exposed for what I must again call a "normal" time, that is sufficiently, cut in halves, and the two portions developed respectively in restrained and unrestrained solutions until no further action seems to go on in the high lights, there will not be much difference in their density at the finish, although the two images generally will be widely different. Even if the action of the restrained solution be continued until the shadows contain as much detail as in the other half of the plate, the general effect will only be one of increasing softness without any greater density in the lights. The unrestrained solution will, in fact, if of sufficient strength, and with sufficient exposure, give all the density required, but there will be a strong tendency to veil the shadows with fog.

Those who have failed to apply metol satisfactorily through attempting to achieve the great increase of rapidity claimed for it in some quarters, should try again, and content themselves with securing its other good qualities. Among these I have no doubt many will reckon its wonderful rapidity of action; but this, as I have shown, must be at least partially relinquished, though, if bromide be used in the proportions given in the first formula published by the manufacturers, it is still a rapidly acting developer. But it must be always borne in mind that under-exposure is fatal to density, as is also the too great dilution of the solution. The last formula published, containing only about one and a quarter grain of metol to the ounce of developer, is only applicable to subjects in which there are no heavy contrasts. I prefer to keep up the quantity to at least four, and preferably five, grains of metol to each ounce of mixed solution, to which quantity I add one grain of bromide and three minims of strong ammonia. In this form it is comparatively slow in its action, though not slower than pyro, but beautifully regular, and gives an image that for printing quality can scarcely be surpassed.

The proportion of sulphite, I had almost forgotten to say, is a point of the greatest importance in conjunction with density, as, if this is at all curtailed, the action is slow and incomplete, however much alkali may be added. The quantities given by the manufacturers—namely, ten of sulphite to one of metol—are what I use, and nothing is gained by either increasing or reducing the sulphite.

It may be urged that, at present prices, metol is an expensive developer, but I do not think it will be found so in practice. I have never hitherto been an advocate for the repeated use of the same solution, nor have I been a believer in the principle of an automatic developer. But I am constrained to confess that latterly I have come to regard metol as a near approach to automatism, and to rather like it in consequence. The same solution may be used over and over again—at any rate, to the extent of six or eight times—with the only result that it gets a little slower in action, but not much. Should it get too slow, an occasional addition of a little more alkali, or, if it fail in giving density, a small pinch of metol added will keep it in working order for a long time. A few days since I developed eight $7\frac{1}{2} \times 5$ plates with three ounces of solution, the last being undistinguishable from the first. W. B. Bolton.

ON THINGS IN GENERAL.

I should like to join in a few words of the highest commendation in the laudatory remarks made upon Messrs. Grundy and Haddon's paper, read some little while ago before the London and Provincial Photographic Association, upon the "Amounts of silver and hypo left in albumenised paper at different stages of washing." If such an abstraction as myself can offer thanks, I should desire to tender mine with effusion for one of the most valuable papers connected with practical and theoretical photography that has been presented to us for a long time. Only those conversant with such matters can appreciate the extensive labour involved in making the experiments recorded, and the results given have a very practical bearing upon photographic printing practice. I heartily endorse what these gentlemen say about the chief factor towards ensuring permanency being the use of plenty of hypo.

The singular point in connexion with the yellowing of a silver print on albumenised paper is that it is frequently accompanied by a fading of the dark parts. That unfading prints, or rather, as it would be better to say, unfaded prints, have been produced is undoubted. What we want to make certain of is the cause of the fading where it exists. I hold a strong opinion. Granted a picture well washed after toning, properly fixed with an ample supply of hypo, and sufficiently washed afterwards, I believe it will, when unmounted, not fade when the air is kept from it. I have dozens of unmounted pictures, taken at different periods and more than twenty-five years ago, which are as bright, and as good, and free from fading and yellowness (where air has not had access) as they were the first day they were produced. But it is desirable that this experience be not misunderstood. The pictures are unmounted: the mounts of the present day, or some of them, have much to answer for.

I was much interested in reading Mr. Kidd's letter about the Convention group, and was pleased to note, as would only be expected by those acquainted with that gentleman, that he did not attempt to take the group without first obtaining permission, for I hold that no one whatever ought to take a snap-shot of the Convention group, arranged and composed by the local photographers, without permission granted. It robs the latter of credit justly due to him for his previous preparation and his composition of the figures. We learn that Mr. Kidd's camera was used, but that the local photographers' staff exposed the plate and supplied the developer. Mr. Kidd said, "Hold, enough," when he considered the plate developed, and then the staff came in again and finished the negative. Surely Mr. Kidd is quizzing us in suggesting that the whole credit of the photograph did not practically belong to Messrs. Heath & Co.

Much interest attaches to the discussion between Messrs. Debenham and Dennis Taylor on perspective topics—"optical truth and visual truth." I notice in Mr. Taylor's paper a good *résumé* of optical theories, which might almost be looked upon as a paraphrase of Le Conte's views on the subject, even to the reference to the difficulty of judging the distance of a horizontally stretched rope without putting the head on one side. Le Conte's own example shows the difficulty more clearly, for he speaks of two stretched ropes, one further from the eye than the other. It will be well to point out, with regard to Mr. Debenham's illustration of a block of buildings viewed in perspective and a model, one-tenth scale, viewed at one-tenth the distance, that it is the front surface of this building that is stated to have the same dimensions in each case, not its vanishing lines—two very different matters indeed. Most disputants upon perspective representations of the human figure lose sight of a prime factor of comparison. An artist's life-size painting of a sitter is usually placed and painted so as to be seen from a distance, and from such a distance as few photographers work at. If it be desired to produce a photograph that will resemble such a painting, the plan will be to put the sitter thirty or forty feet away, take a small negative, and then enlarge to life size. No one then will talk of distorted hands and feet.

When perspective or optical matters come into discussion, it is most singular how it most frequently happens that the writer makes some slip or other. Now we are all familiar, for example, with Mr. Chadwick's excellent popular explanations of some optical matters; yet when he begins to deal with subjects of which it is to be presumed, he not being a surgeon, his knowledge is obtained from sources outside his own experience, he makes a slip. He says, describing the eyeball, "We have a nearly globular chamber composed of a thick, strong, white substance—the sclerotic coat—part of which is seen as the white of the eye. The inside of this chamber is interlaced with minute blood vessels, covered again by a thick black pigment called the retina, and the whole is filled with a transparent jelly." Now, it is very probably a slip of the pen in writing, which he will thank me for calling attention to; but, as a matter of fact, the black coating (the choroid) does not cover the retina, it lies behind it, between retina and sclerotic. It is, in fact, the physiological analogue of plate backing, and prevents halation. We have read a good deal about who discovered how to prevent halation, and here the method was before (or in) our eyes all the time.

I often pity platemakers when I hear plates complained of when the fault lies with the user himself, but my imagination never soared to the possibility of such heights of complaint as those given by a correspondent—"S. A. Y."—in a recent issue of this Journal. He wants to know why, as everything foreign is cheap, dry plates are not. Further he says, "It would be a great boon to an amateur if he could buy his plates cheaper." This is really nauseating! Quarter-plates at a penny a piece, and he wants them cheaper! He had better send the hat round at once! Free Lance.

THE PRINCIPLES INVOLVED IN THE CALCULATION OF EXPOSURES FOR CONTACT PRINTS ON BROMIDE PAPER.

[Presidential Address at Inaugural Meeting of the Widnes Photographic Society.]

You are probably aware that Dr. Hurter and I have together devoted a great deal of attention to the scientific aspect of photography, the result of which has been to convince us that all the operations involved are amenable to calculation and predetermination. I was, therefore, influenced in my selection of a subject to-night by a desire to bring forcibly home to you at the outset the practical advantages of the methods we advocate, and I made the selection I did because it seemed the implest for my purpose.

Our subject involves a consideration of the properties of the negative to be used, and of the paper upon which the print is to be made. We will refer to the negative first. A negative image consists of metallic silver deposited over the surface of its support in more or less widely varying quantities, which quantities, of course, determine the varying amounts of light which the negative, in its different parts, allows to pass through it. The quantity of silver on any one spot of the negative is represented by what we term the "density" of that spot. When I say "we," I refer to my friend Dr. Hurter and myself, as we were the first to use the term density in this sense, and I may tell you we found ourselves in very hot water for rightly applying a term which photographers had previously misapplied. However, the term density implies the relative quantity of silver deposited per unit area, and I particularly want you to do your best to grasp the meaning of the definitions I shall give you to-night. This is of the utmost importance, and will be of the greatest assistance later on.

Every point, say, in a landscape we are about to photograph reflects a certain amount of light, and our object is to produce a negative which will yield a print in which the light intensities reflected by the landscape are faithfully reproduced. The negative itself is only a means to an end; but, if it is to be capable of producing a true print, it is clear there must be a definite relationship between its densities and the light intensities which produced them, and it is also clear that a perfect negative must be capable of transmitting amount of light through its varying densities, which are related to each othe

as are the light intensities reflected by the objects which form the picture. This brings us to two other definitions, namely, transparency, and its inverse, opacity. The opacity simply expresses the optical property of a substance (in our case, silver) to impede the passage through it of light. The transparency of a substance is the inverse of this, and is measured by that fraction of the original light which the substance allows to pass through it. A deposit of silver, of which the opacity is two, transmits half the light it receives.

Now, in order to be able to calculate the exposures to be given in the case of printing processes by development, it is clearly necessary to establish the connexion which exists between the light intensity used for printing and the opacity of the negative, which determines the amount of the original light which the negative actually transmits. It is easy to ascertain what the effect will be upon bromide paper of a certain exposure to a naked light of known intensity; but we have to ascertain to what extent this original intensity will be affected by the interposition of the negative. This renders it necessary, in the first place, to measure the opacity of the negative. We do not, however, for very good reasons, measure the opacity of the negative directly, but we measure the density; and, as the relation between the opacity and the density is of a simple character, we can easily arrive at the former when we know the latter.

The connexion between density and opacity is expressed by saying that the density is the logarithm of the opacity. If, therefore, we can, by measurement, ascertain the density, it is easy to calculate the opacity. The photometer which we devised for this purpose renders this operation extremely easy and expeditious. As a simple example which you can easily remember, suppose we have a uniform deposit of silver of which the opacity is two. In this case the plate will allow one-half the light to pass through it, or it will have a transparency of one-half; and, in order to possess this property of transmitting one-half the light it receives, it must have a density of 0·301, this being the common logarithm of two. Now, in talking about logarithms, I am most anxious not to alarm you; they may not be things you are much in the habit of dropping across, but there is nothing very alarming about them; and I venture to think you will soon be as familiar with their use as you are with the use of the multiplication table. They form an absolutely indispensable element in photographic arithmetic, and all the logarithms necessary for photographic work can be placed on a card the size of a quarter-plate.

I must here digress for a few moments, in order to say a word or two about our unit of light and exposure. Our unit of light is that amount emitted by a standard candle acting for one second, at a distance of one metre: this we call one "candle-metre second." As you all know, the intensity of a given light varies inversely as the square of the distance; and it is all the same thing whether the light be allowed to act for one second at one metre distance, for four seconds at two metres distance, or for a quarter of a second at half a metre distance. The candle-metre second is therefore the unit in terms of which we express all our exposures. Whether this source of light be the sun, gas, paraffin, or magnesium, we always refer it back to the standard candle.

We have so far considered the part played by the negative in the production of the print, and we will now turn our attention to the bromide paper upon which the print is to be made. You will easily understand that the various gradations of the finished print must be included within a range, limited, on the one hand, by the natural white of the paper; and, on the other hand, by the extreme black of the deposited silver when examined by reflected light. In order to produce the best possible print upon a given paper, the negative must have a range of densities which coincides with the range of gradation of the paper, otherwise the negative and the paper are not suited to each other, and an inferior print must result.

In order to ascertain the density range of the negative, we submit it to actual measurement; but, as the merits of the finished print will be finally judged by the eye, ocular inspection, instead of measurement, will serve our purpose in deciding the range of our paper. All we have to do is to ascertain what exposures correspond with the gradations of the paper ranging from extreme white to extreme black. At first sight, you would naturally suggest that the way to do this would be to give a series of exposures on different patches of the same strip of bromide paper, beginning, say, with one second, and proceeding with two, three, four, five seconds, and so on. This would be a perfectly correct method of obtaining the information we require; but I am afraid you would be very tired of the operation before you reached the end of it, for, in the case of the paper we shall use to-night, you would have to give a series of about seven hundred exposures, increasing arithmetically from one second to about twelve minutes. Such a formidable operation as this would prohibit the practical application of our principles; but, fortunately, there is a short cut to the attainment of our object. By causing our exposures to increase geometrically, instead of arithmetically, we shall obtain the information we require in nine, instead of 700, exposures; and, further, by means of a simple piece of apparatus, we can make the nine exposures concurrently. By a geometrical progression of exposures, I mean one in which each successive exposure is the same multiple of the previous one—for example, one, two, four, eight, sixteen, and so on. I have brought with me to show you a strip of the bromide paper we are going to use for our experiment to-night. This strip of paper has received nine different exposures, each double the preceding one, and progressing from two and a half to 640 cm. The strip is divided into ten parts, nine for the exposures, and the first, which was protected from the light while the exposures were made, represents the natural white of the paper.

Now, you will notice that the shortest exposure which has produced any deposit at all on this paper is five cm. The first exposure of two and a half cm. has produced absolutely no result. At the other end of the range you will see that the maximum blackness by reflected light is reached by an exposure of 320 cm.; the exposure prolonged to 640 cm. has not produced any increased blackness, though it has, of course, produced an increased deposit of silver, which would be apparent by transmitted light; but, as our print is to be viewed by reflected light, this increased deposit has not the slightest value. We therefore consider that the available range of this paper lies within the limits of exposure of five and 320 cm.

Having obtained this knowledge, we must next consider the paper and the negative in conjunction; and, to make the matter as clear to you as I possibly can, we will first of all consider a negative consisting of one uniform density, such as I hand round. This negative I have measured and marked accordingly. Its density is 1·05, its opacity is 11, and its transparency is $\frac{1}{11}$. Now, imagine this negative in contact with a piece of bromide paper of which we have ascertained the range in the manner described, and let us set ourselves this simple problem, What exposure must we give through this negative in order to produce upon the paper the same amount of deposit as was produced by an exposure of eighty cm. to the naked light? The opacity of our negative is 11, and as it, therefore, only transmits $\frac{1}{11}$ of the light it receives, we must obviously multiply 80 (the direct exposure to which we want the equivalent) by 11. $80 \times 11 = 880$, and this is the exposure in cm. which we must give through this negative in order to produce upon the paper the same result as an exposure of eighty cm. to the naked light.

You will see from this example how simple the principle is which underlies the determination of the exposure; but when we come to deal with an ordinary negative, with its varying ranges of densities, the considerations involved are somewhat more complicated. The calculation is, however, just as simple. We will now, therefore, devote our attention to the particular negative from which we are going to produce a print this evening, and consider its range of densities in relation to the range of gradation of the paper.

I did not elect to bring a negative of my own for our experiment to-night, because it might have suggested a suspicion that I had made a sly preliminary trial; I therefore asked Mr. Warner to provide a negative, and this he has kindly done, and he will vouch for it that I never handled the negative except in his presence, and then only to measure its densities. I had intended to have measured the negative here to-night, but this would have involved explanations as to the photometer, for which we shall have more time upon another occasion. This negative of Mr. Warner's I have measured in two places, corresponding to the highest and lowest densities, and this is all that is required. These densities I found to be:—

Negative.

Density:	max. 2·34	mean 1·80	min. 1·27
Opacity:	„ 218	„ 63	„ 18·6

The densities, you will remember, are logarithms of the opacities, and, knowing the former, we can easily ascertain the latter from a table of logarithms. Having found the opacities corresponding to the maximum and minimum densities of the negative, we learn that these densities transmit respectively one two-hundred-and-eighteenth, and, roughly, one-eighteenth of the light they receive. Let us now refer again for a moment to the bromide paper upon which the light intensities transmitted by this negative are to be brought to bear. We found that the range of this paper extended from an exposure of 5 cm. to one of 320 cm.

Paper.

Exposure:	cm. 5	mean	40	320
Log. of exposure:	„ 0·699	„	1·602	2·505

If our negative were exactly capable of utilising the entire range

of the paper, the exposure would be arrived at by considering either that, through the maximum density of the negative, it must be such as to leave the normal white of the paper untouched, or that the exposure, through the minimum density of the negative, must be such as to allow the paper to acquire maximum blackness; that is to say, all we should have to do would be to multiply $2\frac{1}{2}$ (the exposure which just failed to produce any deposit on the paper) by 218, the maximum opacity of the negative, or to multiply 320 (the exposure corresponding to extreme blackness) by 18 6, the minimum opacity of negative. Either method would lead to the same result if the paper and the negative were absolutely suited to each other. Unfortunately we do not, as a rule, pay that amount of attention which we might do to procuring the exact quality of negative which is calculated to yield the best possible results by any particular printing process. We have therefore had to find a method of procedure for ascertaining that exposure which will yield the best possible results with the particular negative and paper we wish to use in conjunction. We have found it best in practice to regard the range of the paper as extending from the shortest exposure producing the blackest deposit to that exposure which just gave the first evidence of deposit. We then base our calculation upon the *mean* density of the negative, which we refer to the exposure which corresponds with the *mean* gradation of the paper. This adapts the negative, and the paper ranges to each other in the best possible way.

The mean density of the negative is 1·80, and the corresponding opacity is 63. We do not, however, for mathematical reasons, take the arithmetical, but the geometrical, mean of the exposure which produced the paper gradations, and this mean is forty cm. We are now in a position to determine the exposure we are going to give to-night, and to simplify matters by regarding our negative as though it consisted of one uniform density of 1·80, and as uniformly transmitting one sixty-third of the light it receives. Our next consideration is that, through the mean density of the negative, we have to produce a deposit on the paper equal to that produced by an exposure of forty cm. to the naked light.

For optical reasons, which I propose to give you when, on some future occasion, we go into the question of enlargements, it is necessary to somewhat reduce our mean density to the extent of multiplying it by 0·8.* $1{\cdot}80 \times 0{\cdot}8 = 1{\cdot}44$, our modified mean density, to which corresponds an opacity of 27·5, and the following figures must now be taken as our working data:—

Mean density × 0·8	1·44
Mean corresponding opacity	27·5
Mean exposure of paper range	40 cm.

We have only now, as in our first example, to multiply the mean exposure of the paper range by the mean opacity of the negative, $40 \times 27{\cdot}5 = 1100$ cms., which is the exposure we shall give to-night.

In making this calculation I have chosen to work with the opacity of the negative rather than with its logarithm, the density, because I thought the former would appeal to you better than the latter. I should, however, like to show you how, in practice, I prefer to make the calculation myself. We have already been compelled to refer to our logarithm tables in order to derive the opacities of the negative from the densities, so that it would be no more trouble to refer to the tables for the logarithms of the paper range exposures instead. We should then have the following data to work from:—

Mean density × 0·8	1·44
Log. of mean exposure of paper range	1·602.

We simply add these two numbers together, $1{\cdot}44 + 1{\cdot}602 = 3{\cdot}042$, and, by referring again to our tables for the number corresponding to this sum, we should once more find the answer we require, namely, 1100 cm.

We will now proceed to make our exposure, and I have little doubt I shall be able to show you the best possible result which can be obtained upon this particular paper and from this particular negative. As I do not suppose you will care to sit for 1100 seconds, or $18\frac{1}{3}$ minutes while we make our exposure to the light of a standard candle, I am going to show you the means we adopt when we have these long exposures to deal with. We shall make our exposure to the light of a duplex paraffin lamp, and this piece of apparatus enables me, at will, to make the lamp equal to any number of candles I may require. To-night we shall make it equal to twenty candles, and, as our source of light will be equal to that of twenty candles, we divide our required exposure of 1100 cm. by 20, which gives us an actual exposure to the lamp of fifty-five seconds. This apparatus consists of a shadow photometer, and the candle is placed at such a distance from the screen that, when the shadows thrown by the candle and the lamp are of equal intensity, the light of the lamp is equal to that of twenty candles. An appropriate scale provides data upon which to base the calculation necessary if it be desired to make the lamp equal to any other multiple of the candle.

Mr. Warner actually found me *two* negatives for my experiment to-night, and the one of which I have given you the measurements I selected because its density range better suited the range of the paper. The second negative is, however, so different from the first that I thought, while we were about it, you would be interested to see a print from it as well. The requisite data for calculating the exposure for this second negative are as follows:—

Maximum density	1·725
Minimum „	0·880
Mean „	1·302
Mean density × 0·8	1·041
Mean corresponding opacity	11
Mean exposure of paper range	40 cm.

The required exposure is therefore $40 \times 11 = 440$ cm. and, with the lamp at twenty candles, $\frac{440}{20} = 22$ seconds; our two exposures, then, are, to the light of the lamp, fifty-five seconds for the first, and twenty-two seconds for the second negative.

Here are our results, and you must judge for yourselves how nearly I have hit, by calculation, the best exposures for the negatives and paper we have used. One very great advantage of this method is that, having ascertained the range of different papers, and the extreme densities of the negative, it is easy to tell which paper will give the best print from the negative. The more nearly the difference between the extreme densities of the negative agree with the difference between the logarithms of the exposures at the extreme limits of the paper range, the better are negative and paper suited to each other, and the better will be the result. Through no fault of Mr. Warner's, the range of the negatives and the paper we have used to-night do not coincide as well as they might; and, if you will refer again to the strip of bromide paper showing its gradations, you will see that I have marked upon it the extent and position of the range actually utilised in the first print we have just made. You will notice that the print does not nearly utilise the entire range of the paper. If you care to see them, I will pass round a number of bromide prints upon the same paper we have used to-night. You will see that they are produced from negatives considerably varying in density ranges, and the exposures vary consequently from 1200 cm. to 153 cm. I should say that all the negatives from which these prints were made were developed with ferrous oxalate.

In conclusion, I have done my best to make it as clear as I possibly could how to arrive at the best exposure for a bromide print, and, while I can hardly hope that I have enabled you to go home and put the operation into immediate practice, I do hope that I may have led you to see the advantage of working by methods of precalculation. Judged at first sight, you may be inclined to question whether the game is worth the candle; I can only assure you from long experience that it is well worth it. Not only will you, by the adoption of this system, save an enormous quantity of material, but I can assure you you will find the pleasure of working at photography vastly enhanced when you come to substitute calculation and almost absolute certainty of result for rule of thumb and depressing failures. Do not any of you go home with the idea that what I have said is beyond you; take my word for it, it is not. What has taken me a long time to tell you is really only an account of operations which, in practice, occupy but a few minutes to carry out, and with which you may very soon familiarise yourselves.

Of course, I have been obliged to refer to the principles involved, but it is only by understanding these that you can work intelligently, and ever hope to reap full satisfaction from the adoption of scientific methods; and I will tell you in confidence that there is one little spot in my heart wherein dwells the glimmer of a hope that the Widnes Photographic Society may become, from conviction and choice, our warm ally in the promotion of photography by precalculation.

VERO C. DRIFFIELD.

* I will only say that one consideration affecting this factor is the colour of the negative, consequent upon the developer used.

THE EVOLUTION OF ARTISTIC PHOTOGRAPHY.*

RETOUCHING has become a necessity from the public standpoint, and, if it was kept within bounds, it is a very valuable auxiliary to photography proper; but, abused as it is in so many cases. the advantage is very often problematical. Landscape work has also had much attention paid to its artistic bearings, with the most happy results; something more is now expected than a mere representation of nature.

* Concluded from page 591.

Atmosphere and composition are qualities absolutely necessary in any good landscape. Not that this has not always been the case, but much more critical attention has been bestowed on these special qualities than ever before. However we may disagree with Emerson's dicta, it was the chief means of calling attention to these particular qualities, and many who had previously paid but slight attention to the matter were induced to examine it more seriously, from a new standpoint, with results that have undoubtedly added to the improvement of photography from a pictorial point of view. *Sometimes* a fuzzy, out-of-focus picture possesses very many art qualities, and has very great charms for a true artist, whether he is a photographer or not; but the charm does not lie in the fuzziness, but in certain leading beautiful lines which are emphasised by all minor or less important ones being suppressed or indistinct; generally speaking, the success of a fuzzy picture is somewhat of a fluke, and, if any photographer starts an exposure with a predetermined blurr effect, the chances are very much against anything but a dead failure rewarding his exertions. I do not think our art will be much benefited by any *deliberate attempt* to produce out-of-focus pictures, merely *relying on this* for atmosphere, when atmospheric effect can be obtained by other means than imperfect instruments or faulty manipulation, which is implied by the out-of-focus systems.

We have many photographers who are undeniably artists in the best sense of the term, and who impress their individuality on their work in a greater or less degree, accordingly as they work in the ordinary grooves or deviate from them. A man will be successful with one particular style, and, having achieved with it a certain amount of popularity, feels disinclined to adopt any other; at least, whatever his inclination, he, as a rule, keeps to the one by which he gained his reputation. If we analyse any of these styles, we shall find their beauty entirely depends on their strict accordance with art rules, and the clever adaptation of peculiarities of the subject in carrying them out.

With the greater development of purely artistic treatment has grown up that excessively bad or good thing, retouching, without which nothing is saleable in the realms of portraiture. Human nature rarely objects to flattery, and, when that thing that never lies shows you to be younger by many years and better-looking than you are, you accept the soft insinuation, and half believe you must have made a mistake about dates and crow's-feet, for the last new cabinet proves it. There is a good deal to be said in defence of retouching, *very much* more commercially than artistically all the same; but, as we are chatting about the improvements, and not the profits, we will confine ourselves to the estimation of retouching entirely on its merits. That the legitimate use of the process is an immense power in the hands of the photographer there is no shadow of doubt, as photography itself is apt to exaggerate lines and markings on the human face divine: the judicious use of the pencil will balance matters, and make a much more *truthful* presentment than would be possible by unassisted chemistry. Now, this is the legitimate application of retouching; accentuating a light or reducing a shadow is also perfectly legitimate, and, if retouching was confined to these limits, there would be nothing to say against it. But, unfortunately, the possession of the means to do much more makes much more done, and to such an extent, that flesh rivals marble in solidity and egg-shell in texture, and the likeness—well, the less said about that the better. But not only is the texture of the skin misrepresented, but the features themselves are altered and shaped to suit the retoucher's idea of what they should be—crooked noses are straightened, ugly mouths are made to rival Cupid's bow in contour, small eyes are enlarged, fat people are made slim, round shoulders are made straight, and the completed photograph is nothing but a delusion and a snare, and becomes as difficult of identification as a suicide that has been a month in the water. This excess of hand work, reprehensible in itself, has good results indirectly, by causing the photographer to become a better artist in his struggle to represent the beautiful; it improves his correctness of drawing, and indicates those points it is best to avoid or to give least prominence to, as well as to make the most of the good ones with which nature has endowed the sitter. From this point of view retouching has its advantages, and decidedly the artistic qualities of photography are increased; but, when the vanity of the person insists on a remodelling throughout, and many do, the conscientious photographer is in this difficulty, he must please his sitter or lose his customer—it need not be said that the former alternative is generally chosen; but whether even this concession pays in the long run is doubtful. The sitter is undoubtedly gratified at first, but soon—unless for advertising purposes—the most striking *likeness* will be preferred. It must be borne in mind that the most elaborate finish will not secure the approval of friends unless the likeness is good; but, given a good resemblance *and* expression, the portrait will have an enduring reputation, conduce to better business and more general satisfaction, as well as meriting greater praise from a purely artistic standpoint.

Vanity has much to answer for in the propagation of the worked-up monstrosities with which we are, unfortunately, so familiar, and some photographers encourage the public in this wretched taste, on the plea that it gives satisfaction and brings in the money. What can we want more? That is just it—what do we want more? We want a portrait to be a portrait; a similitude to the living person, and a true reminder of those who have passed away; to those who esteem the living, it is a notorious fact that hundreds of pretty enough pictures are no more like the originals than if they had never sat for the negative, but had sent a deputy instead. But with all these faults, which are remediable, there is undoubtedly an immense improvement in the art feeling displayed in ordinary work to that of a few years ago, an improvement we may fairly attribute to the facilities provided in gelatine plates, which do away with any anxiety in regard to the manipulative part, and leave the artist nothing to think of except the lighting, posing, and exposures. In landscape work we seem to improve irregularly, if one can so term it. We have a great number now of exceedingly good pictures made—pictures in every sense of the word—but, with few exceptions, successes are not repeated by the same individual, which suggests that the success was more a matter of chance than design.

Of course, the occurrence of certain atmospheric conditions necessary for some special effect cannot be relied on, or scarcely anticipated, and they often happen when we are in an unprepared state. The same may be said of many necessary items that go to help the composition of the picture; at the same time, by watching and waiting, we may often secure a picture equal to, or better, than the one we had mentally pictured to ourselves, so there is no reason why good pictures should not be the rule, if we only *know what we want* and have the patience to wait for it. "Knowing what we want" is, I think, the key to the position; at any rate, unless we do, success will be only gained by a fluke. This does not imply that a picture should be mentally arranged sometimes *in advance*, but that, given a view with certain accessories, we should be able to *imagine a picture* composed of the material presented to us, and so see how it combines to form the picture we intend to produce; we then select our point of view, to get the composition *as near as we can* to our imaginary picture. In doing this it often happens that we shall have to content ourselves by securing the leading characteristics, as the detail will not come as we had desired: but, in our attempt, we may get a composition equally satisfactory, but one we did not realise at the outset; anyway, our photograph is made with a definite purpose, and, as a picture, it will be much better than one produced by the happy-go-lucky system, without due consideration, so generally adopted. The snap-shot system has a good deal to answer for in this connexion, for it engenders a habit of making exposures the instant things *seem about right*, without taking the necessary deliberation most good compositions require. It is very seldom, indeed, we see a subject to the *best* advantage immediately we look at it; a little study will show us how far from perfect our first impressions were, although they may be tolerably correct on the whole; and, now that the process is divested of any necessity for hurry, the photographer of the future will have to show carefulness of construction, as well as other pictorial qualities, are necessary for all true photographic works of art.

EDWARD DUNMORE.

CENTRAL PHOTOGRAPHIC CLUB.

A LARGELY attended meeting of members of the Central Photographic Club and others interested was held at Coleman's Hotel (late Ashley's) Henrietta-street, Covent Garden, W.C., on Wednesday, September 13. The meeting was called to give members an opportunity of becoming acquainted with the premises the executive had chosen, as well as to elect officers, receive report of progress, and consider certain desirable alterations in the rules. Mr. George Mason occupied the chair, and among those supporting him were Messrs. J. Howson, T. Fall, Birt Acres, A. C. Edwards, R. Beckett, E. J. Wall, H. Snowden Ward, Thomas Bedding, F. P. Cembrano, A. Cowan, W. F. Slater, J. S. Teape, L. E. Morgan, — Turnbull, Child Bayley, G. H. James, W. Fenton Jones and C. H. Oakden (Hon. Secs.), — Jacobs, — Wilkes, H. E. Farmer, F. W. Munro, J. Birtles, and many others.

Mr. Oakden (Hon. Sec.) reported progress, detailing the difficulties the Committee had expeirenced in the selection of suitable premises, and stating that finally it had been decided to take rooms at Coleman's Hotel. Two rooms and a dark room would be permanently at the disposal of members there, and a large meeting room for meeting nights as might be required. The terms were moderate, and there was an advantage in

being able to obtain refreshments and service without difficulty. For country members staying in the hotel there would be a reduced tariff. The report was formally adopted.

The meeting then passed to the consideration of the rules, which, after much discussion, were adopted in the following form:—

Rules of the Central Photographic Club.

1. The title of the Club shall be the Central Photographic Club.
2. The object of the Club is to provide a central meeting-place for those interested in photography where they may enjoy social and technical advantages.
3. All gentlemen interested in photography shall be eligible for membership.
4. The annual subscription for town members shall be 1*l.* 1*s.*, and for country members 10*s.* 6*d.* For life membership a payment of 10*l.* 10*s.* shall be required from town members, and 5*l.* 5*s.* from country members. The first 300 members will be admitted without entrance fee. Those joining after that number has been reached shall pay an entrance fee of 1*l.* 1*s.* for town members, and 10*s.* 6*d.* for country. Gentlemen residing within a radius of twenty miles of Charing Cross shall be deemed town members.
5. The management of the Club shall be vested in a committee of twelve town members, and six country members, four to form a quorum exclusive of officers, to be elected by the members in general meeting annually. The Committee shall have power to fill up vacancies during the current year, and also to make bye-laws as may be found necessary, such bye-laws to be binding on the members after being posted in the Club-rooms.
6. The property of the Club shall be vested in two Trustees.
7. The President, Trustees, Hon. Treasurer, Hon. Secretaries, and an Hon. Librarian shall be elected by the members annually in general meeting, and shall be *ex-officio* members of the Committee.
8. All officers and Committee shall be nominated in writing at the ordinary meeting of the Club fourteen days previous to the annual meeting. The election to be by ballot at the annual meeting, verbally or in writing.
9. Candidates for membership must be proposed and seconded by two members of the Club. The name and address of the candidate, and the names of the proposer and seconder must be sent to the Hon. Secretaries at or before the stated meeting previous to the one at which it is proposed to submit such candidates for election. Such name shall be read by one of the Secretaries to the meeting, and posted on board till the next meeting.
10. The election of members shall be by ballot at any stated meeting of the Club, and a vote of four-fifths of the members present and voting shall be necessary to elect a new member.
11. Every candidate on his election shall be notified in writing with a request for payment of his subscription and entrance fee.
12. No member shall be entitled to use the Club until his subscription for the current year has been paid.
13. The annual subscription shall be payable in advance on the first day of October in each year.
14 Members joining the Club before December 51 shall pay the full subscription. After the end of December and before March 31 the payment shall be two-thirds; after the end of March, and before June 30, one-third; the subscription of any member elected after August 31 shall be considered payment for the following year.
15. Any person who shall by any means cease to be a member of the Club shall, nevertheless, remain liable for and shall pay to the Club all moneys which at the time may be due by him to the Club. Any person ceasing to be a member from any cause shall forfeit all interest and rights in the Club.
16. Any member making himself obnoxious to the members of the Club shall be reported to the Committee, who shall investigate, and, if necessary, call a special meeting of the Club to discuss the matter; then, if the majority so decide, the offending member shall be expelled the Club, and lose all interest and benefit in it, such decision to be taken by ballot.
17. An annual general meeting of the members shall be held in the first week in October to receive the report of the Committee, to pass the accounts, having been audited by two members, not being members of the Committee, chosen at the previous meeting of the Club, to appoint officers for the ensuing twelve months, and to elect members of the Committee to supply to supply the places of those retiring. The newly elected officers and members of the Committee shall come into office at the conclusion of such meeting.
18. Ordinary meetings of the members shall be held weekly.
19. The Committee may, whenever they think fit, and they shall on a requisition made in writing by ten members, convene an extraordinary general meeting. Any such requisition shall specify the object of the meeting required, and shall be signed by the members making the same, and shall be delivered to the Secretaries.
20. The Chairman shall have a casting vote in addition to the vote to which he may be entitled as a member.
21. No alteration of, or addition to, these rules shall be made except at the annual meeting, or at a meeting specially convened for that purpose. Notice of such intended alteration or addition shall be posted on the notice board not less than fourteen days previously.

The Chairman next read the following address:—

"At this, the opening meeting of the Central Photograph Club, I wish it unbounded success, and may it have a big future before it. If the success prove equal to the need for such an institution, it cannot fail to be successful beyond our anticipation. After much trouble and anxiety in looking out for suitable accommodation for us, the executive have done well in securing these premises, where we will find ourselves free from so many conditions and restrictions that clogged up the freedom of arrangements in all previous negotiations for a suitable place.

"Here we have comfortable rooms, refreshments at hand always, lodgings if desired by our country friends, and in a very central position—all these combined should prove no mean factor in inducing all the brotherhood of the Black Art to gather round and claim membership. The fee is so small that it must come easily within reach of all, and not to be considered if the possible advantages are put against it.

"I have said elsewhere that, in the interests of the provincial photographer, such an institution is of incalculable benefit, because it provides for him a place where he can at all times find kindred spirits and special interests there focussed, so to speak, and saving no end of trouble in going in search of friends and information; and as a centre for informal meetings it should be of great value.

"I place a great value on informal meetings, where a few friends, over a pipe, talk out the many experiments (successes and failures) that one and all have experienced in their professional career. This is an education of itself, and that of no mean order. As a place for formal meetings of all professional kinds this Club should hold a very prominent place, and there is no reason why many of the London Societies should not make it their headquarters, and by this means draw the bonds of brotherhood closer.

"Many other points of mutual interest will suggest themselves to you as we proceed on our way; and, wishing the enterprise all the good that can be wished, I launch our bark upon the photographic stream.

And in closing, I would propose a hearty vote of thanks to the executive for all the labours that they have undergone—labours that have so successfully terminated."

Mr. Mason having been cordially thanked for his address, the election of officers was proceeded with, and resulted as follows:—

President: George Mason.—*Trustees:* Thomas Fall and George Mason.—*Hon. Treasurer:* John Howson.—*Committee:* T. Sebastian Davis, Dr. G. Lindsay Johnson, Alexander Cowan, Birt Acres, Robert Beckett, A. Horsley Hinton, F. W. Hindley, J. S. Teape, F. P. Cembrano, jun., Andrew Pringle, H. Van der Weyde, T. E. Freshwater, R. Keene (Derby), Lyddell Sawyer (Newcastle), W. M. Warneuke (Glasgow), J. Stuart (Glasgow), Paul Lange (Liverpool).—*Hon. Secretaries:* W. Fenton-Jones and C. H. Oakden. The election of librarian was left to the committee.

The meeting night was fixed for Friday in each week. The Club premises will be opened on Monday, October 2. A vote of thanks to the chairman concluded the proceedings.

NOVELTIES IN CAMERAS.

The Hawk-Eye of the European Blair Camera Company.

It speaks well for the high reputation of London as the commercial capital of Europe and the East that the great American manufacturing companies are selecting it as a distributing centre.

The Blair Camera Company, of America, constitutes the latest arrival in this great metropolis, their business being constituted under the title of "The European Blair Camera Company, Limited." It is being organized under the personal supervision of Mr. T. H. Blair, the founder of the American firms, for the Company already have premises in New York, Boston, and Chicago. The generic name of their camera, of which they make a speciality, is the Hawk-eye, and of this there are some varieties, of which, by the aid of cuts, we shall endeavour to give a description, feeling assured that English readers will be interested in knowing something about some of the instruments in popular use by their American brethren.

In the first cut (Fig. 1) is shown an exterior view of the Hawk-eye, arranged as a hand camera, this particular one being intended for either 5 × 4 plates in double dark slides, for cut films in double slides of thinner make than the previous ones, or for a roll-holder. It is capable of being focussed, the focal range extending from within a few feet to infinity. This is done by rotating a circular scale shown on the top, and graduated from six feet to 100 feet. There are two finders, adapted respectively for a vertical or horizontal picture. The shutter is set by moving a small lever, and it is so constructed

as to give three different rapidities. The exposure is made for instantaneous impressions by pressing a small button on top; for time exposures, a button of different form from the other is provided, pressure upon which throws the lens open, in which condition it remains until closed by a second pressure upon either of the exposing buttons.

When used as a landscape camera a cover of a square aperture in

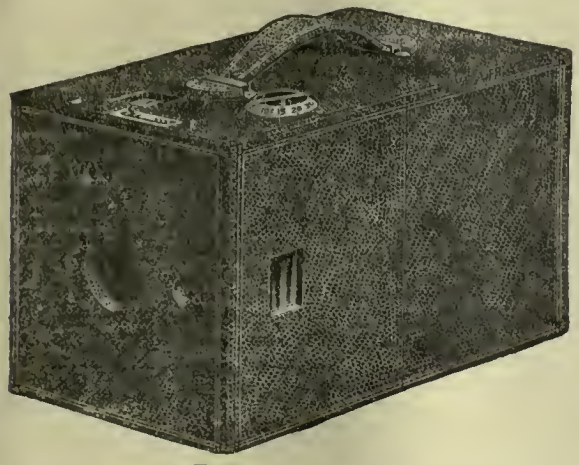

Fig. 1.

the back is removed, revealing a ground-glass focussing screen in the interior, on which the picture may be arranged and focussed if desired, instead of trusting to the scale of distances. This is shown in the cut following (Fig. 2).

In the cut (Fig. 3), we find the side thrown open on its hinges, displaying to view a roll-holder, for which, as already stated, the camera is adapted equally as for slides. The lower or left hand shows the action of bringing a fresh width of film into the line of exposure by the

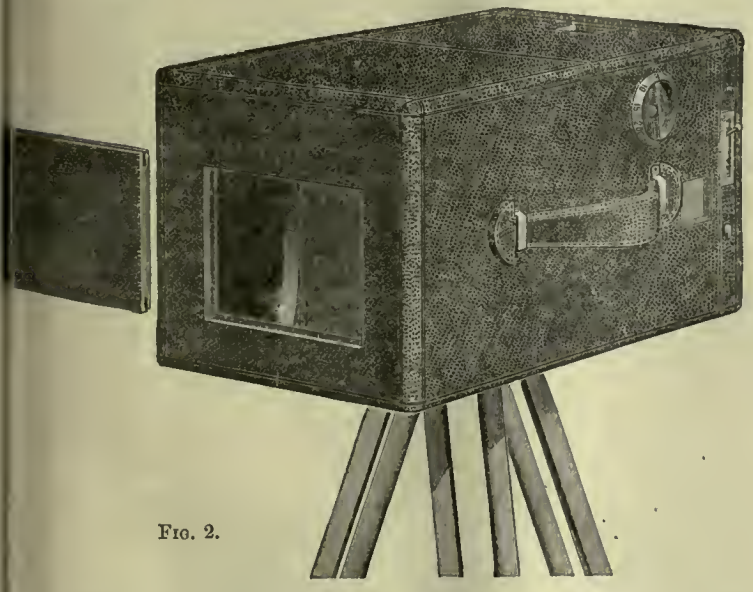

Fig. 2.

action of the finger and thumb. There is an index showing the number of exposures that have been made.

On opening the front of the Hawk-eye (Fig. 4), it is seen that the whole of the exposing appliances are placed, concealed, in that front, that the lens support is fixed, and that it is the back that is actuated by the focussing rack and pinion.

A word as to the lens, which, being, like the Hawk-eye itself, of American manufacture, we examined rather particularly in order to discover how Americans stand in respect of this branch of manufacture compared with their European brethren. In the first place, we are pleased to observe that they have had the good taste and good sense to adopt the standard flange screw of the Photographic Society of Great Britain. The one we specially examined is a rapid rectilinear of six and a half inches equivalent focus, and even with a large aperture covers the 5 × 4 plate brilliantly and well. It has rotating stops, and in finish and other qualities compares favourably with the best European productions.

A modification of the Hawk-eye, known in America as the "Columbus," camera, differs from the preceding one, using roll films only. It is less bulky than the other when packed, but is capable of

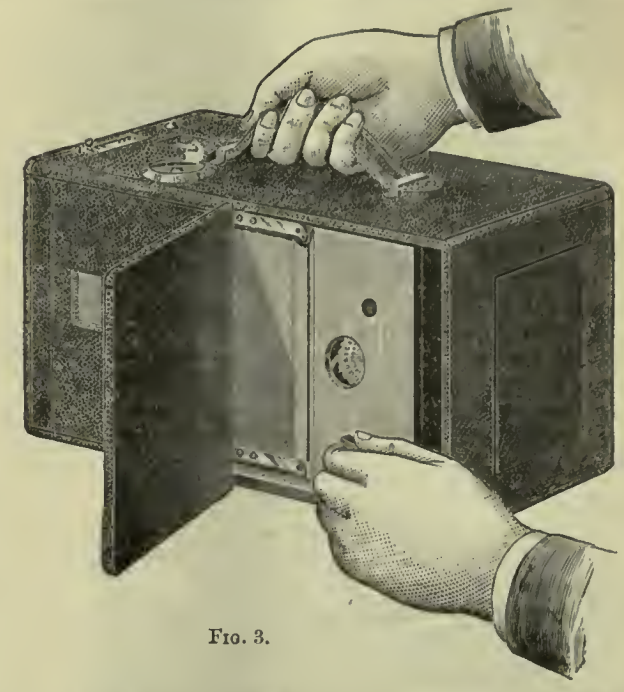

Fig. 3.

being expanded by the pulling out of the front with its lens and finders, as shown in the cut (Fig. 5).

Still another modification is shown in a folding Hawk-eye (Fig. 6), the front of which folds down and forms a baseboard, on which the inner body is supported when drawn out, and on which it is adjusted

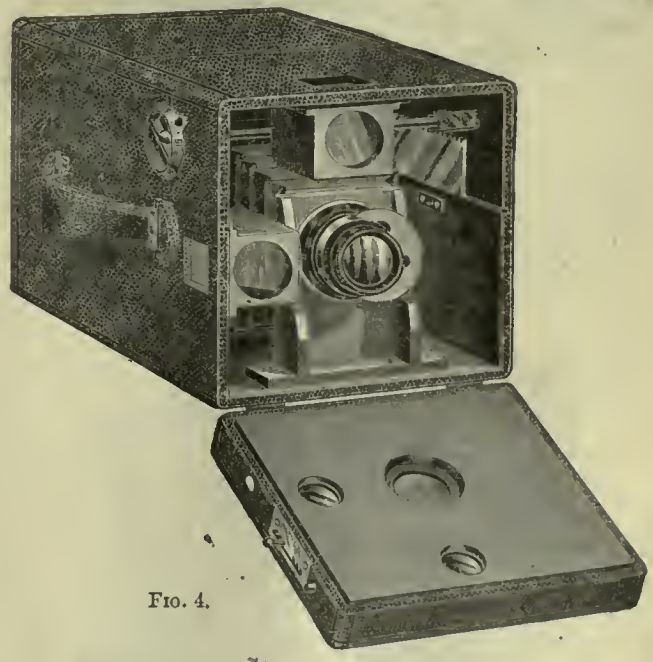

Fig. 4.

by rack and pinion. The one here shown is made for 7 × 5 plates or films. It has a double swing and a double sliding front, is fitted with a Bausch and Lomb iris diaphragm shutter, and a Taylor & Hobson lens. Several of the Hawk-eyes, especially the folding ones, are made for sizes up to 8½ × 6½, and have aluminium fittings.

Probably the neatest, most compact, and elegant of the whole series is the one we now show (Fig. 7).

When folded up, it is thin—somewhat like a moderately thick book—but, when unfolded, presents the appearance shown. It is fitted

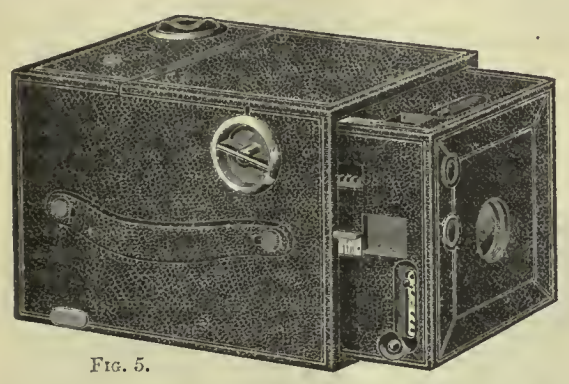

Fig. 5.

with a roll-holder, with a capacity of fifty 5×4 exposures. It is designated "The 400," doubtless out of deference to the *élite*, or west-enders of New York and Boston, to whom this numerical term is

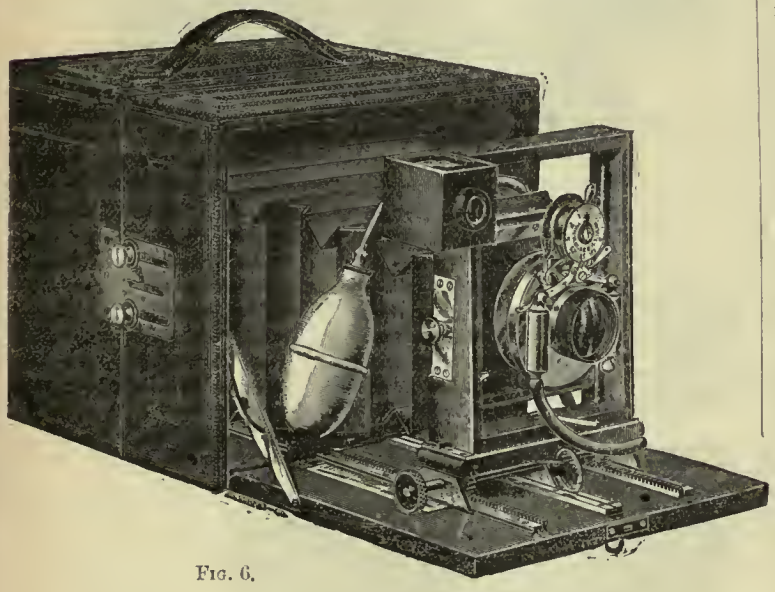

Fig. 6.

applied, and who allow no considerations of expense to stand in their way of obtaining a high-toned instrument.

The cameras now described and illustrated will enable our readers

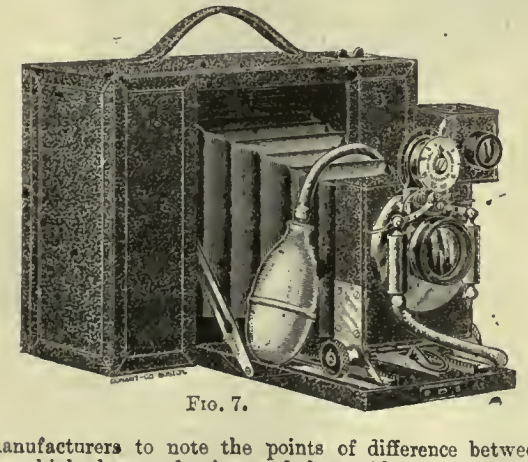

Fig. 7.

and manufacturers to note the points of difference between these American high-class productions and those of home manufacture. It only remains to be said that the workmanship on the former is equal to the ingenuity displayed in their design and construction, and reflect the greatest credit upon Mr. Blair.

ROYAL CORNWALL POLYTECHNIC SOCIETY'S EXHIBITION AT FALMOUTH.

Judges' Report on the Photographic Department.

The Judges on examining the exhibits were much impressed by the general high level of excellence reached by most of the exhibitors, and by the almost total absence of mediocre and common place work.

In many exhibitions the fact that wall space is paid for seems to deter the Hanging Committees from excluding any work that may be sent in, lest the finances should suffer, and the result is that the good work has often to be painfully picked out from amidst very inferior surroundings. This the Judges are glad to observe is not the case at Falmouth, and the absence of any charge for wall space, and the distinction conferred by winning the medals of the Society, have the effect of encouraging merit and excluding the failures of the incompetent.

Turning now to the exhibits, and taking them in the catalogue order, the Judges observed that Nos. 701–704 (R. Terras), although sharp enough in one plane, have little depth of focus, and the very dark backgrounds swallow up the subject. Nos. 708–711, by the same artist, are well composed and well lighted, though low in tone, but the detail is not sharp, and the models unprepossessing. No. 713 (R. H. Lord, first silver medal), is one of the most perfect things of its kind ever produced, even by the famous Rejlander, and has all the character and humour of a Webster, with better drawing. Nos. 714–718 (R. Frost, first silver medal for 714, *Iris*), are remarkable for the perfect focal rendering of the different planes of the objects, and for the exquisite delicacy of the gradations in the high lights of the petals. This is particularly seen in the prints on gelatino-chloride paper, and the picture No. 715 on bromide paper, shows strikingly its failure in that direction.

Nos. 720–724 (J. H. Coath, first bronze medal) are cleverly told stories, but are somewhat too suggestive of the shop show-frame.

Nos. 734–739 (W. J. Byrne).—Of these, No. 735 (first silver medal), *A Budget of Newspapers*, is delightfully original, well thought out, and capitally photographed. A little variety in the models would have improved it. Another first silver medal was awarded this artist for No. 738, *The Judging at Richmond Horse Show*, a good series of quick outdoor work in a branch unaccountably much neglected by professionals.

Nos. 740–744 (E. D. Lavender, first silver medal).—Two large frames of panel portraits in platinotype, as good in all respects as it is possible to make them, and three large direct portraits, of which No. 744 is perfectly charming.

Nos. 748–750 (E. Scamell, first bronze medal for No. 750).—No. 748, *At Home Portrait*, should have stopped there, and No. 749, *The Houses of Parliament*, are spoilt by an obtrusively painted-in boat; but No. 750, *Interior of St. Mary's Church*, is a splendid specimen of a church interior in correct perspective, and well worthy of a medal.

Nos. 757–760 (F. W. Edwards, first silver medal).—*Interiors of Westminster Abbey*. Perfect work printed in a most unpleasant colour.

No. 764 (J. H. Gear, highly commended).—Cattle lying down and nicely grouped. No. 767, by the same artist, is a beautifully rendered picture of the shrine of Edward the Confessor, and the difficulties of halation are quite successfully overcome in this case.

Amateur Section.

Amateur photography does not show up this year so well as usual, hand-camera work, the speciality of the amateur of the latest fashion in photography, being badly represented, and the more serious work of the scientific amateur hardly at all. The faults of under-exposure and lack of sharpness are painfully visible.

Nos. 851–854 are under-exposed and considerably worked up, apparently with black chalk.

Nos. 855–860 (A. R. Dresser, highly commended) are enough to show what an amateur can do who really knows something of the art. No. 859, a study of the heads of two "doggy" gentlemen, is full of character, as is also No. 855 by the same artist.

Nos. 871–874 (C. Court Cole), stained-glass windows, rendered on isochromatic plates in something like their true value, and also Nos. 875–878 (first bronze medal for No. 877) beautifully crisp Thames scenes, with sky and its reflections in running water perfectly rendered.

Nos. 879–882 (C. R. Taunton, first bronze medal for series).—Hand-camera work, tolerable, but under-exposed. Pity there was not a better display in this popular branch.

Nos. 883–885 (E. Dockree, first bronze medal).—Good and correct studies of architecture.

No. 887.—Ought not to have been sent; they look like first attempts with an objective, not corrected for photographic use; the magnification is insufficient, and the definition left out.

Nos. 888–894 (A. W. Gotlieb, first bronze medal for No. 893).—Meritorious.

Nos. 895, 896 (A. G. Tagliaferro, second silver medal).—No. 896 is a well-arranged study, sharp and well composed as to details. No. 895, a French peasant girl sticking wild flowers about a wayside image of the Virgin, is equally good.

Nos. 902–908.—Fair average work; the Roman baths at Bath perhaps the best.

There was no exhibit of apparatus this year. One hand-camera holding six plates 5×4 was brought up from the mechanical department for

inspection, and this, though showing much ingenuity and admirable workmanship by its inventor, was considered too complicated and bulky for honourable mention. It showed no practical improvement on existing forms.

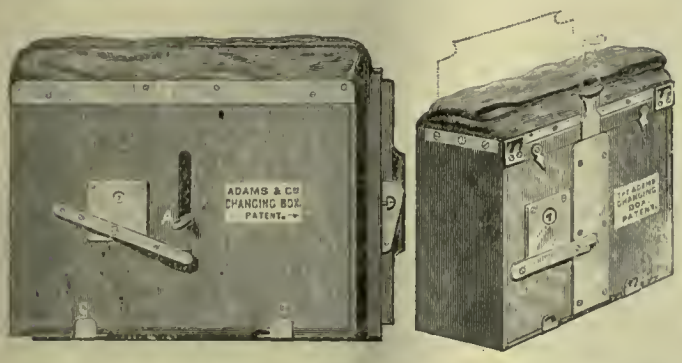
Other exhibitors in the photographic department included—Professional: Messrs. W. H. Harrison, W. Illingworth, G. T. Harris, F. A. Lee, W. M. Warneuke, W. J. Anckorn F. Whaley, Louis Duprez, M. H. Chubb, and J. A. Draycott. Amateurs: Viscount Maitland, Messrs. E. Beringer, S. Tresidder, jun., Sidney Brakspear, and Miss Katie E. Truscott.

(Signed) { W. Gage Tweedy, B.A.
{ W. Naylor Carne.

Our Editorial Table.

The Adams Changing Box.

When we say that we have, without previous experience in its use, effected the transformation from front to back of the twenty-four film sheaths enclosed in this new Changing Box of Messrs. Adams & Co., it will be seen that there is no difficulty in using it. It forms a neat package and contains either twelve glass plates or twenty-four films. By drawing up a slide at the back, the first of the series, which we will imagine has been exposed, is pulled up partially into a flexible bag above, and when grasped by finger and thumb, and drawn up until it is entirely free of the box, it is pushed down again through a suitable recess behind all the others. And thus it goes on till the last one is exposed, when an automatic check catch comes into action, entirely preventing a second exposure of the already exposed plates.



The above cuts show the box as made in two forms, the one for large and the other for smaller plates. Every plate exposed is registered automatically, and plates of varying rapidities may be placed in the box and exposed out of turn if desired. The sensitive surface of the plates or films comes into contact with the register of the box, hence the thickness of these is of no consequence. The bag is made of very soft, pliable leather, and is absolutely light-tight. Its construction is such as to afford ample room for transferring the plate from front to back without difficulty, and, taken all in all, the Adams Changing Box is singularly well adapted for its intended purpose.

A NEW ENAMEL FOR IRON.

Messrs. Fletcher, Russell, & Co., of Warrington, have introduced a new enamel which promises to prove both useful and ornamental, even to such utilitarian objects as cast-iron gas burners, as it entirely prevents rust and stands heat. The film of enamel is so thin that the most microscopic details on the metal are unchanged. The application is new, and admits of a large extension for permanent decorative work of all kinds; castings protected in this manner are not only capable of fine artistic treatment, but they are absolutely permanent and proof against dirt and smoke, which disfigure other work so rapidly.

News and Notes.

*** "Editorial Table," and several "Answers to Correspondents" unavoidably held over.

Photographic Club.—September 27, *Enlarging.*

Northern Photographic and Scientific Association.—September 23, Welwyn.

Hackney Photographic Society.—September 26, *Bromide Enlarging*, by Mr. R. Beckett.

London and Provincial Photographic Association.—September 23, Mr. A. Haddon demonstrates the preparation of plaques for vitro-enamel work. Visitors welcome.

Photographic Society of Great Britain.—Tuesday, September 26—Technical Meeting, at the Gallery, 5A, Pall Mall East. Explanation of the apparatus in the Exhibition by the exhibitors.

On Saturday, September 30, the annual joint outing of the members of the Photographic Club and the London and Provincial Photographic Association will take place to Hampstead. Tea at the "Bull and Bush" at six o'clock.

We are sorry to learn of the death, on Tuesday last, of Mr. W. Morley, the well-known dealer, of 70, Upper-street, Islington, N. The deceased gentleman had a long connexion with photography, to which we hope to refer in detail next week.

Leytonstone Camera Club.—September 23, Along the River Roding, second section from the Red House Bridge, Barking-side. Leader, Mr. F. W. Wates. The Club will assemble at headquarters at three o'clock. Open Social Evening at headquarters at eight o'clock.

People's Palace.—The calendar and syllabus of evening classes for the session 1893-4 is published. Mr. Charles W. Gamble is the lecturer on photography, the courses embracing negative-making, printing, optics, and practical instruction. Mr. Redmond Barrett is the professor of retouching, and the syllabus of the subject shows that it is to be treated completely and practically.

Photographic Section, Stanley Show.—The following gentlemen have kindly consented to act as Judges at the Photographic Section of the Stanley Show in November:—Messrs. J. Traill Taylor, Henry Sturmey, and E. J. Wall. All communications respecting the Photographic Section to be addressed to Walter D. Welford, manager Photographic Section, Stanley Show Office, 57, Chancery-lane, W.C.

Scene: Large West-end photographic establishment. Dark room—Two young assistants developing. Busybody housekeeper, bursts into dark room without knocking. Assistants, most anxious to save their plate from fog, frantically cover their plate and dish with anything that comes first. Busybody Housekeeper: "Ha! ha! my young friends, you are doing something, I am sure, you are ashamed of, or you wouldn't cover it up in such a hurry!"

Central Photographic Club.—We are glad to learn that the Central Photographic Club is at last *un fait accompli*. It has found a home at Coleman's Hotel, Henrietta-street and Maiden-lane, Covent Garden, where club comforts, conjoined to a reduced tariff for town and country members, will be obtainable. At the meeting held on the night of Wednesday week, the rules were revised and a committee appointed. Friday was selected as the meeting night.

A professional photographer writes: "I have been much troubled with old plates which on development have a band round the edge and are otherwise defective, also with plates of different batches which are not uniform in quality, being supplied through dealers. I think we ought to be able to get plates with the date marked on every box and batch number; in the collodion days each bottle of collodion had the date marked on the label when it was made."

A New Society for Queensland (Australia).—A Society was formed on July 8, 1893, called the Ipswich and West Moreton Amateur Photographic Society, having for its headquarters the town of Ipswich, in the colony of Queensland, Australia. It was decided to hold the meetings on the second Thursday and last Wednesday of each month, and the annual meeting on the second Thursday in the month of July of each year. The following office-bearers were then elected:—*President:* Dr. Lightoller.—*Vice-President:* Mr. Bostock.—*Committee:* Messrs. Carey, Ward, and Edwards, who are to act with the other office-bearers.—*Treasurer:* Mr. Durno.—*Secretary:* Mr. T. A. Darker, care of R. T. Darker, Locomotive Superintendent, Government Railway Works, Ipswich, Queensland, Australia.

Nottingham Mechanics' Institution Camera Club.—Annual Exhibition and Prize Competition, 1893.—The following are the Club prizes:—Class I., Instantaneous: prize for best set of three; certificate for second set, donors the Committee. Class II., Landscape: prize, value 1*l.*, for the best set of three, donor Mr. S. Bourne, J.P.; certificate for second set, donors the Committee. Class III., Portraiture: prize for best set of three; certificate for second set, donors the Committee. Class IV., Lantern Slides (the slides winning the medals to become the property of Messrs. Guy & Co., and the set, winning the certificate to become the property of the Club, the donors of the prizes): silver medal for best set of six; bronze medal for second best set of six, donors Messrs. Guy & Co.; certificate for third best set of six, donors the Committee. Class V., Pictures taken at the Club Excursions: prize, value 1*l.* 1*s.*, for the best set of three; certificate for second set; donors the Committee. The above classes are open to members only, and subject to the competition rules of the Club. Survey Exhibition Work, 1893.—Class VI., Six Photographs of Street Scenes in the Borough of Nottingham: first prize, silver medal, donor Mr. Councillor A. Pratt; second prize, certificate, donors the Committee. Class VII., Six Photographs of Nottinghamshire Churches—Three Interior and Three Exterior: first prize, silver medal, donor the Hon. Secretary; second prize, certificate, donors the Committee. Class VIII., Three Photographs of Buildings in the Borough of Nottingham: first prize, silver medal, donor Mr. Councillor J. A. H. Green; second prize, certificate, donors the Committee. Class IX., Three Photographs of Nottinghamshire Peasantry: first prize, silver medal, donor Mr. A. Flowerdew; second prize, certificate, donors the Committee. Class X., Six Photographs of Places of Interest in the County of Nottingham, not included in the previous Classes: first prize, silver medal, donor Mr. G. H. Wallis, F.S.A.; second prize, certificate, donor, the Committee. Classes VI. to X. are open to any one, either members of the Club or non-members, subject to the competition and Survey Exhibition rules of the Club. All photographs, either for exhibition or competition, to be sent in to the Hon. Secretary on or before December 1, 1893.

THE PHOTOGRAPHERS' BENEVOLENT ASSOCIATION.—Committee meeting was held on Friday, September 15, at the rooms of the Photographic Society of Great Britain, Mr. A. Mackie in the chair. The applications for assistance were as follows:—First.—An assistant who stated that he had come from the North of England on an engagement with a London photographer, and had been dismissed after working two and a half days without notice or salary in lieu of notice. He asked for legal assistance in obtaining the money due, and a small loan to enable him to live until he could obtain the arrears or find a new situation. An immediate loan of 1*l.* was granted, and the Secretary was instructed to instruct solicitor to proceed for recovery. Second.—Application for loan of 20*l.* from assistant who stated that his wife had been seriously ill for ten months, and was now quite unlikely to recover. The doctor's and other expenses had taken the whole of his savings, and he was now threatened with proceedings for rent and rates. The loan was granted. Third.—Application for a grant of 1*l.* to enable the purchase of a larger camera than the one at present possessed by applicant. He stated that he had been thirteen years in one situation, not as a photographer, and that he earned additional money by practising photography. In his situation he was receiving a salary of 18*s.* per week. The loan was refused, as the Committee considered it was not a fit case for assistance. Fourth.—Applicant wrote from a workhouse infirmary. He stated that he was to be discharged cured in a day or two, after being in the institution three months. Applied for a grant of 8*s.* for railway fare to a town where he had promise of wet-plate work, and a few shillings for subsistence until first wage should be due. A grant of 15*s.* was made. Fifth.—Application for loan of 5*l.* to enable applicant to pay small debts and reach a situation. Referred back to Secretary for further particulars and inquiries. Sixth.—Application for assistance, sum not stated, by an operator who stated that he was penniless owing to illness, which had prevented him working for some months. Referred back for further inquiries to be made. Seventh.—Application for loan of 20*l.* to assist in building a studio. Applicant had been many years in business, and stated the reasons which had caused him to fail. He had very small amount of capital in hand, and required 20*l.* further to enable him to start again. Referred back for further inquiries. The Secretary reported on the position of several persons who had been assisted during the spring, and said that two of them who appeared to be in a position to repay, at any rate, a portion of the loans granted to them had failed to do so. The Secretary was instructed to write these people further, and to take advice as to the possibility of instituting County Court proceedings in one case, and criminal proceedings in another. The Secretary reported that several of the applicants who had been assisted last winter and during the spring were progressing favourably. Arrangements were made for the lantern evening, which had been granted to the Benevolent by the Photographic Society of Great Britain. Messrs. E. Floate, Frank Hallen Smith, F. Nunn, J. H. Napier, W. T. M. Davidson, A. D. Fisher, McIsaac & Riddle, and Misses Hardy and L. Hicks were elected subscribers. Mr. George Mason was elected an honorary life governor. Donations of 5*l.* 5*s.* from Mr. George Mason, 5*l.* from the Convention, per Messrs. W. D. Welford and Hedley M. Smith were acknowledged with thanks.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

SEPTEMBER 14,—Mr. J. Weir-Brown in the chair.

PHOTO-HELIOCHROMY.

Mr. T. BOLAS showed specimens of three-colour heliochromy made at the State Paper Office, St. Petersburg, under the direction of M. Weissenberger, who was engaged by the Russian Government to work out the process. The subjects embraced landscapes, portraits, and old street views. He (Mr. Bolas) thought the results went beyond anything in the nature of three-colour printing on paper hitherto produced. The general effect was such as a skilled lithographer would not get with twenty stones by ordinary chromo-lithography. The general principles of three-colour heliochromy were set forth by Henry Collen many years ago, three negatives being taken, each one corresponding to one of the primary sensations, and printed in pigment or superimposed in some other way. Mr. Bolas showed, besides the finished results, prints in yellow, red, and blue. The printings were made in that order. A different effect would be produced if they were not printed in that order. As examples of photo-heliochromy, the results shown by Mr. Bolas were considered extremely fine.

In reply to the Chairman, Mr. BOLAS said only about two hundred first-class impressions could be obtained from one plate. If more were wanted, it was easy to make fresh plates. The results he showed were really photography in colours, no work being introduced beyond careful manipulation.

The CHAIRMAN observed that the process might easily fail in the hands of a cheap printer.

Mr. W. E. DEBENHAM remarked that it was essential that the superposed colours, and especially the last, should be transparent, although the first one might be opaque.

Mr. BOLAS pointed out that each separate colour picture seemed to be wonderfully complete in itself. This seemed to point to the fact that ordinary objects radiated all colours.

EFFECT OF METOL ON THE SKIN.

Mr. J. A. SINCLAIR had been developing largely with metol, and had found that the latter had a painful effect on the skin, ammonia being the alkali.

After the discussion of other matters the meeting adjourned.

MANCHESTER PHOTOGRAPHIC SOCIETY.

SEPTEMBER 14, Mr. A. Brothers, F.R.A.S. (vice-president) in the chair.

Mr. S. HERBERT FRY gave an address and demonstration on the "Sandell" multiple-coated dry plates. His contention was that with these plates the photographer was freer to devote his attention to the selection and posing of his pictures, not being hampered with so many technical restrictions, the double and triple films giving a great amount of latitude in exposure, and if developed in an intelligent manner, having regard to the action of the varying sensitiveness of the different films, good negatives could be produced of subjects which, with single-coated plates, would require an extra amount of care and preparation.

Hackney Photographic Society.—September 14, Mr. J. O. Grant in the chair. Messrs. Dean, Fort, Moore, Roberts, and Roofe showed work. From the question-box: "In taking photograph of factory with men at work, what kind of plate should be used?" Summarising the replies, backed and very rapid plate advised. Mr. BECKETT had tried Powell's backing, and would expect it to answer for all ordinary cases. Mr. SODEAU said, when caramel is slow in drying, he would advise applying a piece of slightly greased paper to the back of the plate before applying the backing. The Hon. Secretary showed one of Dyson's vignette backgrounds. Considering the price, it was thought wonderfully cheap. Mr. Barker showed a platinotype print much marked. The paper appeared at fault. Mr. Fort showed a negative having a mottled sky. It was thought irregular drying was the cause. Mr. F. W. Dodd showed a negative having marks on. The HON. SECRETARY thought the negative had been rubbed whilst wet. Mr. Gosling showed a negative which, by retouching, had been cured of line-markings. Mr. Dean showed a negative with silver stains. Methylated spirits were advised being used. Mr. Hudson handed up some negatives on which he failed to secure proper density. Mr. BECKETT said they were much under-exposed.

East London Photographic Society.—September 12, Mr. E. Stone occupied the chair.—Mr. Aldridge showed two whole-plate negatives, one an improved plate and one a Barnett, both of good quality. Prints shown by Mr. G. E. Bennett, and also some lantern slides. The date for sending in prints for the forthcoming Exhibition was altered from October 10 to October 24 for members' classes only. Mr. WILKINSON showed a very neat method of mounting P.O.P., which was to take the print from the water, lay it face downwards upon a slab of glass, remove the surplus water with a piece of blotting-paper, then apply the mountant (starch preferred), and place upon the mount. This, he said, gave a very nice finish to the picture. The HON. SECRETARY announced that at the next meeting (September 26) Mr. S. H. Fry would give a demonstration upon Sanedl plates.

FORTHCOMING EXHIBITIONS.

1893.	
September 25–Nov. 15	*Photographic Society of Great Britain, 5A, Pall Mall East, S.W. Assistant Secretary, R. Child-Bayley, 50, Great Russell-street, W.C.
October 1–31	*Hamburg. Das Ausstellungs Committé des Amateur Photographen Verein, Schwanenwik, 33, Hamburg.
,, 2–14	Midland Camera Club, Botanical Gardens, Moseley, Birmingham. Hon. Secretary, C. J. Fowler, 4, Woodstock-road, Moseley, Birmingham.
,, 9–Nov. ...	*Photographic Salon, Dudley Gallery, Piccadilly, W. Hon. Secretary of Organizing Committee, A. Maskell, 215, Shaftesbury-avenue, W.C.
,, 17–19	*Hackney Photographic Society, Morley Hall. Hon. Secretary, W. Fenton Jones, 12, King Edward-road, Hackney, N.E.

October 30, 31 ..... *East London Photographic Society, New Tabernacle, Old-street, E.C. Hon. Secretary, W. R. Gould, 61, Gibraltar-walk, Bethnal Green, E.

November 7-11 ..... *South London Photographic Society. Hon. Secretary, C. H. Oakden, 51, Melbourne-grove, Dulwich, S.E.

,, 20-25..... *Leytonstone Camera Club. Hon. Secretary, A. E. Bailey, Rose Bank, South-west-road, Leytonstone.

December..... *Madras. The Hon. Secretary Amateur Photographic Society, Madras.

,, 18-Jan. 22, 1893 *Bristol Triennial International Academy of Arts, Bristol. Hon. Secretary, F. Bligh Bond, 36, Corn-street, Bristol.

* Signifies that there are open classes.

PHOTO-MICROGRAPHY.

To the EDITOR.

SIR,—Touching the letter of Mr. Ives to you in your issue of September 15, may I offer a few remarks? Mr. Ives' first point evidently is that some achromatic microscopic objectives are as good as, or better than, apochromatics. In low powers he knows of some achromatics "with flatter field and greater resolving power than the Zeiss apochromatic of the same focal length." These achromatics "define details so minute that it is only just possible to see them with the naked eye in the photographs" which are at about × 30, if I read aright. When it is considered that the Zeiss one-inch apochromatic has numerical aperture 0·3, and will resolve somewhere near 38,000 lines to the inch with photographic light—rays of the spectrum—Mr. Ives' description of his low-power achromatic will strike the average microscopist as somewhat vague, to say the least. Does Mr. Ives suggest that a Zeiss 24 mm. glass will *not* resolve details so minute that it is "only just possible to see them" with the unaided eye at × 30? If so—and I can see no other meaning in his words—he certainly has much to learn about apochromatic glasses, as, indeed, I have suspected from the first. I cannot gainsay Mr. Ives' statement about the comparative flatness of field of his achromatics and Zeiss apochromatics at equal apertures and magnifications; but I have never seen, nor till now heard of, achromatics surpassing apochromatics in this matter, especially in the lower powers.

Mr. Ives goes on to say that an achromatic objective has been made which resolves *A. Pellucida* "with ordinary white cloud and mirror illumination." I have also heard that about seventeen years ago this diatom was resolved in America with a quarter-inch objective. I cannot contradict either statement. I suspect we require a definition of the word "resolution."

Mr. Ives overlooks, or rather distorts, what I wrote about my own repeated statements as to the good qualities of achromatic glasses. I did not write that I had made the statement in "one" paper or journal; what I wrote was that I had made the statement in nearly all my communications, oral and written. My impression is that I have never once omitted to say that good work can be done with achromatic glasses, and more than once I have shown what I called good work done with such objectives.

I had no idea of sarcasm in thanking Mr. Ives for recommending my book, nor is there any need for Mr. Ives' production of evidence in proof of the quality of his own work. As I have never seen any of his work, I could not very well belittle it; but if he wanted evidence of his powers, surely he might have found something more convincing than ordinary journal criticism. I, too, have produced work with ordinary glasses which was used as proving the fine quality of the objectives; but the work was not to be compared with what I did with apochromatics, and nobody thought it was. I cannot see what bearing on the matter has the fact that Dr. Nicol took for aristotypes what were albumen prints, nor was I aware that Dr. Nicol was an authority on photo-micrography, though he is pretty smart in matters of ordinary photography. If Mr. Ives did not get beyond "beads" on *S. Gemma*, he did not get very far ahead, and why he used such an aperture as 1·3 for this exploit I cannot conceive. As to "secondary structure of diatoms," that is a very wide phrase; a half-inch or even a one-inch apochromatic will show this in some diatoms. Mr. Ives does not tell us whether he has seen the work of the men I named in my last letter—Nelson, Van Heurck, Comber, Smith, &c.—but I think he ought to make himself familiar with this class of work, and try to rival it with his achromatics, and *then* let us have his opinion on the relative merits of the glasses. It is no good to say so-and-so can be done with achromatic glasses; let Mr. Ives do it and show it. I never could do it, and I have never met any one who could.

By "highest-class" work I mean the most difficult work with the best results. As tests of Mr. Ives' ability and of his achromatic glasses, I suggest:—A good clear resolution with oblique light of *A. Pellucida* in *striæ*, the white intervals about four times as wide as the black lines—I say nothing about "dots"—a fair resolution of the same diatom with axial *conified* illumination. *C. Asteromphalus* with *dots and festoons*, *N. Rhomboides*, or even *S. Gemma* in dots. If he does not care to tackle diatoms he can amuse himself with the spike and barb on human spermatozoon, or even the *flagellum* of one of the smaller bacteria—say, *B. Termo*. When these are as well done with the achromatic as they have been done with the apochromatic, Mr. Ives can report progress, and we will try to find him something still more fascinatiog.

It may be, as Mr. Ives says, that there are achromatics equal to apochromatics. All I can say is, that I have never seen them, and would very much like to see even one of them. "Achromatic" and "apochromatic" are not merely trade designations; they represent different glass metals and different constructions. I have always understood "real authorities" to pronounce the latter to be superior to the former, and in my own experience they have shown themselves very distinctly superior. Apologising for the length of this letter,—I am, yours, &c.,

ANDREW PRINOLE.

P.S.—Mr. T. F. Smith and I have in the main agreed from the beginning as to facts, only we went to different lengths. Ordinary "uncorrected" glasses are made for the visual rays specially; colour-corrected plates are abnormally relatively sensitive to the same rays. I take it that the colour-correct plates pick out, and are affected by the rays which they absorb and are specially sensitive to, and reject the outstanding spectrum rays which with an ordinary plate are taken up and represented by blur. But I do not at all plume myself on being a theorist.

"ALUMINIUM *VERSUS* MAGNESIUM."

To the EDITOR.

SIR,—In your issue of September 7, 1893 (page 572), mention is made of "Aluminium *versus* Magnesium." I, and no doubt many other photographers, would esteem it a favour if Mr. Bolas or some other gentleman would be kind enough to inform me, through your columns, where "aluminium powder" of sufficient fineness to use in an ordinary flash lamp could be obtained, and its price, post free, per ounce, as I am desirous of taking portraits and groups by artificial light during the coming winter, and would like to give the aluminium powder a trial.

Can the oily matter with which the above powder seems to be at present contaminated be removed by stirring it up in *strong methylated spirit* and, after pouring the latter off, drying the powder on blotting-paper in the air, or should it be placed *in ether* after the spirit, in order that the powder may dry more rapidly after being freed from the oily matter? If the above process would not be suitable, would treatment with a solution of soda or potash be effective, removing the alkali afterwards by several waters? If not, how is it to be extracted? Any information on the above will greatly oblige.—I am, yours, &c,

J. T. HACKETT.

The Victoria Studio, Albert-street, Fleet, Hants, September 12, 1893.

HACKNEY PHOTOGRAPHIC SOCIETY'S EXHIBITION.

To the EDITOR.

SIR,—Will you allow me to correct a wrong impression which appears to exist about Class F in our forthcoming Exhibition? It reads as though amateurs are excluded. This is wrong. Amateurs are not excluded this class, the idea, in the first place, being to permit photographic firms to compete as such—*i.e.*, not being compelled to be the work entirely of one man. It would be better understood if the words "Professional class—no restriction" were expunged.—I am, yours, &c.,

September 18, 1893. W. FENTON JONES, *Hon. Sec.*

A CORRECTION.

To the EDITOR.

SIR,—I find two typographical errors in my letter (pp. 598–599). In the fifth paragraph "the proboscis" should be "the proboscis of a blow-fly." In the sixth paragraph, "provided that the photograph with the achromatic" should read, "provided that the photograph with the *apo*-chromatic," &c.—I am, yours, &c., F. E. IVES.

116, *Charing Cross-road, London, W.C., September* 15, 1893.

Answers to Correspondents.

*** *All matters intended for the text portion of this* JOURNAL, *including queries and Exchanges, must be addressed to* "THE EDITOR, THE BRITISH JOURNAL OF PHOTOGRAPHY," 2, *York-street, Covent Garden, London. Inattention to this ensures delay.*

*** *Correspondents are informed that we cannot undertake to answer communications through the post.*

*** *Communications relating to Advertisements and general business affairs should be addressed to Messrs.* HENRY GREENWOOD & Co., 2 *York-street, Covent Garden, London.*

*** *It would be convenient if friends desiring advice respecting apparatus, failures in practice, or other information, would call at the Editorial Office either on Wednesdays from* 4 *to* 6, *or Thursdays from* 9 *to* 12 *noon, when some one of the Editorial staff will be present.*

*** Several answers are unavoidably held over.

J. H. A.—We note your remarks.

A. B.—Write to the Superintendent of Police of the locality named and state the case.

J. E. G.—The "Kangaroo" changing-box, by J. R. Gotz, 19, Buckingham-street, Strand, W.C.

A. C. TYLER.—We do not know the name and address of the maker of the "Excellens" lenses.

G. V. S.—Use your ordinary developer, but increase the reducing agent, and diminish the quantity of alkali to commence with.

S. W. B.—The solution should be clear. We cannot account for the blue colouration on the data given. Let us have samples of the ingredients of the developer.

WASP.—1, 2, and 3. Place the solutions in one receptacle, and precipitate with potassium sulphide ("liver of sulphur"). 4. Proper exposure and a sufficiency of amidol. 5. Possibly not. 6. Messrs. Marion & Co.

G. B.—1. The collodion you are using is unsuited for enamelling. It should dry transparent. 2. To prevent collodion from leaving the glass, run a little diluted albumen around the margin. 3. Filter the gelatine solution.

49.—We have no experience with the formulæ, but the reason that one advises a much larger quantity of pyro than the other is due to the fact that it is meant for rapid plates, while the one with the smaller quantity is for slow plates.

SPOTTY.—The spots look as if caused by iron or other impurity. Carelessness as regards particles of dust may cause them, as the dust stirred up in a photographic dark room is usually of a highly complex and deleterious character. This, however, is merely a suggestion, beyond which we fear we cannot help you.

LIVERPOOL.—Eosine is seldom to be obtained at an ordinary chemist's, but it is kept by most drysalters or dealers in dyer's material. There are several varieties of it, but the best way to ensure having the right kind for photographic purposes is to obtain it from such a house as that of Hopkin & Williams, Cross-street, Hatton Garden.

T. H. B.—By the way the sheets are described as sticking together, it is obvious that the paper has been kept in a damp place, and has absorbed sufficient moisture to soften the albumen. Under these circumstances we are not surprised that the paper, after sensitising, prints with a mottled appearance.

H. NEVILLE.—The best lens for taking portraits in an ordinary room is the "Petzval" form—the ordinary portrait lens—on account of its rapidity. Next to this a lens of the "Rapid" type would be the most useful. Of course, any lens would do equally as well as either of the above if the time of exposure were not a consideration.

WINDONE.—Canary medium is a very pleasant light to work with, and two thicknesses in front of a No. 3 fish-tail burner would be quite safe, and supply sufficient illumination. Although this medium is trustworthy with ordinary plates, it would not be so with plates orthochromatised with eosine, as they are sensitive to the yellow rays. When using such plates, the medium should be supplemented by one of red—say, a sheet of ruby glass.

S. E. WALLEY.—The stereoscopic lenses may have been accurately paired; but, as you say one has been used much more than the other, it is probable that the blacking on the tube of that has become, to an extent, polished, and so reflects a certain amount of light. If this be the case, one half of the negative might have the appearance of having had more exposure than the other. Probably, if both tubes were reblacked, the lenses would be found in unison.

AMATEUR.—It is very doubtful if the district surveyor will permit you, although the neighbours may not object, to erect a studio in the back garden constructed of wood, zinc, and glass. According to the Metropolitan Building Act, such a building must be "fireproof." But this is sometimes a very elastic term, and it seems to vary with different surveyors. Our advice is to consult that functionary before commencing the erection; it may save a deal of trouble in the end.

S. PANNELL.—The doubled appearance in the negative is due to movement. If you are sure that the camera did not move during the exposure, the plate must have dropped in the slide, owing to its not being placed at the bottom of the rabbet, and the spring being too weak to retain it in position.

NOVICE says: "In my first attempt at sensitising albumenised paper, I made my fingers in a sad mess, which sand and pumice would not remove; and I also got some on my cuffs and handkerchief. Can you tell me how to get them out?"—The rough-and-ready way is to treat them with a strong solution of cyanide of potassium. A more refined way is to treat them, in the first place, with a solution of iodine in iodide of potassium, followed by one of hyposulphite of soda or cyanide of potassium.

MECHANIC.—There is no firm in London that make a speciality of supplying apparatus and material for Woodburytype printing, and we cannot say where the paper ready prepared is to be had. This process is very little worked in this country now. Only two or three firms, we believe, work it to any great extent. One or other of these may supply you with the paper. Try Waterlow & Sons or Eyre & Spottiswoode. Liesegang, of Düsseldorf, used to stock Woodburytype papers, and, so far as we know, does so still.

T. COURTENEY says: "In sensitising albumenised paper I am much troubled with a marbled-like appearance on the surface. Some sheets are worse than others, and some are quite free from it, although the same solution is used. What can be the cause?"—It arises from scum on the solution. This is almost sure to form if the solution is allowed to remain an hour or two in the dish out of use. The surface of the solution should always be skimmed by drawing a slip of blotting-paper over it before recommencing to sensitise.

C. W.—Coignet's and gelatines of a similar kind are not suitable for mounting photographs, as they set too quickly when applied to the print, and hence do not retain their adhesive properties. Furthermore, they are usually decidedly acid, a thing to be avoided with silver prints. The sort of gelatine best for the purpose is one of a poorer quality, as a gelatine such as those sold as "soup strengtheners." These, if of English make, are generally quite free from acids. Try Nelson's No. 2 Soluble. It is the best for the purpose that we know of.

R. C.—Preparing copper plates to make them suitable for photo-etching purposes from the rolled copper of the metal warehouses, is very troublesome and tedious work for a novice to undertake. It will be found, as the plates are planished, that they contain numerous small holes or indentations which have to be hammered up from the back, even after the plate has been well hammered to harden it. Anyhow, there is no harm in trying your hand at it. First clean the surface of the metal with pumice-stone and water; after that, smooth with snake-stone and water, always in one direction only. Then polish with a stick of charcoal and oil, and finally finish with the oil rubber.

G. PERRY says: "I have often seen it stated that lenses all work with the same rapidity, provided the ratio of aperture to focal length is the same. My reason for doubting this is that I have two lenses of the same form (rapid rectilinear type), one is a whole-plate, and the other a ten by eight. When used with their full apertures *f*-8, or with smaller stops, the latter is always the quickest. I at first thought that the ratio of the stops was not the same with both lenses, but by careful measurement I find they are. Why, then, is one lens quicker than the other?"—All things being equal, the rapidity of the lenses should be identical; but there are disturbing causes. The glasses of one instrument may be more colourless than those of the other, or the balsam with which those of one is cemented may have become yellow. If the glasses be laid singly on a sheet of white paper, no doubt a difference in colour will be detected which will account for the discrepancy.

T. BIGGS writes as follows: "I have made several attempts at carbon printing, but cannot manage the development satisfactorily. I cannot hit the right time to stop development. Sometimes the prints, when finished, are too light, and at others, although some parts of the face are light enough, the darker portions of the picture are too dark, and are not distinct; they appear to have a lot of unaltered gelatine that seems as if it ought to be washed away. Can you give me any idea how long I should develop at a given temperature of water, say, 100°?"—Our correspondent's trouble arises entirely from under-exposure. The prints have not been exposed long enough to fix the image in the lighter parts, so as to allow of the proper development—that is, the complete washing away of all the unaltered gelatine not required to form the picture. If he will give considerably more exposure, and develop the picture until it appears as it should be when finished—bearing in mind one point, however, namely, that carbon prints dry a little darker than they appear in the water—his difficulty will be at an end.

THE BRITISH
JOURNAL OF PHOTOGRAPHY.

No. 1743. Vol. XL.—SEPTEMBER 29, 1893.

HOW THE EXHIBITION STRIKES ONE.

For details of the Annual Exhibition of the Photographic Society of Great Britain we refer our readers to another article in which these are dealt with.

The first thing that strikes one is the paucity of portrait exhibits. This is a department in which amateurs cannot hope to compete with professionals, whose studios are specially arranged for it, and hence the latter, in all save a few cases, may be expected to remain masters of the field. It is in landscape or general out-of-door work that both classes compete on equal terms.

For such work photographers now seem to be getting alive to the advantages of making their prints on a rough-surface paper, and, for the purpose of producing effective pictures of large dimensions for the walls of an Exhibition, there is no doubt as to its value, especially when the subjects selected for pictorial representation are such as lend themselves to a coarse texture —that is, when they are of a broad character, and do not possess features of fine detail, necessitating close inspection. This is the fashion at present; whether it survives many years time alone must show. It need scarcely be said that this applies mainly to large pictures intended for wall decoration.

A few of those of this class in the Exhibition, whether enlargements or taken direct we need not pause to inquire, are of a cold tone, which is not by any means so attractive as when the prevalent tone partakes more of a sepia or red nature. There being such a charm about the rough-surfaced paper, it is probable that its admirers will be speedily able to procure it from all dealers throughout the land.

Instructions for converting the cold tones of enlargements produced on gelatino-bromide prints have recently been given in such full detail that it is not now necessary to refer to this topic, except so far perhaps as it refers to the more recently introduced method of toning Nikko paper by the agency of sulphur. Sulphide of silver, when produced under the proper conditions, has long been known to be a most stable substance, and we see no reason for doubting the statements of those chemists who have been making a study of this renaissance, and who say that, when produced in the presence of gelatine containing silver obtained from the decomposition of silver bromide by a developing agent, it stands every reasonable test for unalterability. We know, and every other experimentalist knows, that this is not so when produced on albumenised paper, which is a pity, as its colour is often so beautiful. But albumen and gelatine as applied to photographic surfaces, whether for negatives or positives, are two entirely different things.

How there can exist any mystery, as spoken of in a daily paper, concerning the production of one of the pictures in the Exhibition (No. 103, *The Proud Turk*, by J. S. Bergheim) puzzles us. This is a photograph on a textile fabric such as oil paintings are painted upon, and similar things were, and perhaps still are, as "common as blackberries." The production of a photograph on prepared canvas has, for much over a score of years, been a regular item in commercial photography. The dingy yellow "whites," indicating the affinity of the photographic material, whether silver or anything else, for the surface preparation of the canvas or other substance, are all there, much as they were a quarter of a century since. But it appears to have bewitched the Judges, who have awarded it a medal. The sleepy-looking eyes of this "Proud Turk," although but barely visible to the ordinary spectator, appear to have still further hypnotised the Judges, who, while under the influence, have awarded another medal to a photograph which is catalogued as having been taken by a lady, but concerning which, at the risk of being considered ungallant, we must confess to sympathising with the almost universal feeling that there are considerably over three hundred specimens in the Exhibition (there are but three hundred and thirty-four altogether) better entitled to the honour. Indeed, the picture just hinted at is such a one as is weekly exhibited at our suburban and provincial societies by neophytes of a fortnight's standing, and who want to know the causes of their failures. A wise Judge abstains from giving the reasons for his verdict, but we imagine that there will be such a strong outcry concerning the reasons which have operated in the case of the judging of the Exhibition this year as must compel them to speak out. With most of the other awards made by the Judges no particular fault is to be found.

The abolition of the screens formerly present is an improvement which seems to be appreciated by the visitors. Something like five hundred pictures are said to have been rejected; but, from what we learn from those competent to form a judgment, some of these might, with great advantage, have been allowed to supplant others now remaining on the walls. And yet, notwithstanding these grumblings, the Exhibition, as a whole, is an excellent one, and will well repay one or more visits to it.

RAPID INTENSIFICATION.

When the necessity arises for the intensification of a negative, more especially if it be wanted in a hurry, the greatest trouble arises from the very careful washing required in order to ensure the entire success of the operation. The rule holds good more or less, whatever may be the particular process adopted, and

especially so with the most generally popular method based upon the use of mercuric chloride followed by weak ammonia solution.

When the mercury salt is employed it is essential in the first place that the negative be very thoroughly washed after fixing, much more so than is requisite when intensification is not to be performed. Where time permits, the efficiency of the washing or the complete elimination of the hyposulphite is promoted by allowing the negative to dry after a fair amount of washing, and then reimmersing it in fresh water, when any remaining crystalline matter is almost instantaneously removed in a more effective manner than would be the case after a considerable prolongation of the original soaking; but, when time is an object, this course can scarcely be pursued with advantage.

Some years ago the proposal was made by a member of the Photographic Society of France to utilise alcohol for the purpose of rapidly removing hypo from the negative film after fixing, though, as was pointed out at the time, there appeared to be some misapprehension as to the precise action of the alcohol, and we question whether, applied as was proposed, the result would not be rather injurious than beneficial; but certainly alcohol may be utilised for the purpose of indirectly hastening the removal of the hypo if it will not itself perform the part of eliminator.

Thus, if a negative be taken from the fixing bath, and after a brief rinse in water plunged into a dish of methylated alcohol, the transparent portion—the shadows—will be found to be filled up with a dense opalescence, caused by the precipitation in the gelatine film of the hyposulphites of soda and silver soluble in water but not in alcohol. A portion of the salts may be thrown down in minute crystals in the liquid itself, but the bulk will remain *in situ* in the gelatine, under which circumstances they can scarcely be considered to be in a safe condition; but, if the negative be again immersed in water, the opalescence will quickly disappear, and by the time the water runs evenly over the gelatine surface all soluble matter will be found to have been practically removed by the rapid diffusion of the alcohol clinging to the film. This method of treatment, in fact, produces precisely the same effect as drying and subsequent rewashing, but in a much shorter time, and leaves the negative ready for any further treatment that may be necessary.

But the most careful washing is required after the bleaching with mercuric chloride, and it is here that most failures are made, for, unless every trace of soluble mercuric salt be removed before the application of the darkening agent, a more or less heavy veil will be formed in the shadows of the negative. Such, at least, is the case with most of the reagents employed, such as ammonia or other alkali, the alkaline sulphides or ferrous oxalate; but we pointed out some years ago that sulphite of soda differs from those in not forming an insoluble compound with the bichloride, and it therefore presents little or no chance of fogging or veiling the image if the washing be insufficient.

Sulphite of soda, however, as a rule, gives but little increase in density, the result, such as it is, being more of the character of a change of colour than an increase in the opacity of the image. When but a slight augmentation of density is necessary, sulphite answers admirably, and gives a beautifully clean and bright result, the cleanness and absence of veil going far to compensate for its inferiority in intensifying power, while the reduction in the time required in washing is an item of some importance.

Having occasion, a short time back, to intensify a negative that was required immediately, we resolved to use the sulphite method; but, unfortunately, the sulphite bottle proved to be empty. We had at hand, however, a stock solution of metol and sulphite, which was called into use in place of the plain sulphite, and with such a satisfactory result that we have little hesitation in placing it at the head of the list of reducing agents for use after mercurial bleaching. Not only does it afford the same immunity from veil and stain as in the case of sulphite alone, and the reduced necessity for prolonged washing, but it gives as great an increase of density as can be secured with ammonia, while the colour and character of the image, and the clearness and brightness of the shadows are much better. The colour is, in fact, the nearest approach to the rich purple-black of the best type of wet-collodion negative that we have yet seen, and it is entirely free from the dull opacity that too frequently marks the negative that has been intensified with mercury.

There are no special precautions to be observed beyond giving a fair amount of washing after the application of the mercury solution. Three or four minutes under the flow of a tap, or a slight wash in that manner, followed by ten minutes' soaking in two or three changes of water, will prove ample. The strength of the metol solution does not seem to be very material, though we fancy the best result is obtained with a comparatively weak solution, containing from one to one and a half grain of metol, and ten times that quantity of sulphite to the ounce. This, if kept by itself, may be used repeatedly, though, if the films are carelessly washed, it soon becomes yellow. This does not, however, destroy its reducing power, nor, apparently, create any tendency to discolouration of the film.

The negative should be removed from this solution as soon as the bleached image has been reduced throughout its whole thickness, which will be recognised by the disappearance of the white colour from the back of the plate. If allowed to remain for any lengthened period in the reducing, there is a chance of the formation of a metallic scum on the surface of the negative, which is very difficult of removal; but, if the plate be washed as soon as the required result is attained, no danger arises.

It must be understood that no alkali is added to the metol solution, otherwise the same degree of care in washing will be required as with ammonia, and the quality of image obtained with metol and sulphite will be lost. It is this peculiar character of image which, in fact, especially recommends the process, which we can heartily recommend to those desiring a rapid and reliable method of intensification.

PHOTOGRAPHING HIGHLY POLISHED SURFACES.

When an ordinary portrait photographer is called upon to take a negative of an object, or group of objects, with highly polished or burnished surfaces, he is, if we may judge from several letters received of late, sometimes at a loss how to proceed. Of course, those who are familiar with this class of work know quite well that it presents no difficulties to them, but evidently the case is different with those who are not. The topic is a wide one, too wide, indeed, to be dealt with in a single article. Therefore, we propose to divide it into two. The experienced hand is well acquainted with a series of dodges that can gene-

rally be resorted to, such as might be termed sophistication of the articles themselves. But there are cases where this is not allowable, and, even if it were, would not help matters in any material degree.

We shall here treat the matter as in the latter proposition, that is, the objects have to be dealt with as they are, leaving for a future article a series of what may be classed as "dodges," or, at any rate, means to an end. What, however, is to be said now will apply equally well even when the surfaces can, to an extent, be modified.

Let us take, in the first place, by way of example, some silver plate that must be photographed in its natural state, and some of its parts are frosted, or matt, while others are highly burnished. The latter, as seen from some directions, will appear almost, if not quite, black, while the former will be brilliantly white. To add to the troubles of the photographer, some of the articles may have an inscription that it is desired should appear in the picture. Now, it will be admitted that this is a somewhat difficult subject to deal with under any circumstances, and particularly by those unaccustomed to such work. Unfortunately, it is impossible to give any very definite instructions that will answer under all conditions. It may, however, be said that success or failure is mainly a question of lighting. It should always be borne in mind, in photographing brilliant objects, that the angle of reflection equals the angle of incidence, and the illumination must always be arranged so that the reflections are not in the direction of the lens, but away from it. Hence it will be seen that direct front light must be strictly avoided. So important is this point that, when possible, a large black curtain should be hung from the roof of the studio, in front of the camera, and not at a very great distance from the object to be copied, with an aperture only sufficiently large for the lens to see the subjects without obstruction. Next, the whole of the light from one side should be stopped out as well as that from the direct top. Here, then, we have concentrated our light, so that it comes from one direction only, and it will at once be seen, on looking at the image on the ground glass, that many of the reflections have been overcome, and detail in the high lights, which could not be seen before, are now tolerably distinct.

The light, however, requires still more concentration. This is effected by further closing the curtains and blinds on the light side, so that the direct light falls on the plate at an angle of forty-five degrees; then the reflection will be at a similar angle and quite away from the lens; that is, this would be the case if the plate were a flat surface; but, more generally than not, it has many curved surfaces of varying radii, in which case much may be accomplished by slightly turning the different objects round so as to reduce what reflections there are in the direction of the lens to a minimum. With a little care it will be found that the major portions of the reflections towards the lens may be entirely got rid of. When that is accomplished, it will be seen, on examination of the image on the focussing screen, that there is full detail in the finest engraving and chasing, but that the shadows are very dark, because highly burnished silver is black when in shadow. Therefore it is necessary, in timing the exposure, to go on the good old maxim of exposing for the shadows, leaving the lights to take care of themselves.

The development must be tentative, and the density of the image kept back until full detail in the shadows is secured. To do this effectually with subjects such as we are now dealing with will require considerable ability on the part of the operator. What will be found a better plan by some is to ameliorate the darkness of the shadows with reflected light; but it will have to be done with judgment, and care must be exercised that the light projected by the reflector is not again reflected from the silver surface in the direction of the camera. A white reflector should be avoided. One of tolerably dark blue, French grey, or light green, will be preferable. If there is much fine chasing on the work, or engraved inscriptions, it may be advisable to illuminate with a more direct side light than one of forty-five degrees, so that the edges of the lettering throw a strong cast shadow, and care must be taken that this is not destroyed if a reflector be employed.

As a further illustration of our remarks on the illumination of highly polished surfaces for copying, let us take the case of a Daguerreotype. If this be illumined by a direct front light, it is impossible to obtain a good copy, as the light from it is reflected back into the lens; but if the front light be entirely stopped off, and the picture lighted only from one side, and then in the direction in which the metal plate was "buffed," excellent copies may be obtained even if the plate was somewhat scratched in the final polishing.

What has been said with regard to plates, whether silver or gold, for there is really no difference to be made, except in the matter of exposure, applies equally well to glass and china, so far as illumination is concerned, though with the last-named, if it be elaborately painted, it will be advisable to employ orthochromatised plates, and, if blue predominates, a yellow screen as well. Jewellery generally gives some trouble, as the innumerable small facets of the gems all reflect a brilliant light, and it is impossible to so arrange them that they reflect it all in the same direction. Still, as will now be seen, much may be accomplished by paying attention to the method of lighting. Coins and medals, when the photograph has to be made direct from them, sometimes give a little trouble, particularly when the relief is low, and gold, silver, and bronze have to be included on the same plate. Here, however, the same principle is followed, and it is advisable to use a somewhat high side light, so as to produce strong cast shadows from the relievo portion.

With reference to the photographic part of the subject, much might be said; but this is unnecessary here, as we assumed, when saying that, in the development of the image, density is to be avoided till full detail is obtained in the darker portions, the operator knows quite well how that is to be accomplished. We might, however, emphasise that the chief things to be avoided in this class of work are under-exposure and forced development. If dry plates be used, they should always be backed, to avoid halation in the highest lights. If the negatives are—and more generally than not they are—required for any of the photo-mechanical processes, collodion ones are preferable, and, if they are taken, they will be best developed with a strong developer, so as to secure, in the first instance, a thin image, full of detail, that can afterwards be intensified to the required degree.

Of course, in an article of this kind, it is manifestly impossible to make reference to even a tithe of the numerous things, with highly glazed articles that have, from time to time, to be depicted by photography. But sufficient has been said to indicate to the novice the direction in which he must proceed. In another article, as already mentioned, we shall give some of the dodges often resorted to for modifying the surface of the work, when that is allowable, before operations are commenced.

The Photographic Congress.—We draw attention to the first Congress of the Photographic Society of Great Britain, which will be held at the rooms of the Society of Arts on October 11 and 12, when many important papers will be read. A special lantern display will be held at the Exhibition Gallery on Thursday, October 12, and on Friday, at the Frascati Restaurant, a dinner is projected, at which it is hoped members of many affiliated Societies, including country members who may then be in town, will be present.

Fading of Eosine.—Touching the use of eosine, which, either of itself or in one of its many compounds, is the sheet-anchor of those who make isochromatic plates, it is interesting to note the results of one of the British Association communications—that on *The Action of Light upon Dyed Colours*. The authors made a vast number of experiments with the various natural and artificial dyestuffs in use by dyers generally. They were exposed to sunlight for different periods of time in an atmosphere removed from the smoke and gases of a town. It was found that of all the reds experimented with, dyed either on silk or wool, those which were first acted upon by light were the eosines and their allies.

A New Use for the Radiometer.—It has always been looked upon as a misfortune that this marvellous instrument could not be directly utilised in photographic practice; but hitherto such has been the state of the case. It is well known, for example, that a rapid revolution can be given to the vanes by simply blowing with the mouth upon the bulb of the instrument. However, Herr N. Tesla has put the radiometer to a valuable scientific use for determining the radiant transparency of bodies. It is arranged in such a manner that its velocity of rotation is determinable, and Herr Tesla finds this velocity and the intensity of the incident light to bear a definite proportion to one another. In his paper on the subject he gives tables showing the relative transparencies of various liquids ascertained in this manner.

Cheap Aluminium.—This metal, which now forms a staple quotation in the prices of lens-makers' catalogues, though a comparatively short time ago being scarcely ever quoted, is constantly forming the subject of newspaper paragraphs, as to probable increased cheapness. Many of these are so wild as to be capable of dismissal with a smile: but the most recent utterance in this direction seems very plausible. It is to the effect that the Government chemist has returned to Washington, after examining a new process rejected by the Patent Office at first because the process was held to be impossible, a report that the plan is operative, and that he has made three entirely satisfactory tests. The discoverer of the new process and his Dulak associates assert that they can produce metallic aluminium at a price cheaper, bulk for bulk, than copper.

Mr. A. A. Common on Lord Rayleigh's Suggestion.—Writing to *Nature* upon the suggestion of Lord Rayleigh to use specially constructed isochromatic plates in preference to specially constructed expensive telescopic object-glasses, Mr. Common says of this "novel suggestion," as he rightly terms it, that "if this can be done by a variation of the photographic process without paying too dearly for it, a good deal will be gained in many ways. The great doubt in my mind is whether it is possible to get rid of the blue rays without the use of screens." He further remarks, with surprise, upon the continued preference of expensive refractors to reflectors of comparatively low cost for this kind of work. With regard to the need of a screen, it must not be lost sight of that the necessarily thick object-glass must form of itself a coloured screen, for no glass is colourless, and, in view of possible experiments on the lines of Lord Rayleigh's suggestion, it would first be eminently desirable to have some definite data as to the particular portion of the spectrum diminished by passing through the object-glass, if for no other reason than to diminish the number of factors the isochromatic plate maker would have to deal with.

A Light and Vision-measurer.—The subject of relative visual illumination of the dark room has always been a topic of importance to the photographer, and has given rise to as much discussion, perhaps, as any one disputed question in photographic technics. From the days of the great "cathedral green" controversy down to the present time a definite standard of visibility has never yet been arrived at, but a new contrivance designed by Dr. Simonoff seems to offer a fair solution of the difficulty. He arranges a book of twenty-four pages, the first being a clear grey tint, and the succeeding pages advancing evenly in increasing depth of colour till the last is almost black—twenty-four times the intensity of page one. On every page a few phrases in black letters are printed. When the illumination is very good, the printing is visible on the last page, and, as the light diminishes, the observer has to turn nearer to page one before the type is legible. The instrument is only intended to be used inside a room, and it is anticipated that it will be of value in schoolrooms. If such books were easily obtainable, and made in such a way as to be capable of reproduction in a standard manner, it would be possible for photographers in any part of the world to describe with any necessary exactitude the intensity of illumination of their dark rooms generally, or at any particular point. Such a standard would be of immense value in experimenting with various coloured media for dark-room windows.

EXHIBITION OF THE PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

The Thirty-eighth Exhibition of the Photographic Society of Great Britain was preceded, on the evening of Saturday last, by a Conversazione, to which the Council had issued numerous invitations. The President (Captain W. de W. Abney, C.B., F.R.S.) and Mrs. Abney received the guests, among whom we observed:—Mr. J. Spiller, F.I.C. (Vice-President); Messrs. T. Bolas, F.I.C.; F. P. Cembrano, jun.; T. Sebastian Davis, F.C.S.; W. E. Debenham, W. England, T. E. Freshwater, F.R.M.S.; Colonel J. Gale, F. Hollyer, H. A. Lawrance, F.I.C.; A. Mackie, J. W. Swan, M.A.; J. Traill Taylor, Leon Warnerke, G. Scamell, E. Clifton, H. Chapman Jones, F.I.C. (Hon. Sec.), Members of Council; Mr. F. E. Ives, Mr. and Mrs. Snowden Ward, Miss Taylor, Mr. R. L. Kidd and Mrs. Kidd, Mr. H. M. Dennis, Mr. G. W. Atkins and Mrs. Atkins, Mr. F. A. Bridge, Mr. E. J. Wall and Mrs. Wall, Mr. C. R. Rowe, Mr. Thomas Bedding, Mr. H. E. Davis, Mr. G. W. Webster, Mr. J. A. Sinclair, Mr. A. S. Newman, Mr. L. Medland, Mr. J. Birtles and the Misses Birtles, Mr. J. J. Gerard, Mr. F. C. L. Wratten, Mr. S. H. Wratten, Mr. W. J. Belton, Mr. H. Smart, Mr. J. W. Marchant, Mr. C. W. Gamble, Mr. W. S. Bird, Mr. Birt Acres, Mr. J. Hay Taylor and Mrs. Taylor, Mr. H. M. Smith, Mr. A. Haddon, Mr. J. S. Teape, Mr. Charles W. Hastings, Mr. Conrad Beck, Mr. A. J. Golding, Mr. J. H. Avery, Mr. J. C. S. Mummery, Mr. C. Beadle, Mr. Perigal, Mr. A. Glendinning, Mr. N. A. Monnickendam, Mr. G. Gosling, Mr. R. R. Beard, Mr. J. D. England, Mr. T. Samuels, Mr. R. Child Bayley (Assistant Secretary), and many others. In the course of the evening nearly 400 were present, and locomotion was, at all times easy on account of the abolition of screens, the rearrangement of the apparatus tables, and the improved lantern-stand, which not only improve the appearance of the room, but give increased space.

There are 334 frames of pictures on the walls, eighteen exhibits of lantern slides, &c., and forty-three of apparatus, making a total of 395, a falling off of nearly three hundred as compared with last year, when 693 was the grand total. On this occasion there are 160 exhibitors, 49 of whom are members of the Society. Last year the numbers were 202 and 64 respectively. The comparative smallness of the Exhibition, however, implies no lack of desire on the part of the exhibiting public to find a place for their photographs on its walls, inasmuch as we understand that the number submitted to the Judges exceeded that of last year, a more rigorous weeding out than hitherto being therefore responsible for the comparative smallness of the display. Nine medals were awarded, as against seventeen last year. The Judges were Mr. P. H. Emerson, Colonel J. Gale, Mr. F. Hollyer, Mr. F. M. Sutcliffe, and Mr. J. B. B. Wellington, and, as scientific experts, Mr. Chapman Jones and Mr. Pringle. Great credit is due to the Hanging Committee for the excellent disposition of the pictures,

little room being left for complaint either on the part of exhibitors or spectators.

Analysing our impressions of the Exhibition in comparative and qualitative senses, we must come to the conclusion that, though undoubtedly good, it falls behind its immediate predecessors, whether considered from general or particular standpoints. Portraiture does not shine at its best, landscape remains virtually where it was, no new advances being apparent, while in the domain of *genre* studies, architectural work, enlarging, photo-mechanieal process work, and photography in its purely scientific uses, although each department is occasionally well represented, the aggregate effect is slightly disappointing. We do not envy those who may undertake the task of selecting a series of pictures of the year for reproduction, as, in that sense of the term, there are none which stand out with sufficient distinctness from their surroundings to warrant the appellation. It is gratifying to find, however, that, while most of the old supporters of the Society have preserved their allegiance to the Exhibition, several comparatively new men have come to the fore and secured recognition of their efforts. But the awards of the Judges constitute a puzzle which it would probably baffle even them to solve now, at least four of the medals having been given to obviously indifferent photographs *as* photographs, and which, considered as art studies, could not possibly appeal to anybody as such, unless so labelled by the Judges. They remind us very much of the juvenile's attempt at animal drawing, under which, in order that his intentions should be understanded of his critics, he obligingly writes, "This is a dog."

The Medal Pictures.

Nos. 3 and 72.—A series of thirty-five prints in all, depicting life *'mongst Mines and Miners*, for which Mr. J. C. Burrows deservedly gains an award. They are taken with a combination of magnesium and limelights, and are interesting as showing various phases of mine life. But, besides this, they are equally noteworthy as triumphs over abnormal difficulties in applied photography, being well exposed and carefully printed on gelatino-chloride paper. Photography shines here in its most useful educational aspect.

No. 18, *Study of a Child*, by Mr. W. A. Cadby.—This is a weak bromide enlargement of a seated child in slight drapery. The pose of the figure is undeniably good, but it is wanting in modelling and roundness, for which the very subdued tone and delicacy of treatment scarcely compensate. All the same, it is an able piece of work.

No. 30, *Un Harem en Déplacement*, by Emile Frecton.—One of a splendid series of highly refined collotypes, showing a group of well-loaded camels in progress across a piece of desert-like country. Clever alike in selection and execution, the process chosen exactly suits the subject, and the whole is an unconventional study, well worthy of the distinction it has received.

No. 40, *Omegna, Lake Orta*, by J. A. Sinclair.—A pretty view, with sepia-like tone, the introduction of the figure of a woman in the foreground materially aiding the effect. Mr. Sinclair is a prolific contributor to the Exhibition, and, to our taste, is more successful in many of his other studies, to which we shall presently refer.

No. 55, *After Sundown*, by Charles Moss.—This is a small study, in warm carbon. The sun has set behind a mill, and the night shadows are creeping over the rugged country towards an irregular sky line. The picture is quite in the recognised style of those whose aim it is to imitate by photographic means effects obtainable by brushwork, and is clever and successful—of its kind.

No. 103, *The Proud Turk*, by Mr. J. S. Bergheim.—The head of a distinguished-looking Mohammedan, tolerably well posed and lighted. The photograph appears to have been printed on some textile support, to which a tone of a bilious yellow has been imparted. If we take away this striking characteristic, there is probably nothing left to entitle the work to higher rank than many other portraits on the wall. As to the "yellow tint," it is, doubtless, meant for something which, after forty-eight hours' cogitation, we have not discovered, so we give it up. But it is the reverse of agreeable, at any rate.

No. 241, *Figure Study*.—One of about twenty figure studies from the nude, with (where necessary, which is frequent) classical drapings and surroundings. The artist, Count W. Gloeden, has evidently devoted a lot of time and trouble to the work, and is, in the main, to be congratulated on his results. The posings and groupings are, in most cases, exceedingly skilful, while the rendering of the flesh is excellent, both in lighting and texture, no coarseness or flatness being apparent. The prints are of a warm tint, which, of course, harmonises with the subjects.

No. 248.—Mr. Howson has chosen poetry for the title of his picture. It is a study of sea-craft before an imminent storm, and in active preparation to resist the same. The picture was enlarged by Mr. Howson from a small negative, and is in sepia on Alpha paper. The tone was happily chosen, gives realism to the effect aimed at, and is well printed and framed.

No. 254, *Waiting and Watching*, by Miss Emma J. Fitz.—A female figure, possibly that of a French peasant woman, is seated in the gloaming, apparently in an attitude of expectation, waiting and watching, we suppose, for some person (or persons) unknown. But, as Ibsen says, "they don't do these things." Her place should have been indoors, preparing supper. Had that been the case in this instance, Miss Fitz would have spared us and many more a great deal of wonderment as to what the picture really meant. If it be in the province of photography to produce effects which leave everything to the imagination, while violating the essentials of technique, we suppose we ought not to grudge Miss Fitz her medal; but, candidly, even the risk of being dubbed unchivalrous shall not stop us from saying that, while five photographers think she deserved it, there are probably as many hundreds who would not have awarded it her had they had the opportunity of doing so.

The Unmedalled Pictures.

Let us now pass to the general exhibits. Earliest to arrest attention among a lot of commonplace work, are four views (Nos. 6–9), by Colonel Gale: *The Rippling Brook; Sunrise on Salisbury Plain; Down by the Mill Ford; Ploughing and Twitch Burning.* What a pity these gems were not in competition! They exhibit Colonel Gale's faultless art to perfection and obviate criticism. In *The Postman* (No. 10) Mr. Terras shows the useful public servant at the door of a cottage, the female occupants of which are betraying interest in the contents of his bag. It is a nice piece of work, but a hackneyed subject. Mr. F. Downess' platinum portrait of Mr. Goodall, R.A. (No. 11), is striking and out of the common in posing. Passing by a careful bromide enlargement (No. 14) of clouds descending the Zermatt Valley, by Mr. W. England, and a *Mont Blanc by Moonlight;* (No. 15) taken at 10 p.m. on Jan. 7, by Captain Abney, we come to (No. 17), an unconstrained *Study of a Girl's Head*, by Mr. C. Beadle, soft and harmonious in lighting, and a rather chalky bromide (No. 19) study of a lady seated with distended bare arms, by Mr. W. Grove. Mr. Terras's study (No. 20), the head of a wrinkled old lady in a cap, is a passable one. Dr. Emerson is represented by two large carbon enlargements by the Autotype Company (No. 29), *Buckenham Ferry*, a not very interesting subject in the earlier Emersonian style, and (No. 33) *The Wherry*. This represents one of those popular craft on a river in the morning, and the light which strikes across the picture is cleverly rendered, while the distant mist and reflections in the water are also ably caught. Mr. Lewis Cohen's large platinum study (No. 32) of cloud, water, and mountain, with the sun striking a bright path down from the latter, is very effective, and in No. 35 Mr. H. K. Stephens shows a skilful instantaneous picture of *Football: Blackheath* v. *Kensington, Stoddart kicking a Goal.* Mr. W. Dawes in *Dibbling* (No. 41) portrays two or three men engaged in that occupation; but, although they are apparently working in a row, the face of one of them is quite indistinct. The *Nine Interiors* (No. 38) of Miss Weaver Arding, taken on multiple-coated plates, are excellent, at least two of the subjects having the maximum of difficulty. Mr. Henry Stevens shows (No. 31) *Chrysanthemums*, (No. 44) *White Lilies*, both in his usual style, and (No. 251) a youngster looking disagreeable because *Daddy wouldn't buy him a Bow-wow.* By the way, we do not see Mr. Stevens' well-known fox-terrier on the walls this year; we hope nothing has happened to him. *A Bivouac* (No. 45), by Mr. Cohen, is a thoughtful study of two horsemen making preparations for the night in a lonely spot. Captain Abney shows (No. 47) another Alpine moonlight view, Mr. Stewart Smith (No. 48) good yacht bits *On the Clyde:* and Mr. B. Gay Wilkinson a study of sheep coming *Down from the Hills*, apparently to avoid a storm.

Mr. W. M. Warneuke's large picture in platinum (No. 51) of *Sands of Iona—Twilight*, with the figures of two women on the shore; his *Conquest* (No. 97), a *rencontre* between two young lovers in a glade; *Kelp Gathering* (No. 113), in which figures are again skilfully introduced; and *At the Well* (No. 182), a study of a lady with charmingly rural surroundings, are all beautiful examples of sound work. We should have liked to have seen some of Mr. Warneuke's portraits, however. In Nos. 53, 54, and 55 Mr. Charles Moss shows similar work to his medal picture, but we prefer Mr. G. Ardaseer's delicate study (No. 59), *A Calm Evening*, where there is evidence of the highest artistic feeling, allied with brilliancy of treatment. We thought at one time Mr. Ardaseer was going over body and soul to the "blurrers," but he is saved! Mr. H. D. Warner's *Ice Storm* (No. 62) is well done, the contrast between the wintry-clad trees and a dark house in the view being not over accentuated. Mr. George McDonald has a small photograph (No. 63) purporting to represent *Brambles and Gorse*. It is difficult to tell which is which. *En recanche*, Mr. McDonald has some excellent photographs of flowers on the other walls. Nos. 69, 70, 114, 118, 180, and 184 are chiefly hand-camera studies in Italy by Mr. Sinclair, showing a wonderful degree of skill in treatment, the detail being ideally crisp and their whole effect most charming. One of them is evidently the original from which his medal picture is enlarged. On every ground we prefer the original, and so does everybody else, save five.

Good portrait work is shown by Messrs. Lutzel (No. 71), Mendelssohn (Nos. 75–8, rich, warm-toned pictures), Mowell and Morrison (No. 78). A series in different coloured carbons by Messrs. Lutzel are very attractive. A selection of rather muddy land and water scapes (Nos. 74, 82, 83, 92, 93, and 94) on sepia platinum are probably intended by Mr. J. McGrove to illustrate the utmost extent of diffused treatment to which a lenticularly produced picture may be subjected. We are agreeably surprised to find how well the same gentleman can use a photographic objective in (No. 128) *Dinner Time*, a little child beating the dinner gong, a natural and amusing bit of humour. As examples of the printing process (silver and gelatino-chloride platinum toned), Mr. J. Kidson Taylor's four contributions are technically perfect, while pictorially he shows that the best definition is not inimical to artistic effect, his *Low Tide* (No. 88), *Gleam of Sunshine* (No. 91), *A Snug Berth* (No. 98), and *Welsh Farmyard* (No. 99), being among the best in the room. Mr. T. Birtles is represented by half a dozen interesting progressive views of the Manchester Ship Canal, and Mr. Herbert W. Hughes by a series (No. 106) representing life in *Coal Mines*. Mr. R. H. Lord has two studies, both inferior to *How's That? Good News* (No. 95) shows an old couple seated at tea, the wife placidly listening while the husband placidly reads a letter, presumably from an absent son. Both faces are singularly destitute of emotion, so that we must take Mr. Lord's word for it that the news is good. We should not have known it otherwise. Mr. Lord's other effort shows a schoolmaster rebuking (No. 116) *A Stupid Boy* for having made a mistake in his sums. Mr. E. B. Wain, with a rustic twilight scene (No. 102), spoils the poetry of it by introducing a boy with a round felt hat, but is entirely successful with a tender study of (No. 111) *Quiet Waters*. Mr. W. Thomas has a number of hand-camera studies of river life, &c., and which are as good as those Mr. Thomas usually turns out; and in Nos. 61, 129, 132, 304, and 310, Miss Emma Justine Farnworth shows variations in the posing of the female figure which betray great artistic skill and poetical insight, as well as sound photographic knowledge. Mr. R. Keene's *Interiors of Gwdyr Castle* (No. 136) are beautiful examples of this kind of work, and Mr. W. Snell Anderson's hand-camera studies (No. 135) would be difficult to beat. Mr. Karl Gregor has eight views (Nos. 147–150 and 159–162) of pastoral subjects, better if anything than those which gained him a medal last year, as several of them have more sparkle.

This is a "warm" corner of the room, as there are quite a number of pictures in red carbon, notable among them being Mr. G. W. Webster's *Jack*, portrait of Henry Talbot, Esq. (No. 153), a portrait of a little lad in an unaffected standing position, and with an equally natural expression of face, which so many photographers strive after and so few obtain. Messrs. Russell (No. 154), and Messrs. Byrne (No. 154), and Mr. Bullingham (No. 156), also show capital portrait work. There are some excellently rendered clouds in Mr. B. G. Wilkinson's *Blowing up for Rain* (No. 157), but there is no effect of wind, as given by trees, so we will take the title on trust. Of Mr. Cembrano's exhibits, we prefer his large carbon picture of *A Moorland Mill* (No. 167); but, in the *Evening Glow* (No. 168), the effect sought is very good. Nos. 173 to 179 are familiar Derwentwater scenes in platinum by Mr. Pellet; and Mr. Bernard Lintott (No. 183), shows creditable examples of the same kind of work. Mr. Sandland's *Animals at the Zoo* (Nos. 189 and 197) are always worth studying, but we do not like *Ring a Ring of Roses* (No. 190), by Mr. C. E. Whitaker. The children are playing the game in a village street, and consciousness of being photographed is reflected in each of their faces. Mr. R. L. Kidd's carbon enlargement (No. 193), *Evening*, a riverside study, is an admirable piece of work, and here, too, is a delightful portrait group by Mr. Mendelssohn (No. 202), *Mrs. Waterlow and Sisters*, a quite easy and unrestrained piece of grouping. *Worn Out* (No. 212), by the Rev. R. C. Macleod, is badly named; the old fellow it shows, notwithstanding his bleached locks and wrinkled face, is good for several years yet. In *Such a Treat* (No. 225) Mr. Fred Boissonas, delineates a series of instantaneous portraits of the same child—studies of expression taken in about fifteen minutes; and in (No. 226), *An Artist's Rise and Fall*, two children at play in full liberty, taken in about twenty minutes. As specimens of instantaneous work, and cleverness in catching the varying attitudes and expressions of children, the two series are notable, but the humour of them is not very clearly brought out.

Commendably good work is also contributed by Messrs. R. J. Fry, J. H. Avery, A. R. Dresser, A. J. Golding, T. C. Hepworth (a rugged but effective blacksmith's forge), J. N. Hignett (excellent landscape), T. M. Brownrigg (painstaking as usual), Bedford Lemere, G. T. Harris, and many others.

Messrs. Marion show a series of studies, by Mr. W. E. Downey, of artistically posed ladies, well printed in collotype; Mrs. Main, a collection of Alpine studies, taken just as Mrs. Main knows how to take them. As for the rest of the Exhibition, at this part of the room, which comprises prints other than those made by photo-mechanical means, we can only deal with it in the briefest possible manner for two reasons: 1. We have not much more space to spare this week. 2. Many of the pictures do not deserve any space at all, either here or on the Society's wall. We must, therefore, content ourselves with passing a word of praise to Mr. F. Hollyer for his admirable photographs of flowers applied to decorate the new lantern stand, which looks uncommonly like a pulpit; to Mr. W. H. Grove for three nice portraits of a lady; to Mr. E. D. Stern for an interesting picture of the Caravel "Santa Maria" leaving Santa Cruz on its way to New York; and to Mr. G. Renwick for some frost studies.

The final section of the Exhibition includes a colossal direct carbon portrait by Mr. A. Werner; some comparative tests of tele-photography, as against enlargement. by Mr. W K. Burton; a tele-photograph of the solar eclipse, by Mr. L. Malein; some balloon views of Philadelphia, by Mr. W. N. Jennings, taken with tele-photo lenses, and resulting in, perhaps, the finest balloon views we have seen; and reproductions after Holbein, by Mr. Hollyer. There is a vast but admirable carbon enlargement of the *West Front of Exeter Cathedral*, made from a quarter-plate hand-camera negative of Mr. Birt Acres', by Messrs. Elliott & Son, who also contribute one of the most interesting exhibits in the room (No. 334), *A Yacht Race*, a carbon enlargement in colour, the effect being obtained by a series of different printings in coloured carbon. The picture where it hangs looks like a water-colour drawing, and is exceedingly effective. Coloured carbon would be a dangerous rival to heliochromic processes for certain kinds of work, and we should think easier to control. Lastly, reference must be made to the exhibits of the Autotype Company, which, as usual, are very numerous, and well illustrate the excellence and the variety of the many methods of reproduction practised by the House. In addition to numerous carbon enlargements from negatives by Major Nott, F. Bayley, Mendelssohn, Harold Baker, and others, the Company are represented by three gravure reproductions from paintings, which, especially the *Newhaven Packet*, after Henry Moore, are extremely fine.

We shall deal with the lantern slides, &c., and several other matters

of interest connected with the Exhibition, next week, and in, for the present, closing this part of our notice it is our pleasing task, as was the case last year, to acknowledge the courtesy and readiness with which the Assistant Secretary, Mr. R. Child-Bayley, afforded ourselves and other members of the Press such information as was sought after.

Apparatus.

The "Number 2 Frena," exhibited by Messrs. R. & J. Beck, is in several respects a very decided improvement upon their former one. Like it, this one when charged contains forty cut films, but the size of these is larger, being quarter-plate, whereas the original is for lantern size. The mechanism, too, differs materially from that of the other, and is much more effective. Films and card-backings with notched edges are used, as in the "Frena No. 1," but they are all cut to an exactly identical shape. The alternating notches in the Frena pack, which are necessary to the working of the Frena system, are obtained by packing the consecutive films in opposite directions. These notches are so arranged that the films and cards can be placed upon each other so that they are exactly superimposed and the notches coincide, forming, as it were, a solid block of films and cards, with notched channels running through the entire block. When packed for use, however, every other film, together with its backing card, is reversed end for end, the notches being alternate, so as to form the Frena pack. If a non-actinic backing were applied to the film, which, we think, could very easily be done, nearly twice as many films might be stored in the camera, as the use of the interleaving cards would be done away with. There is a chamber at the back of the camera, into which the films are shot after exposure. In the new Frena all springs and ratchets are absent, and every element of uncertainty is removed. The focussing adjustment is ingenious. Assuming that the lens is one of five and a half inches focus, and that the focus is fixed for objects beyond twenty feet away, a few supplementary lenses are provided, which, when inserted in front of the principal one, shorten the focus in a very slight degree, by which objects within the twenty feet mentioned, even to only three feet, can be sharply represented by the insertion of a suitable lens. This system is much to be commended.

The same firm exhibits a negative store album, a cycle carrier, and a developing clip, this last permitting of a film being developed without wetting the fingers.

Holmes & Watson exhibit a portable optical lantern. In this a light metal casing fits over the limelight, and prevents all leakage of light. The space between the condenser and the objective is left uncovered. Lantern-slide printing frames are shown by Mr. C. S. Scott, and oil and water colours, for transparency painting, by Barnard & Son.

Four cameras, for studio, hand, and field, the last being an improved form of the well-known "Acme," are exhibited by T. P. Watson (Watson & Sons). This has its fittings made of aluminium. The others include the "Vanneck" and "Alpha" hand cameras.

Adams & Co. exhibit three cameras of the "hand" variety, together with one for lantern slides, a pantoscope with chromoscope attachment, aluminium view meter, and other apparatus. These, with the apparatus of Messrs. Watson, have only recently been fully described in these pages.

The Unilux Biunial lantern, by Archer & Sons, suggests two lanterns placed back to back, but having only one lime cylinder common to both, though each has its own gas jet playing on opposite sides of the cylinder. The light is directed on the screen by a rectangular prism or mirror placed at the outer end of each object-glass, in manner like to the lanterns of Beechy or Keevil.

The "Allendale" lantern is contributed by an anonymous exhibitor, and Mr. Thomas Samuels exhibits a changing back, in which the lifting frame is attached to the bag and draws right up.

In the "Psycho" camera of Mr. J. R. Gotz we have the rack and pinion of a spiral form, similar to those of many microscopes now in use. This greatly conduces to smoothness of action.

Lenses are exhibited by Swift & Son and Taylor, Taylor, & Hobson. These are locked up in show-cases.

THE DAILY PRESS ON THE PHOTOGRAPHIC SOCIETY'S EXHIBITION.

The Daily News says:—"If the collection now arranged is not of more than average interest, there is plenty of work that is sufficiently important, either artistically or scientifically. Novelty is not a conspicuous feature, though it is noticeable that there is an increasing tendency amongst both landscape and figure photographers to make their productions as much like those of the painter as possible."

The Daily Telegraph says:—"Rarely has a more attractive show been held, the high pitch of perfection to which many of the works are brought giving visitors a first impression that they gaze upon delicately finished water colours or artistic crayons rather than products of the camera. Every branch of skilful development receives full representation, and where so much is delightful and clever the Judges must have found it a hard task to allot their favours."

The Morning Post says:—"The collection of photographs is a very fine one, and considerable care has been taken in their arrangement."

The Times says:—"The Photographic Society is not an artistic but rather a scientific society. Its principal aims are eminently to foster the researches of science in the advancement of the optical and chemical investigations which result in the triumphant discoveries with which photography from time to time startles the world; to encourage perfection in the instruments and apparatus employed; and to preserve the standard of perfect technique so necessary for the successful application of theory to practice. To the scientific photographer the terms perfect negative and perfect technique have absolute and definite meanings. Qualities such as clearness and brilliancy would appear to be essential. On the other hand, in the production of results which would appeal more strongly to the eye of an artist than the ordinary topographical view or commercial portrait, negatives would probably be used and methods employed which it would be the duty of a jury of scientific photographers to dismiss as imperfect. On the whole, it is a very good exhibition; the best, perhaps, that the Society has yet given us."

The Daily Chronicle says:—"The collection of photographs included every variety, and was of considerable interest."

FILM WORKING.

[London and Provincial Photographic Association.]

In introduction it may be remarked that the celluloid films of to-day are the outcome of various endeavours made from time to substitute as a support for the sensitive film something lighter than glass and less liable to breakage, and so to reduce the weight of the photographer's outfit. From its special suitability for the purpose, celluloid has come to be almost universally used as a support for the gelatine emulsion in the manufacture of negative films. That it is in all respects as perfect as glass for this purpose can hardly be contended; but it represents our present stage of advancement in this direction.

The exact composition of different makes of celluloid probably varies, but, broadly speaking, the sheet of celluloid as coated (the solvents employed having then evaporated) consists mainly of converted pyroxyline and camphor, both of which are inert to the chemicals used in photography.

It may here be noted, for the benefit of those persons who labour under the impression that all our photographic improvements come from abroad, that the two essential items in the celluloid film are the result of English research and invention, celluloid being due to the late Mr. Parkes, of Birmingham, and gelatino-bromide emulsion to the labour of English experimenters.

Among the principal advantages obtained by using films are the saving effected in weight and bulk—points of great importance, not only to the amateur travelling, but also to the professional photographer doing outdoor work of any kind. The gain on these points is very apparent in the case of magazine hand cameras, it being possible to carry so many more exposures. A comparison between the weight and bulk of films and plates respectively will illustrate this more freely. A gross of quarter-plates weighs thirteen and a half pounds, while the same quantity of films weighs two pounds one ounce; a gross of half-plates, thirty and a half pounds; films, four and a quarter pounds, in each case inclusive of packages. Again, a gross of plates packed will measure sixteen inches in height, while the same quantity of films measures only four inches; so you see, bulk for bulk, films take only a quarter the space, and weigh considerably less than a sixth of the same quantity of plates.

Other points of advantage which films possess are the non-liability to breakage, the small amount of room required for the storage of the negatives, and a lessened tendency to halation.

A considerable amount of want of confidence seems to exist in the minds of many who have tried to make their negatives on films

instead of glass in the early days of film photography; some of these defects were, doubtless, defects in the manufacture, due to want of experience in the use of a new material, while other, and perhaps the larger number of, failures were due to the fact that the manipulation which answered perfectly with glass plates required to be modified to some extent when using a material of such a different character.

The defects of manufacture have mostly been overcome by improved processes, and very little extra care is required to avoid the defects arising from errors in manipulation.

The question is frequently asked whether films keep as well as glass plates, and I have heard many condemnatory remarks concerning films in this respect, not at all justified by my own experience of them. An emulsion which keeps well when coated on glass will, so far as my observation goes, keep equally well on celluloid.

With regard to the suitability of the material, from a chemical point of view, to take the place of glass, I have already stated that the celluloid film is, when the solvents have evaporated, composed of substances which are photographically inert. We know this to be the case as regards the pyroxyline so long used as a vehicle in the wet-collodion process. With regard to the camphor, some of which undoubtedly remains in the film, and is supposed to tend to deterioration, with a view to set this matter at rest, I have made a few experiments, of which I now show you the results:—

No. 1 is a plate exposed as taken from the box, without being treated in any way.

No. 2 is a plate from the same box. A slab of camphor three inches squre had one face carefully scraped over a straight edge to make it as level as possible. This was pressed closely in contact with the emulsion side of the plate, and allowed to remain in this position for thirty-six hours.

No. 3 is also a plate from the same box. It was placed in a grooved box with a quantity of broken camphor, and left for thirty-six hours.

These plates were all exposed on the same subject, for the same time, and developed together in one dish, and there is no evidence of any effect produced by the camphor.

I have here also some negatives taken on films treated to ascertain the effect of pressure. A packet of six half-plate films in the paper envelopes only were placed in the ordinary letter-copying press, six pennies were laid singly on the package, and the press screwed down very tightly; after thirty-six hours the films were taken out, exposed, and developed, and, although the pressure was sufficient to cause a perfectly glossy circular mark on the face of the film, where the penny had rested, no difference is observable after development.

There is an idea prevalent in the minds of some that an emulsion coated on celluloid is less sensitive than when coated on glass. I frequently try films and glass plates coated with the same emulsion, and do not find this to be the case.

We now come to the question of exposure. Celluloid films may easily be exposed in ordinary dark slides by placing black cardboard of the same size at the back of the film to keep them flat and take the pressure of the spring. This method works well when the rebate of the slide is fairly wide; but, with narrow rebates, some difficulty arises, and film-carriers to hold the film are certainly more generally convenient. The films should slip quite loosely into the carrier, as, if they fit at all tightly, this causes a buckling of the film and there is also a danger of strippring the emulsion from the celluloid by the sharp edge of the metal grooving. Several patterns of film-carriers are in the market, and which, I dare say, are known to you. I have here one recently introduced by Messrs. B. J. Edwards & Co., which you will see is very simple and can be easily worked by following the directions printed on the back of the card.

In this way films can be worked very conveniently in ordinary slides; but, to gain the fullest measure of advantage from their use, slides specially designed for films should be used, as these can be made much lighter and less bulky.

Here is a dark slide specially designed for films, but which can also be used for plates. This, like the film-carrier I have just shown, is the invention of Mr. B. J. Edwards. It will hold two films or plates, and two of these slides take up about the same space as an ordinary wooden one, and weigh considerably less. The shutter is of xylonite, coloured black on one side and red on the other. Black outside indicates unexposed films or plates; this draws right out, and after exposure is replaced, red outwards, which not only shows at a glance exposed and unexposed films or plates, but the red side can be written on with lead pencil, and thus affords space to make memoranda in reference to exposure, &c. Afterwards the writing can be erased with a damp sponge or cloth.

The development of films may be conducted in the same way as plates if it is only required to do one at a time. It is, well, however, to have a full quantity of developer, and the use of a brush to ensure the absence of air bells is certainly to be recommended; but, even when developing them singly, films are less convenient to handle than glass plates, and, unless some contrivance is used to prevent them floating over one another, several cannot satisfactorily be developed at once. I have utilised for this purpose the metal frame of the film-carrier I have just shown, after giving it a coat of varnish. The films are simply slipped into the groove, without the card backing, in which they remain during the operations of developing, fixing, washing, and drying. The opening in the frame allows you to judge of density during development.

This is, however, somewhat of a makeshift contrivance, and I hope on a future occasion to be able to show you a more perfect holder which Mr. Edwards has recently designed.

In this way a film becomes as easy to manipulate as a glass plate, and several may be developed at the same time.

Developers.—With respect to the developers most suitable for films, it is best to use the developer with the peculiarities of which you are best acquainted; a developer suitable for plates will answer equally well for films.

Personally I have always given pyro and ammonia the premier position as regards the quality of the negatives obtained.

Pyro and soda has, to a considerable extent, superseded it of late years, but the pyro and soda-developing formulæ generally in use appear to me to give negatives lacking something of the quality obtained with pyro and ammonia.

In order to arrive, if possible, at a pyro and soda formula equal to pyro and ammonia, I have recently made a somewhat exhaustive series of trials, with varied proportions of soda and sulphite, in this developer, and have also tried various modifications of it. The following formula is the outcome of these trials, and I believe it to be decidedly superior to those generally in use. It is the only one I have employed that gives negatives quite equal to those developed with pyro and ammonia.

No. 1 Solution.

Pyrogallic acid	1 ounce.
Metabisulphite of potassium	1 „
Water	80 ounces.

No. 2 Solution.

Carbonate of soda (crystals)	12 ounces.
Water	80 „

No. 3 Solution.

Bromide of potassium	1 ounce.
Water	9 ounces.

To develop, mix equal parts of Nos. 1 and 2. For most purposes the addition of five minims of No. 3 to each ounce of the mixed developer is recommended (or one and a half ounces of No. 3 may be added to the eighty ounces of No. 2). For instantaneous exposures, where under-exposure is probable, the bromide may be omitted, and also for studio work. This point, as to the addition of bromide, must, in fact, be left to the discretion of the operator.

If the colour of negative given by this developer is not considered grey enough, a greyer image may be obtained by adding two ounces of sulphite of soda to the No. 2 solution.

Fixing.—Very little need be said on this point. If the film negatives are manipulated without holders, it is advisable to fix in a *deep* dish, and to see that the films are well under the surface of the solution, otherwise stains may result. An acid fixing bath may be used; a ready method of mixing this is to add two ounces of metabisulphite of potassium to each pound of hypo crystals. One ounce of the metabisulphite will answer, but I prefer the larger proportion.

Washing.—When a holder is not used, it is best, in placing the films in the washing tank, to place two back to back in one groove.

Drying.—After washing, they are best hung up to dry by means of spring clips; the clips answer very well. The method of hastening the drying of negatives by immersing them in alcohol must not be practised with film negatives, as the alcohol attacks the celluloid.

Varnishing.—It is certainly advisable to varnish the film negatives, and this can be readily accomplished by means of this varnish, which is specially prepared for the purpose. Some of the varnish is poured into a dish, and the film is immersed for one or two minutes, and then hung up for the varnish to dry and harden; no warming of the negative is required.

Cleaning the Varnish off a Negative.—Should the removal of the varnish from a varnished film negative be necessary for intensification or other purpose, this is best effected by soaking the negative in some of the varnish for five or ten minutes, rubbing the surface with a pledget of cotton-wool, and then well washing it under the tap.

W. H. Barnes.

THE PHOTOGRAPHIC CONGRESS AUXILIARY OF THE WORLD'S COLUMBIAN EXPOSITION.

THE following additional papers were read:—

PHOTOGRAPHY FOR ILLUSTRATING THE PRACTICE OF MEDICINE AND SURGERY IN A GREAT HOSPITAL.

WHEN the sturdy manhood of our forefathers led them to the declaration "that all men are created free and equal, with certain unalienable rights," they publicly recognised the brotherhood of the entire human race. They had unwavering faith in their belief and the justice of their cause. They established the broad principle of public right to do the greatest good to the greatest number. In their customs and declared principles they recognised the imperative law that the physical well-being of a people is an important factor in its progress; hence they made public provision for the treatment of public disease, and their descendants, imbued with the broad classification of public good in private welfare, have nobly extended the principle of public treatment to private ills. This principle has made it possible to establish and maintain great hospitals at public expense, and has engendered that wide-spread feeling of philanthropy which leads to the ample endowment of the many noble institutions, almost yearly added to the list, for the better treatment of those not blessed with the requisite means for home treatment. In each of these great gatherings of human pain, and its large staff of skilled practitioners of the healing arts, are found opportunities never seen in private practice, and, until the discovery of that universal panacea with which the ancients hoped to effect a cure for all the ills of life, there will be cause for study and comparison in the treatment of disease in its almost innumerable varieties.

What affects one member of a family may affect all. A neglected ill may engender a pestilence. A deed for the relief of a single individual may effect the delivery of a whole people from impending calamity. That which first attacks the lowest and weakest often pulls down the highest and strongest. Disease is a condition in the life of every individual. That knowledge is the forerunner of power, and that the best lessons for our guidance in the future are learned by a careful study of the past, are as true now as when first promulgated. When the facilities for communication have become so vast that the history of yesterday is read on the printed page of to-day, and the means of recording facts are so simple, our followers may reasonably expect to find help in the record of our work. From long observation it is known that certain ills are almost sure to follow certain modes of life. Natural traits are found to produce certain deformities and diseases. Many proofs soon change an hypothesis to a well-established fact. A properly illustrated record of the facts thus established is of great value in the treatment of future cases of like character. The advantages and disadvantages of methods of treatment are clearly indicated. Mistakes and successes are readily recognised. The what, how, and why of certain lines of treatment are plainly shown. Shall they be followed, modified, or discarded, are the questions with which the succeeding practitioner has to deal, and, in order that he may be successful, the word and picture record should be correct even in the most minute detail.

Hasty sketches are not sufficient for such purpose. The importance of the subject demands the use of the best means available, and to this work photography is most admirably suited. Photography gives correct location, form, and size, with an amount of detail otherwise unattainable. No human hand can rival the work done by actinic light and the lens. In cases requiring colour for their proper representation, that element can be added by hand and the printing-press, as seen in many recent works. In the early days of photographic work at Bellevue Hospital more than a quarter of a century ago, only the most marked or prominent deformities, dislocations, tumours, and operations were illustrated in the photographical department.

As each succeeding year made the work more widely known, and its importance as an auxiliary in the treatment of disease received more general recognition, the field of operation rapidly extended. At first the members of the staff having in charge the surgical wards were the only ones calling to their service the assistance of photography. Their cases before, during, and after treatment were so successfully illustrated, that the members having in charge the medical wards soon began the illustration of their prominent cases. Skin diseases, changes in outline and enlargements of various members of the body, position and expression, resulting from derangement of the nervous system, the effects produced by stimulants and various exciting causes, were added to the list passing through the photographical department. Outline drawings in crayon, charcoal, or other easy removable pigment are made upon the skin of the patient, for the purpose of showing in the photograph the exact location, extent, and so forth of the internal disease under treatment. By placing in front of the nude or partially nude patient especially constructed wire screens, with fixed scales reading both horizontally and perpendicularly, it is quite possible to record changes of outline by inhalation and exhalation, and peculiarities of posture occasioned by certain diseases or modes of treatment. In much of this work very rapid plates and instantaneous exposures are required. After long experience in ordinary and general photographic work, and twenty-five years of continus hospital service, it has been found that, in order to treat all this great variety successfully, certain conditions and appliances not seen in ordinary photographic establishments are necessary. These have, as far as possible, been supplied and utilised at Bellevue. The operating or exposure-room is on the seventh floor of the central or administrative portion of the main building, and is easy of access by elevator from all parts. The walls of this room are about eight feet high, and painted a light grey without gloss.

The floor is covered with heavy cork-surfaced cloth, painted light slate colour, also without gloss. The operating window reaches from the floor up the north wall of the room and across the entire top to the south wall. The angle of inclination is with that of the roof and just enough to shed water. It is situated just below the great dome of the amphitheatre, which protects it from direct sunlight most of the day. The glazing of the window is plain clear glass. All necessary controlling in direction and amount of light is done by curtains, screens, and reflectors of cloth, paper, and glass. The heating and ventilation of this room is as perfect as possible, and so arranged as to be under ready and complete control of the operator. Neither a broiling nor freezing atmosphere are conducive to the successful photographic treatment of living matter. Upon a low platform, mounted on castors, is placed a rotating disc, which carries the operating chair. This arrangement admits the patients being moved in any direction without leaving their first position. Reclining chairs, couches, and tables in necessary number are ready for use. Special rests for hands, arms, feet, and various parts of the body are easy of access. Plate-glass tanks for photographing under water or other fluids are at hand. The photographic apparatus is of the best procurable, and ample in variety for all sizes, from microscopic to full size of the human figure. What is best for one class of illustration may be almost valueless for another. A series of quick-acting lenses, provided with adjustable exposure or "shutter" appliances, prove to be of paramount importance. All the exposures in the department are made by this means. Many patients are in almost constant pain, and more sensitive to surrounding influence than those in health. Hence the temperature of the room should be well regulated, and as little time occupied in their treatment as is consistent without apparent haste. The cameras are easy to adjust, and modifications can be quickly made to suit the case in hand. Several dozen double plateholders are kept filled with various sizes used. These are stored in a case near the camera. The backgrounds, of various shades, are mounted on self-acting spring rollers, carried on a frame so arranged as to be easily placed where desired.

In the illustration of important cases before a class or when a large number of assistants are required, either the large square operating-room or the amphitheatre are utilised. In the first-named the operating window in the north wall is thirteen feet high and eighteen feet wide, while in the latter the light is from a top window twenty feet square, and a side window ten by fifteen feet. Among the articles less frequently found in photographic workrooms, but which are almost indispensable in a practice like that at Bellevue, are the electric-signal clock, which never allows the workman to forget his duty at a prearranged time, and the mechanical motor in the chemical room can be implicitly trusted to keep the developing pans in constant motion during any chosen length of time less than two hours. The tentative method in development with a liberal use of ice in warm weather is practised. Most of the exposures are on subjects which will not admit any risk in result, as the conditions are often greatly changed soon after the patient leaves the photographical department. Some capital operation or treatment may make the appearance quite dissimilar. The developing-room is so constructed that natural or artificial light may be used, or, if necessary, it can in fifteen seconds be made totally dark, and yet permit free entrance and exit while work is being done, while it can by the large door and window be as freely opened, in a moment, to air and view, as any other room in the series. The entire surface of this room —floor, walls, and ceiling—together with all the fixtures in it, are painted a dark tint of "Indian red," which effectually prevents the reflection of actinic light, in case such should by mistake be admitted from outside, or the artificial illuminants used. The other workrooms are a general shop

with benches, lathes, and mechanical appliances for the repair and construction of the many special devices found necessary in practice. The printing, mounting, and finishing-room on the south side of the dome contains such apparatus and furniture as is usually found in like places. One peculiarity of the printing-room is a sliding window four feet by six feet, put in flush with the wall. This window is so arranged that the ordinary sash can be slid away, leaving a clear opening of four feet by six feet. In cold, or windy, stormy weather a single plate of glass is slid into the space usually occupied by the ordinary sash. For direct sunlight effects, or for reflecting light into deep cavities, this window is convenient. As the photographical rooms are all situated in the highest part of the building, the light is not obscured by any surrounding objects, a distant horizon is seen in all directions. O. G. Mason.

(To be continued.)

PHOTO-MECHANICAL PROCESSES IN ENGLAND—HALF-TONE BLOCKS FOR TYPE PRINTING.

To England must be given the honour of being the home of photo-mechanical photography, and a casual glance at the publications using photo blocks will show that good use is made of such productions. The gauze used by Fox Talbot in 1854 has given way to perfect ruled screens, which, as a general rule, are made in America.

The old wet-collodion process has no rival for the production of the grained negatives, and at present there is little chance of having any. The prints on the metal are usually made in bitumen, some operators using bichromated albumen, especially in dull weather; but this requires great skill both in the preparation of the film free from dust, as well as in the subsequent rolling up with a sufficiently strong ink resist. Printing the ink image on prepared paper and subsequently transferring to metal is also practised, but this method requires great lithographic experience to get a good image. The metal used is generally zinc, but some firms use copper.

Line Blocks for Type Printing.

This branch of photo-mechanical work is nearly all done by the etching process, the swelled gelatine method being worked by one firm only, who, however, turn out splendid results. The wet-collodion process is here paramount for making negatives, the silvered mirror being used to get the necessary reversal, one or two films only adhering to the method of turning the plate in the dark slide, stripping the film is very seldom practised; when a number of small images are to be put on one sheet of metal, separate exposures are made, the metal plate being resensitised for each print.

Line blocks are produced very cheaply, but there is a constant demand for them; hence they pay in spite of the low price; they are used by the square yard in halfpenny papers as well as in very high-class ones.

Photo-Lithography in Line.

Photo-litho transfers are getting into very general use all over the country; firms who a few years ago would not hear of such a thing are now using large numbers of them; but there is one drawback in the difficulty in obtaining good transfers, so few operators know, or will be told, how important it is to keep the ink spare instead of thick, especially in fine work.

The best method of inking up these transfers is to use a glue roller charged with transfer ink thinned with turpentine, a method which I had the honour of first introducing; and, as it is simple, easy, and efficient, some operators prefer to use the old and clumsy methods of rubbing over the ink with a sponge, or else ink up a stone, place the exposed print upon it, and pull through the press; the sponge method yields heavy and uneven transfers, the inked stone gives rotten lines and dirty whites.

In chromo-lithography, photo transfers are much used when different sizes of one subject are required; then one drawing or set of stones only are prepared; then from each stone a black pull is taken; this is photographed, put on the stone and printed.

Photo-Lithography in Half-Tone.

This process is not very extensively practised; but, where it is, very fine work is produced; the best work is done by transfer from a collographic plate, the necessary grain being obtained by using either ferrocyanide of potassium, or calcium chloride, or both.

Collotype.

This process has been very extensively taken up within the last three years, but there are only about four firms who turn out really good work, simply because the process is starved in initial stage, viz., the negative; money is lavished on machinery, &c., good wages are paid to platemakers and printers, but any one is considered capable of making a dry-plate negative; now and again by a fluke a good collotype is turned out, but as for ninety per cent. it is stale, flat, and unprofitable.

This process is essentially a photographer's process, and only those who are capable of constantly making good negatives can ensure good collotype prints; the process is simplicity itself, given a good negative, but not without.

Photogravure.

England was a short time back very backward with this process, simply because of the difficulty of getting men capable of producing the prints from the intaglio plates; now, thanks to the pluck and enterprise of firms like Annan & Swan (London), English photogravure prints hold their own in comparison with any.

Some firms use the Talbot-Klic process, in which the grain is obtained by dusting with finely powdered resin, the resist being a carbon negative, *i.e.*, a pigmented gelatine print from a transparent positive, mounted upon the copper plate and developed thereon.

Other firms use the method of dusting over a gelatine image with resin in fine powder, and when the image is dry obtain the grain by dissolving out the resin, and then obtain an intaglio plate by electrolysis.

Others, again, prepare gelatine films with plumbago, &c., of varying degrees of coarseness, which, when exposed to light and developed, yield a granular-surfaced image, from which, by the electrotype process, a printing plate can be obtained in copper or steel.

Taken altogether, England has no cause to be ashamed of her photo-mechanical work, and it does not require any great stretch of imagination to say that in the future this satisfaction will be maintained.

W. T. Wilkinson.

FRILLING.

During very hot weather there may be expected complaints of the frilling of gelatine negatives. Some years ago this was by no means an infrequent occurrence; possibly improvements in manufacture, and a series of average summers, have had something—a good deal, in fact—to do with an almost total cessation of grumblings on this ground. But such things are still possible, and it is well to consider what is the best thing to do in the event arising of a necessity to guard against a series of "frillings."

Personally, I don't think plates are so liable to frill as they were in the days of, well, seventy-nines and eighties, but I have had painful experience lately that the thing is by no means to be disregarded.

Although a "water famine" is not without the bounds of practical possibilities, still we may suggest, to start with, the advisability of using the aqueous fluid in as frigid a state as possible. Ice is obtainable, and the professional will, no doubt, take care that the developers are kept at the proper temperatures by the use of either ice or a freezing mixture.

On page 461 of the volume of this Journal for 1881 will be found some observations by an anonymous contributor, which, though scarcely applicable to the workers of to-day, still throw light upon a subject which at that period was of considerable interest. We read that "there are two causes of frilling caused by gelatine—one where a large amount of hard gelatine is employed in making emulsion, the other is where a *very* soft gelatine is used." The latter-day worker, although he doesn't make his own plates, may still appreciate the significance of the above extract. Again, "Hard gelatine frills on account of its rapid expansion when moistened on one side only." Causes of frilling are mentioned as follows, which are not entirely due to the gelatine, viz., "imperfect elimination of the soluble salts"—*i.e.* in making the emulsion; "the imperfect drying of the plates;" "by decomposition being set up in the negative by imperfect washing between the applications of the alum and hypo baths, or *vice versâ*, thereby liberating gases;" lastly, in "the changes of temperature in developing, washing, and fixing solutions." "If a plate which has frilling tendencies be removed from a cold solution to a warmer, the chances of frilling are increased; yet you may allow a plate to remain in the colder solution till it becomes considerably warmer, so long as the change be gradual, without frilling taking place."

We have no longer anything to do with the manufacture of dry plates, therefore our interest will lie naturally with the above concluding quotation only. It is well worth considering, and amounts to this, that we have only to keep our developers and fixing baths at normal temperatures in order to escape the bugbear of frilling. The manufacturers may be given credit, no doubt, for a great deal in the way of immunity from this trouble experienced during past years,

but we can't be too sure, and, of course, our first endeavour should be to use, if requisite, ice or freezing mixtures for the purpose of ensuring "equable temperatures."

Chrome alum in solution, two ounces to a gallon of water, may be effectively used *after* developing, and prior to fixing, to prevent frilling. Chrome alum is cheap, and a little of it goes a long way. I recommend this to be used during the "dog days."

The strength of the "fixing bath" is of importance, *vide* "Editorial," THE BRITISH JOURNAL OF PHOTOGRAPHY, 1883, page 353. "By the use of a weak fixing bath, or by allowing the negative to drain an hour or two after being fixed in a strong bath, a constant source of trouble and worry (frilling) is greatly reduced, if not entirely removed."

A point worth mentioning is, the advisability of using a freshly prepared hypo bath; this will naturally be, if fresh, *cold*. I have on many occasions made a fresh bath in a large dish, and used it as a "cooler" for the developing tray, allowing the latter, an ebonite tray, to float upon the, in this case, freezing mixture, care being taken of course to avoid any risk of contact. The deep ebonite dishes are the best to use.

If the developer, preferably pyro-sulphite and ammonia, or pyro-glycerine and ammonia, or amidol, be used properly reduced in temperature, followed by a freshly prepared, therefore cold, hypo bath, then a bath of chrome alum, one in fifty, may be used for five minutes or so, finally washing in water, not prolonged either, the alum acting somewhat as a hypo eliminator. This method may be reckoned on to prevent frilling.

A suggestion of Captain Abney's, viz., a preliminary coating with plain collodion, should not be forgotten. I have used collodion many times with success when having a batch of plates showing a tendency to frill, as also an application of grease, rubber solution, varnish, or wax, to the edges of the plate previous to developing.

"Frilling," on a wholesale scale, would be a serious matter for the professional, but can, with care, be prevented. It is to the amateur and student sometimes an interesting occurrence. If a film starts to "frill," *encourage* it to do so, and, with a camel's-hair brush, remove it altogether from the glass; transfer to clean water, thence to a larger piece of glass, and allow it to dry, which it does sometimes on a larger scale than before. The application of methylated spirit quickly puts a stop to an incipient "frill." And here, finally, I may remark, with reference to the possibilities of a water famine mentioned before, that frilling having hitherto been always associated with water, would it not be possible to initiate a method of developing and fixing in which "spirits" might take a more important part? Total abstinence doesn't suit every one, and may not be quite the best thing in hot weather for gelatine dry plates.

While on this subject, it may be well to mention a few simple methods of *cooling* solutions. Of course where ice is obtainable, a few lumps of this will be found the best to use, a small piece being immersed bodily into the developer. In the absence of this, I have found nothing better, working in a small way, than to make a freezing compound. Fill a test-tube, cork the same, and carefully cleanse the outside, and place the tube in the mixed developer, using a mixture of sulphate of soda and hydrochloric acid in the proportion of eight parts soda to five of acid. I have in this way frequently lowered the temperature of the developer ten degrees in about four minutes. For cooling larger quantities of fluid, I put the acid and soda into one of the thin glass beakers sold in various sizes by many chemists; pyro bottles may also be used for this purpose. I have suggested soda sulphate, and acid, these being very cheap chemicals. In a retail list at hand I find the former (Glauber salts) quoted at 1*d*. per pound, the latter (common spirits of salts) at 2*d*.—prices reasonable enough.

A freshly made (with cold water) hypo bath is well known to be some degrees below the normal temperature. I have, therefore, utilised this fact, by making a fresh solution in a large glass-bottomed tray, a piece of plate glass to cover this being used as a developing bench. Every little incident of this kind tends to coolness, and is therefore not to be despised. A marked difference is noticed, too, where the bottles, &c., of solutions are kept on a shelf where they are exposed to a good draught of air.

It will not be passed over by readers of a valuable paper lately, *On the Washing of Prints*, that something similar will apply to *gelatine negatives suspended* vertically in water; a negative will, without an inordinate quantity of water, and without agitation or prolonged immersion, become quite sufficiently washed, the process being much assisted (*i.e.*, for getting *clean* negatives) by the application of a wet pledget of wool carefully rubbed over the surface. Far more water is used than is necessary for the perfect washing of negatives, and as it is easier to cool a small bulk of water than a large one, if frilling is feared the fact may be borne in mind.

J. PIKE.

News and Notes.

NORTHERN PHOTOGRAPHIC AND SCIENTIFIC ASSOCIATION.—September 30, Hyde Park.

PUTNEY PHOTOGRAPHIC SOCIETY.—October 2, Introductory Meeting at 116, Upper Richmond-road.

STANLEY SHOW.—The apparatus section this year is to be in the main gallery, whilst the pictures will be hung in the Arcade Gallery as before. Several firms have already secured space.

ERRATUM.—In Mr. Driffield's paper, published last week, the symbol "C.M.S." (candle-metre-second) was converted into "cm." The author's meaning, however, will doubtless be understood.

MESSRS. ADAMSON & SON, of Rothesay, have sent us two most interesting views of Rothesay illuminated on the occasion of a *fête*. One of them contains rockets bursting, showing their path through the air with singular distinctness.

EMERY'S DRY PLATE VARNISH.—Mr. W. Emery, of 24, South-street, Baker-street, has sent us a sample of his Premier Dry Plate Varnish. It is applied to negatives after the latter are warmed, dries quickly, and answers well for the purpose.

MR. H. B. CONSTABLE, who for some time has performed the duties appertaining to the Secretaryship of the Lewes Photographic Society, has resigned that post in consequence of his leaving the town. All communications should be sent to G. Carpenter, 81, High-street, Lewes.

LEYTONSTONE CAMERA CLUB.—September 30, Sewardstone and the Valley of the Lea. Leader, Mr. G. H. Cricks. The Club will proceed by the train leaving Liverpool-street, G.E.R., calling at Stratford at thirty-six minutes past two, arriving at Chingford at one minute past three. Open Social Evening at Headquarters at eight o'clock.

KEEPING PROPERTIES OF COLLODIO-BROMIDE PLATES.—We have received from Mr. H. R. Robertson, Wavertree, two prints which interest us as showing the keeping qualities of collodio-bromide plates. The negative was taken last month on a stereoscopic plate prepared by Mr. Maudsley, of the Liverpool Dry Plate Company, in June, 1870. The prints are perfect.

WHEELER'S "MANCUNIUM" MOUNTS AND RECORDING NEGATIVE ENVELOPES.—Messrs. George Wheeler & Co., of Manchester, are bringing out two specialities which should be useful to amateurs. The "Mancunium" mount is a species of duplex mount made so that the unmounted print may be easily slipped into its proper position. It is a very handy form of mount. The "Recording" envelopes have spaces on their faces for inserting details as to exposure, &c.

THE late Mr. W. H. Morley, whose death we announced last week as having taken place at his residence, The Shrubbery, East Finchley, on the 19th inst., was born in the year 1818, and was thus in his seventy-fifth year. He commenced business in Upper-street, Islington, in 1843, and was assisted by his son, Mr. W. Morley (the founder of the music publishing business in Regent-street), from 1866 to 1882. In 1886 Mr. Morley's son-in-law, Mr. Henry Cooper, became his partner, and, through Mr. Morley's failing health, has practically had the sole management for some years. We understand that the photographic business in Upper-street will in future be carried on entirely by Mr. Cooper, under the style of Morley & Cooper.

HACKNEY PHOTOGRAPHIC SOCIETY'S EXHIBITION, MORLEY HALL.—Arrangements: Open at 7.30, Tuesday, October 17. Judges, Lieut.-Col. Gale, F. P. Cembrano, W. E. Debenham. Results of awards known at opening. Orchestral performance by string band. Wednesday, 18, open at twelve midday. Distribution of awards by Captain Abney at eight. Orchestral performance. Thursday, 19, open at twelve midday. Organ performances by Messrs. S. Moore and W. Fenton-Jones (Hon. Sec.). Lantern slides through lantern. Will exhibitors please note that last day for receiving forms is September 30, and that we have still a little space left for trade apparatus, for the best of which a silver medal is awarded? Messrs. Marion, Platte & Witte, Fuerst, Wray, and others, are exhibiting. Arrangements for October, 1893:—3, *Lenses*, by Mr. E. Wall. 10, *My Italian Campaign*, lantern lecture; an account of my trip *viâ* France and Switzerland, by Mr. W. F. Fenton-Jones. (Ladies' Night.) This lecture will be given in the Drill Hall, entrance through Club premises. Owing to extreme length, it will be necessary to commence punctually at eight p.m. 17, 18, 19, Annual Exhibition at Morley Hall. Prize distribution on 18 by Captain Abney. Lantern on 19. 24, Open Night. 31, *Paget Printing-out Processes*, by Mr. S. H. Fry. Albumen, Emulsions on Opal, Colour, Gradation, Tone, Surface, Permanency, Combined *versus* Single Baths Demonstrations, &c. Important Exhibition Notice. Members are requested to note that, with respect to the condition on "Exhibiting," attendances count from date of last Exhibition, not from the Annual Meeting.

THE South London Photographic Society's Fifth Annual Exhibition will be held at the Peckham Public Hall, Rye-lane, Peckham, S.E., on Tuesday, Wednesday, Thursday, Friday, and Saturday, November 7–11, 1893. The following classes are open to members only:—A. Portraiture and figure study, including animals. B. Architecture. C. Landscape and seascape, above half-plate. D. Landscape and seascape, half-plate and under. E. Enlargements. F. Lantern slides. Medals will be given in the above classes according to the number of competitors and the quality of the work. In addition a silver medal will be given for general excellence. Open classes:—G. Pictures which have previously received an award. H. Pictures not previously medalled. I. Lantern slides which have previously received an awards K. Lantern slides not previously medalled. The silver and bronze medal

competed for in the above classes will be awarded at the discretion of the Judges. Entry forms and further information respecting the Exhibition can be obtained from Charles H. Oakden, Hon. Secretary, 51, Melbourne-grove, East Dulwich, S.E.

PATENTS COMPLETED.

IMPROVEMENTS IN AND APPARATUS FOR THE PRODUCTION OF OXYGEN AND NITROGEN FROM ATMOSPHERIC AIR.

No. 19,078. LEONARD CHAPMAN, 232, Camberwell New-road, Surrey. *August* 26, 1893.

THE object of my invention is to provide means whereby oxygen and nitrogen can be obtained from atmospheric air by a continuous process, avoiding the waste of oxygen which takes place when the operation is carried on intermittently as hitherto, and ensuring a product of greater purity. According to my invention, I provide a pair or a series of vessels or chambers in which the material by which oxygen is absorbed, and from which it is liberated, is contained in a liquid form, or suspended in a liquid, the said material, after it has been peroxidised by absorbing oxygen from the atmospheric air supplied thereto, being caused to pass into the vessel in which the deoxidising takes place, and afterwards to pass back again to the preceding vessel to again be peroxidised. The apparatus, in which my invention may be carried into practical effect, consists, in its simple form, of two vessels which communicate with each other by passages in such manner that a circulation of the material throughout the two vessels is obtained. The communications consist preferably of pipes, which ascend centrally from the bottom of the vessel, and open at top below the level of the liquid therein, the lower ends of the pipes communicating each with the other of the vessels.

An equal pressure above the material in the said vessels can be maintained by means of suitably weighted outlet valves, that of the peroxidising vessel leading to the open air, or to the place where nitrogen or unabsorbed gas or gases is or are to be stored or employed, and that of the deoxidising vessel leading to the condenser or separator, and to the place of storage of the oxygen. A current or circulation of the oxygen-absorbent material is maintained throughout the two vessels, that from the peroxidising vessel, after having absorbed oxygen from the air which is caused to pass therethrough, descends the central pipe and passes into the deoxidising vessel, in which the oxygen is withdrawn or liberated from it by the aid of steam, and then the material flows down the central pipe of the deoxidising vessel, and passes back into the peroxidising vessel, to again absorb oxygen, and this is continuous whilst the apparatus is at work. In order to control the speed of movement of the material, I may use controlling valves to render the movement slower. To hasten the movement, I employ either an injector arrangement for air for the passage between the upper part of the deoxidising vessel and the lower part of the peroxidising vessel, or an injector arrangement for steam for the passage between the upper part of the peroxidising and the lower part of the deoxidising vessel, or I use both such injector arrangements together.

The air and steam used in the said injector arrangements can, in whole or in part, be the air which is used for peroxidising and the steam which is used for deoxidising.

The inlets for air and for steam may be provided with automatic pressure regulating valves.

The vessels are heated by any suitable means, such as by an external furnace or furnaces, and the oxygen-absorbent material may be of any suitable character which will pass from vessel to vessel as described. The two vessels may be heated to the same or to different temperatures.

Although I have named two vessels in the foregoing description, I may conduct the process in a series of any suitable number, having communications from the one to the other for the purpose described.

IMPROVEMENTS IN AND IN CONNEXION WITH PHOTOGRAPHIC CAMERAS.

No. 19,251. EDMUND HAWTHORN MICKLEWOOD, 5, St. Michael's-terrace, Plymouth, Devonshire.—*September* 2, 1893.

MY invention relates to a means of exposing sensitive plates or films in a photographic camera so as to give a due ratio or balance of exposure to all parts, and refers to the invention described in the specification of my Patent No. 9042, dated May 28, 1891. In that invention I effected the desired result by means of a rising and falling shutter in combination with a dark chamber between the lens and the shutter. I now simplify the mechanical details, and produce the same result by having the shutter, still in combination with the said dark chamber, but with a motion in one direction only, under which condition the result may be attained in either of the following methods.

1. The opening in the shutter, which, by passing vertically across front of dark chamber, effects the exposure, may move at a uniform speed, but the actuating mechanism to be so connected with an iris diaphragm on the lens, that the several parts of the sensitive surface shall receive the desired variation of exposure by the expansion or contraction of the diaphragmatic opening.

2. The said opening in the shutter is so controlled by suitable mechanism, that its motion across the exposing aperture shall be one of uniformly accelerated or retarded speed, according as its passage is in an upward or downward direction.

The above result may be attained or enhanced by combining with the actuating mechanism a brake which comes into action during the slow part of the motion only, or allows a graduated speed by a graduated degree of friction.

The slot in the shutter may pass in front of opening of chamber in a horizontal direction at a uniform speed, and the graduation of exposure may be attained by having the slot of a V shape, whereby the wider part exposes the foreground and the narrower part the sky.

It will be apparent from the optical considerations involved that the dark chamber may be formed before or behind the lens, the motion of the shutter being reversed in the latter case on account of the crossing of the rays of light after passing through the lens.

In every case the combination of the dark chamber with the moving shutter at opposite end thereof to the lens is essential, for reasons fully set forth in the specification of my Patent, No. 9042, of 1891.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

SEPTEMBER 26,—Technical Meeting.—The apparatus on view at the Exhibition was explained, several of the exhibitors being present for that purpose. Most of the exhibits will be found described either in back numbers of the JOURNAL or in our notice of the Apparatus Section of the Exhibition.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

SEPTEMBER 21, Mr. Thomas Bedding in the chair.

Mr. P. R. SALMON was unanimously elected a member.

The HON. SECRETARY drew attention to the dinner of members of affiliated Societies to be held at the Frascati Restaurant on Friday, October 13. The tickets (6*s.* each) may be obtained from hon. secretaries of those Societies.

FILM-WORKING.

Mr. W. H. BARNES read a paper on this subject [see page 623].

In the course of a discussion that followed, the Chairman said that he had recently been using a few films, the remainder of a batch he had employed about eighteen months ago, and could not detect any degradation of quality. As to the drying of films, where only a few were used, he thought it a good plan to place their backs in contact with plain sheets of glass, and place them sideways against the wall, in the same manner as glass plates. He had found some films had a greater tendency to curl than others, so that a much greater depth of fixing or other solution was necessary to cover them.

Mr. BARNES showed a reversed negative taken through the back of the film, in which there was no perceptible loss of sharpness.

Mr. W. E. DEBENHAM commented on Mr. Barnes' statement that pyro-ammonia gave greater distinctness between the high lights and the lights that came next to them, and said that, if it were so, it would be contrary to Messrs. Hurter & Driffield's contention.

Mr. B. J. EDWARDS said his experience was that there was no developer that would give the difference between the high lights and the next highest lights so well as pyro-ammonia. Photographing a white patch against black velvet, different developers would give a difference in the amount of detail. A large excess of carbonate of soda would give the high lights black compared with a dilute developer.

Mr. J. S. TEAPE, speaking of the use of cut films, said he had not had much experience of them, but what he had had, did not give him much confidence in them.

Mr. T. E. FRESHWATER said that films had had an advantage in weight when it was desired to send them from place to place.

Mr. BARNES said that, as regards films not being as reliable as plates, they would be found better as the manufacture of them improved.

Mr. A. MACKIE thought that the advantages of films ended with development.

The CHAIRMAN said there were occasional difficulties in the manipulation of film negatives as compared with glass, and instanced the fact that that day he was making some stereoscopic transparencies by copying, and, desiring to use some film negatives, could not do so on account of the carrier not being adapted for them.

Mr. EDWARDS pointed out a particular advantage of always varnishing film negatives, as minute surface scratches on the film would be got rid of.

After other discussion the meeting terminated with a vote of thanks to Mr. Barnes.

North London Photographic Society.—September 19, Mr. Douglas in the chair.—Experiments were made in the development of Nikko paper, the members bringing the developers preferred by them respectively in working bromide papers. The best and very similar results were obtained by the use of eikonogen and metol, only half the exposure being given when metol was used as the developer. The following formulæ were liked best:—*Eikonogen Developer:* Eikonogen, 4 grains; sulphite of soda, 16 grains; carbonate of lithium, 2 grains; bromide of potassium (10 per cent. solution), 1 minim; water, 1 ounce. (This is the formula first introduced, it is believed, by Mr. Cowan.) *Metol Developer:* The standard metol-soda developer of Hanff's diluted with 7 parts water. The pink colour of the paper will restrict its use. In answer to a query as to how the name came to be selected, it was suggested that the manufacturers, with transatlantic modesty, had named it after Nikko, a spot in Japan, so charming that the Japs have a proverb, "He who has not seen *Nikko* (sun brightness) must not say *Kekko* (beautiful)." As there is plenty of shine and colour in the paper, some may contend that the appellation is appropriate.

North Middlesex Photographic Society.—On Wednesday, September 20, another of the series of Instruction Evenings was held, Mr. C. Beadle being in the chair. The subject, *Lantern Slides by Contact*, was dealt with by Mr. A. J. Golding. He described briefly the *modus operandi*, explaining the kind of negatives which would give the best results, the method of obtaining the range of tones from red to black by a difference of exposure and restrained developer, the fixing, clearing, &c., and then demonstrated his remarks by developing two plates. After this the members were set to work under his supervision, the result being that many really good slides were made, to the pleasure and profit of the workers. On October 9 Mr. W. E. Debenham will demonstrate *Wet Collodion*. An interesting evening is anticipated, to which visitors are welcome.

SEPTEMBER 25.—Ordinary Meeting, Mr. W. B. Goodwin, A.R.I.B.A., in the chair.—Mr. THOMAS BEDDING lectured on *Stereoscopic Photography*. [This will appear in our next.] Mr. Traill Taylor, who accompanied Mr. Bedding, produced several stereoscopes and some hundreds of slides, and kept the members interested and amused for some time by the wise and witty remarks and comments he passed upon them. Mr. H. Smith took first place for picturea taken at West Drayton. Next meeting, October 9, *Wet Collodion*, by Mr. W. E. Debenham. Visitors welcome.

Hackney Photographic Society.—September 19, Mr. W. Houghton (president) in the chair.—Mr. S. J. Beckett showed boards for holding prints flat, held together by means of a leather strap. Members' work was shown by Messrs. Sodeau and Grant. Mr. Barnes showed an under-exposed negative developed for half an hour in metol, and asked for a remedy. The general opinion was that it was useless. Messrs. Holmes and Watson showed "Matthews'" portable lantern; its weight is only ten pounds, and is carried in a box 13½×6×5. It was a very ingenious arrangement, and had many improvements to aid the lanternist in exhibiting slides. A report of the Society's outing (under the leadership of Mr. Gosling) was read. The dull weather rather interfered with hand-camera work; however, a few good snapshots were obtained. The excursion was to Kew and Richmond by steamer from Old Swan Pier. The latter part of the evening was devoted to an exhibition of members' slides with the lantern (under the management of Mr. Rose). Slides were shown by Messrs. S. J. Beckett, Carpenter, Cross, Grant, Hankins, Hensler, W. Fenton-Jones, Nunn, Roofe, Rose, Sharman, and Sodeau, from whom some excellent work was exhibited.

South London Photographic Society.—September 18, Mr. F. W. Edwards in the chair. The evening was devoted to a demonstration of *Lantern-slide Making*, by Mr. H. E. Farmer. Several Ilford special lantern plates were exposed under negatives of different characters, and afterwards developed before the members. He sketched the apparatus used by him for making slides by reduction, and explained the method of using the same. Some slides which were too dense for use by over-development were reduced by the use of sulphocyanide of ammonium and ferridcyanide of potassium, which the lecturer considered preferable to hypo and ferridcyanide. Slides requiring more pluck and density were intensified by using a bath consisting of uranium nitrate, red prussiate of potash, acetic acid, and water. In the event of the slides becoming too dense by this method, the red colour can be discharged by using a bath of carbonate of soda, and the toning, after washing, started afresh, but not carried so far. Several methods of rectifying various faults were fully explained by the demonstrator. On October 2 Mr. E. J. Lester will read a paper on *Outdoor Portraiture*.

Brixton and Clapham Camera Club.—September 18, the President, Dr. J. Reynolds, F.R.G.S., in the chair.—A demonstration upon carbon printing was given by one of the members, Mr. F. W. Levett. Four names were given in as candidates for membership, and further names will be gladly received. Photographers residing in the locality are informed that a Committee of Instruction has been formed for the purpose of assisting members, and a Committee of Criticism for the purpose of examining and criticising members' work. Next meeting, October 3. Paper by Mr. E. Dockree on *Gelatino-chloride Papers*.

Birmingham Photographic Society.—September 19, Mr. J. T. Mousley in the chair.—This was the first of the so-called one-man exhibitions inaugurated by the Club, which it is proposed to hold through the winter. The gentleman showing, Mr. J. H. Pickard, had staged for inspection a large number of fine photographs, ranging from the lordly 15×12 to the humble half-plate, and the Exhibition was very much appreciated. Mr. Pickard kindly made the tour of the room, giving interesting details of processes, &c., and answering the numerous questions put to him.

Newcastle and Northern Counties Photographic Association.—The last out-door meeting of the season was held on Thursday, the 21st inst., Ridley Hall Woods and Staward Pele being the places selected for the day's operations. There was a large muster of members, who were reinforced by contingents from the Hexham, Sunderland, and Durham Photographic Societies. The day's work was done under almost perfect conditions as to weather, and many good pictures will, doubtless, result. Mr. J. Pattison Gibson, of Hexham, acted as leader of the expedition.

Wigan Photographic Society.—September 21, Annual meeting.—Annual report and balance-sheet presented showed a balance in hand of 2*l.* 13*s.* All retiring officers, with one exception, were re-elected as follows:—*President:* Mr. J. A. E. Lowe. *Vice-Presidents:* Rev. J. S. Barnes, M.A., and Messrs. R. Wardman and G. R. Newman. *Ordinary Members of Council:* Messrs. J. Smith, J. H. Atherton, B. B. Hartley, S. Richardson, H. H. Hill, P. Clark, and C. R. S. Kirkpatrick. *Hon. Secretary and Treasurer:* Mr. Fred. Betley, 10, Ashland-avenue, Wigan. Meetings held fortnightly on Thursday at Y.M.C.A. Rooms, Rodney-street, Wigan.

FORTHCOMING EXHIBITIONS.

1893.		
September 29–Nov. 15		*Photographic Society of Great Britain, 5A, Pall Mall East, S.W. Assistant Secretary, R. Child-Bayley, 50, Great Russell-street, W.C.
October 1–31	.....	*Hamburg. Das Ansstellungs Committé des Amateur Photographen Verein, Schwanenwik, 33, Hamburg.
,, 2–14	.....	Midland Camera Club, Botanical Gardens, Moseley, Birmingham. Hon. Secretary, C. J. Fowler, 4, Woodstock-road, Moseley, Birmingham.
,, 9–Nov.	...	*Photographic Salon, Dudley Gallery, Piccadilly, W. Hon. Secretary of Organizing Committee, A. Maskell, 215, Shaftesbury-avenue, W.C.
,, 17–19	.....	*Hackney Photographic Society, Morley Hall. Hon. Secretary, W. Fenton Jones, 12, King Edward-road, Hackney, N.E.
,, 30, 31	.....	*East London Photographic Society, New Tabernacle, Old-street, E.C. Hon. Secretary, W. R. Gould, 61, Gibraltar-walk, Bethnal Green, E.
November 7–11	.....	*South London Photographic Society. Hon. Secretary, C. H. Oakden, 51, Melbourne-grove, Dulwich, S.E.
,, 20–25	.....	*Leytonstone Camera Club. Hon. Secretary, A. E. Bailey, Rose Bank, South-west-road, Leytonstone.
December	.....	*Madras. The Hon. Secretary Amateur Photographic Society, Madras.
,, 18–Jan. 22, 1894		*Bristol Triennial International Academy of Arts, Bristol. Hon. Secretary, F. Bligh Bond, 36, Corn-street, Bristol.

* Signifies that there are open classes.

Correspondence.

ALUMINIUM *VERSUS* MAGNESIUM.

To the EDITOR.

SIR,—Your correspondent, Mr. J. T. Hackett, will be able to obtain the fine aluminium powder from Mr. W. C. Home, 2, White Horse-alley,

Cow Cross-street, London, E C., and, I believe, the price of an ounce, post free, would be 1*s.* 6*d.* No. 2 fineness should be asked for.

As regards removing the greasy matter, the method which I recommended—viz., heating to about the temperature of melting zinc—was the result of several experiments, which included the treatment of the powder with neutral fat-dissolving liquids, as suggested by Mr. Hackett, the heating method being more convenient and economical. Methylated spirit is not solvent enough of fat to be useful, but ether or benzole may be employed. Even after treatment with one of these, a sharp drying at a temperature over the boiling point of water is desirable, indeed, almost essential. This drying is substantially as much trouble as sufficient heating to drive off the original oily matter, so there is scarcely any inducement to employ the fat-solvent. Treatment with alkalies is not practicable, as they dissolve the metal, and a mere trace remaining will set up oxidation.

If any considerable demand should arise for aluminium for flashlight purposes, no doubt it will be sold quite ready for use. To free it from the trace of oily matter would not cost one penny a pound on a large scale, but the trace of fatty matter is no disadvantage, but rather the reverse when the metal is used as a dusting bronze.—I am, yours, &c.,

THOMAS BOLAS.

Chemical Laboratories, Chiswick, September 25, 1893.

AMATEUR *VERSUS* PROFESSIONAL.

To the EDITOR.

SIR,—I am sorry Mr. Blair does not approve my tone and conclusions in reference to the subject he writes of. But he neither comprehends clearly, nor represents fairly, what I wrote, and which seems to have called out his "regret." I did not say that the professional had done *nothing* to make outdoor photography a practical affair, but very little in comparison with what the amateur has done. All the dry-plate processes were formulated by amateurs, and, if the commercial manufacture has been more successfully carried out by men who were formerly professionals, that is nothing to the point. When I say that out-door photography is made a practical affair, I mean that it has been made possible by improved processes to use any plates with certainty, and to depend on their keeping for considerable periods and working with a trustworthy regularity. And this was, in the case of the great step of gelatine plates, the work of amateurs; who afterwards takes up the process and furnishes us with plates commercially has done comparatively very little. And, so far as I can remember, every step in the development of the dry plate of to-day, from the Taupenot, through the dry collodion, collodio-bromide of Major Russel, and collodio-bromide emulsion of Sayce and Bolton, to the gelatine of Mr. Bennett, has been made by amateurs, every one of whom has given the general public the benefit of his brains. The plates of Mr. Carbutt or Cramer, and of Edwards, Sandell, Fitch, and all the list of commercial manufacturers, are probably better than I could make for myself, and much cheaper, but if I had them not I should make them myself, as I did the other dry plates for glass before there were such things as commercial plates. These amateur discoverers collectively "made outdoor photography a practical affair."

As for cameras, Mr. Kinnear made the first really portable field camera, and the next advance beyond that, a folding camera, which always had all its parts in their proper position, shutting up like a book, and extending at pleasure, was mine, and nearly every modern extending camera has borrowed the principle I made practical, and have improved it in details.

When, therefore, the benighted professional, straightened in his circumstances, begins to abuse the amateur as the cause of his straightness, I have only to say to him, as I said in the letter to which Mr. Blair objects, "What have you and your fellow professionals attributed to practical photography which will compare with what the amateurs have done? and where would photography be practically if we had waited for professionals to work out the processes, and spend their brains and money in doing what amateurs have done without compensation and (so far as the professionals are concerned, who get their bread by the results) without even a thank-you, but, on the contrary, with great abuse, and proposals to put them on a licence to work their own inventions?"—I am, yours, &c.,

Rome, September 20, 1893. W. J. STILLMAN.

PHOTOGRAPHIC SOPHISTICATION AND PERSPECTIVE.

To the EDITOR.

SIR,—Your contributor, "Free Lance,"—who is generally accurate in optical matters—in criticising my "illustration of a block of buildings viewed in perspective, and a model, one-tenth scale, viewed at one-tenth the distance" implies that the vanishing lines in the two cases would be very different. Will he be good enough to demonstrate this proposition, or admit that for once he has made a mistake?

There is one other point on which I cannot agree with him. He says that, if photographs are taken at a distance of thirty or forty feet, no one will complain of distorted hands and feet. In single-figure pictures, taken in such poses as photographers usually adopt, the difference of size of parts due to perspective is so little, between a figure taken at the distance I mentioned (anything over twenty feet) and of the same figure taken at thirty or forty feet, that I believe few people could discover it. Moreover, if people complain that their heads and waists come out too large—parts not usually enlarged by perspective in a photograph—the mere taking of the picture from a greater distance will not satisfy them. Photography and modern painting have done much towards destroying the conventional ideal which people liked to see themselves resemble. If photo-optical sophistication should ever become at all general, much of this good work would be undone.—I am, yours, &c.,

September 25, 1893. W. E. DEBENHAM.

PHOTO-MICROGRAPHY.

To the EDITOR.

SIR,—Every expert optician knows that achromatic objectives may be as perfectly corrected for the light of a narrow band of the spectrum, as the apochromatics are for a wider band. Every real expert in orthochromatic photography knows that photographs can be made by the light of any part of the spectrum at will, by the use of colour-sensitive plates and colour-screens. It follows that every expert photo-micrographist should know that, except in rare instances, where the colour of the objects affects the conditions, achromatic objectives should be capable of giving as perfect definition in photo-micrography as apochromatic objectives give visually. I recognised this fact, proved it experimentally, and called public attention to it, in a few words, years ago. Mr. Pringle, after writing fifty times as much upon the subject, even now recognises only a part of the facts. "A word to the wise" should be sufficient, and I have far more important work to do than to repeat experiments for the purpose of convincing Mr. Pringle of what I know many experts already recognise as obvious facts.

Mr. Pringle's assumption that I "certainly have much to learn about apochromatic glasses," as he "suspected from the first," is justified only by an altogether wrong interpretation of my reference to low-power achromatics. I meant to make it clear that a flat field with good definition over a large area is more valuable for low-power photo-micrography than better colour correction with a less flat field, provided that the resolving power is more than sufficient for the magnification. There is no advantage in resolving details too small to be seen in the photograph. I gave the preference to an American one-inch objective over an apochromatic of similar focal length only after making actual comparative tests, and because the American objective had the flatter field; but it also had a greater angular aperture.

I also tested some high-power apochromatics, and was the first to convince a sceptical microscopist, the son of a well-known maker of microscope objectives, of the advantages which these objectives actually do possess over even the best possible achromatics. If Mr. Pringle had not been pleased to "suspect from the first" that I was ignorant of the capabilities of the apochromatics, I do not believe that he would have been so easily persuaded to that effect.

With regard to the American objectives Mr. Pringle is sceptical about, I can only say that besides seeing the published testimony of others, I have been assured by two expert microscopists that they saw "*A. pellucida* "unmistakably" resolved by a Gundlach objective, with ordinary mirror illumination; and by another, that he had seen *A. pellucida* resolved by a Jolles "dry" objective, after sitting by for two hours while Jolles himself worked to secure the necessary conditions of illumination. It is recognised that both of these feats are quite possible in theory and although I believe neither of these makers claimed to have succeeded in making another objective of the same kind that would do the same thing, the testimony as to these two appears to be fairly conclusive.

Mr. Pringle thinks getting to "beads" on *S. Gemma* is not getting very far ahead, but that *S Gemma* in "dots" may be regarded as "high-class" photo-micrography. I am made to realise that I used the wrong word. My photograph showed *S. Gemma* with rows of black dots.

There is really no evident reason why Mr. Pringle should assume that I need to be told that apochromatic objectives are of different glass and different construction than achromatics. Nor do I find it pleasant to be charged (unjustly as I believe) with making careless statements, by one who himself explicitly credits me, when he has my letter before him, with an assertion which I never made or would make. I never asserted that "there are achromatics equal to apochromatics." What I did say was that, assuming certain things, supported by certain testimony, "it seems to me to follow that one achromatic objective may be better for high-class photo-micrography than another apochromatic objective," &c. I will now go so far as to say that some achromatic objectives will certainly give better results with yellow light than any apochromatics will with the ordinary white light and ordinary gelatine-bromide plates which Mr. Pringle formerly thought were suitable for "high-class" photo-micrography with apochromatic objectives.

I confess that when I obtained notably fine photographs of all the more difficult subjects reproduced in Mr. Pringle's book, besides others still more difficult, I thought I had fairly demonstrated the possibility of doing "high-class" work with achromatic objectives. If Mr. Pringle denies that such a test proves that possibility, I ask, why did he not see fit to include a single example of "high-class" photo-micrography among many illustrations in his book? And how should I know except through

the "ordinary journalistic criticism," that he had ever done any "high class" photo-micrography?—I am yours, &c., F. E. Ives.

116, *Charing Cross-road, W.C., September* 26, 1893.

SPOTS AND PINHOLES.

To the Editor.

Sir,—The above have recently been discussed in your columns by Mr. Dunmore, who refers only to dust and bubbles as being the sources of pinholes in the negative. Experience leads me to conclude that to these two causes, which it is within the power of the photographer to avoid, may be added a third which is beyond his control, because it is a fault existing within the plate itself. In July, 1887, a year abounding in dust, I was using plates of three different makers; these were all treated in precisely the same way, so far as the avoidance of dust and bubbles was concerned, yet plates of one brand gave negatives full of pinholes, equally distributed over the surface, whilst those of the other two makers were practically free from this defect. The same camera was used for all, the slides were filled indiscriminately, and as the trouble was met with in one set of plates only, and the pinholes were not more abundant on that part of the plate which was placed downwards during exposure (where dust effects most usually are found), it would appear that the mischief must have been owing to defect in the film. I thought that a probable explanation was that during the processes of making the negative minute blisters were formed, that these arose from the glass surface being imperfectly cleaned before it was coated, and that as the gelatine dried and contracted the blisters split into the pinholes which ruined my negatives. The films also tended to frill at the edges, another symptom of imperfect cleansing of the supporting surface. I tried the same make of plates on a future occasion and met with the same defect.

This year has been as prolific of dust as was the never-to-be-forgotten "Jubilee year," but so far I have been quite undisturbed by the appearance of pinholes on my negatives. This desirable condition, I believe, is due to the observance of two precautions. First, beyond the usual dusting of films and slides after the latter are filled, the shutters are pulled in and out two or three times, and the face of the film again dusted as it lies in position. Second, the plates are firmly wedged in the slides so that no rubbing can take place between the edges of the former and the rebates of the latter. I may add that changing of plates has been done in the dark without the aid of light of any kind.—I am, yours, &c.,

September 19th, 1893. F. R. Fisher.

WARMING THE DARK ROOM.

To the Editor.

Sir,—In reply to Mr. J. Tilfor's inquiry, there is not any better gas stove made than "George's Calorigen" for either dark room or any other place; it gives a constant supply of pure warmed air, and does not emit any light—but it has the drawback of requiring two openings making in an outer wall, one for inflow of air to be heated, and one for outflow of the products of combustion. If this requirement can be complied with, it is a perfect stove. It is years since I bought mine, but I think the depôt was then in Regent street, but any ironmonger would supply one. They will *not* answer connected with an ordinary chimney.

If the stove must be placed where no communication can be had with the outer air, then I recommend a "Clark's Syphon Stove;" they can be had fitted with a ruby chimney, which, however, is not by itself a "safe" light, but becomes perfectly so if an outer casing of canary paper be added. These stoves are also made quite dark, but I find it a convenience to have a little light on the floor; if one happens to drop anything it saves a good deal of unparliamentary language during its recovery. They do not require any flue whatever, and all the products of combustion (except carbon dioxide) are carried off into the water-trough.

I do not recommend them to be placed in a room without *any* ventilation, because of the carbon dioxide, but if there be a reasonable access of air they are in my opinion to be preferred to those stoves that have a flue led into an ordinary chimney, in which very frequently there is a down draught.

Damp and sulphur fumes are great enemies to the photographer, and very few are aware of the enormous quantity of water manufactured by gas, an ordinary single gas jet, consuming five cubic feet per hour, will throw into the atmosphere of a room *a pint and a half* of water per twenty-four hours. The Clark Syphon Stove condenses all this, and with it the sulphur and other fumes.

My dark room is 13 ft. × 9 × 10, and was satisfactorily warmed last winter from November 18 to February 17, *night and day*, at a cost of 1*l.* 5*s.* 10*d.* (We are blessed in the North with cheap gas, 2*s.* net per 1000 cubic feet.)

There is a great advantage in using gas and having the heat on all night, no frozen pipes, no ice-cold solutions, no dust, no trouble of any sort.

Clark's address is Park-street, Islington, N., but the stoves can readily be procured through any dealer.—I am, yours, &c., Edward J. Smith.

Park Royd, Halifax, September 19, 1893.

RETOUCHERS' TROUBLES.

To the Editor.

Sir,—It is a source of wonder and amazement to many an old photographer to notice the readiness with which his younger *confrères* settle off-hand doubtful questions and give equally off-hand advice. Take the case of Mr. Pike's letter in a recent issue, under the above heading. A writer has complained of a simple difficulty of a greasiness on the surface of a gelatine negative rendering it difficult to use the pencil. Mr. Pike seems to see that the negative wants *cleansing*, and forthwith recommends the use—presumably for all negatives, thick and thin—of a powerful reducer and *cleanser*. Does he happen to know that this reducer is one of the most dangerous to the gradations of the negative that can be used, and that Messrs. Hurter & Driffield specially caution photographers to beware of its effects? Does he also know that no reducer gives a more shiny and toothless surface to a gelatine film than this, so that, if a film fairly rich in gelatine is used, every negative reduced by it can be instantly seen by the glossy surface amongst a batch of others? If your correspondent had searched industriously for a remedy that should be worse than the disease, he could hardly have hit upon a greater success than in advocating ferridcyanide and hypo as a cure for a greasy surface.—I am, yours, &c., An Old Hand.

THE PHOTOGRAPHIC EXHIBITION.

To the Editor.

Sir,—May I ask you to find room for the following correspondence in your columns, in order that I may not have any credit which is not due to me?

My part consisted in enlarging to the special colour I thought best suited to the subject, inventing the title, and choosing the method of mounting, making the exhibit a harmonious whole, my object being to enforce views which I have frequently expressed as to the great necessity for adapting the colour of a print to the subject, and the advantages offered in this respect by Alpha paper.—I am, yours, &c., John Howson.

Camera Club, Charing Cross-road, W.C., September 25.

"*Telegram to* Child-Bayley, 50, *Great Russell-street, W.C.*

"Just discovered that I omitted to state in entry form that my Alpha enlargement was from a quarter-plate negative by Mr. Howell, of Barbadoes, and I hasten to disclaim any credit not due to me, in case it affects the award.

"Howson."

"50, *Great Russell-street, W.C.*

"Dear Sir,—In reply to your telegram, the omission from entry form will not affect the award in any way.

"You might, of course, make the announcement through the press if you wish.—Yours faithfully, "R. Child-Bayley, *Assistant Sec.*

"J. Howson, Esq."

Exchange Column.

*** *No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance. The full name of the advertiser must in all cases be given for publication, otherwise the Exchanges will not be inserted.*

Will exchange 5×4 set complete for tripod dark slides (double half-plate) and shutter.—Address, R. S. Winterburn, 1 Alexander-terrace, Wealdstone, R.S.O.

Wanted, a 12×10 modern camera, with slides, &c., in exchange for a Ross No. 3 improved portrait lens.—Address, H. Bartholomew, Great Linford, Newport Pagnell.

Wanted, 15×12 studio camera in new condition in exchange for 10×8 brass-bound, square, leather bellows camera, double swing and reversing back, rising front—three double book slides nearly new; cost 14*l.*—Address, H. Bullock, 48, Leicester-street, Leamington Spa.

Answers to Correspondents.

*** *All matters intended for the text portion of this* Journal, *including queries and Exchanges, must be addressed to* "The Editor, The British Journal of Photography," 2, *York-street, Covent Garden, London. Inattention to this ensures delay.*

*** *Correspondents are informed that we cannot undertake to answer communications through the post.*

*** *Communications relating to Advertisements and general business affairs should be addressed to Messrs.* Henry Greenwood & Co., 2 *York-street, Covent Garden, London.*

*** *It would be convenient if friends desiring advice respecting apparatus, failures in practice, or other information, would call at the Editorial Office either on Wednesdays from* 4 *to* 6, *or Thursdays from* 9 *to* 12 *noon, when some one of the Editorial staff will be present.*

Perplexed.—We have forwarded your letter to the gentleman named.

Torbay.—You would require a lens of sixteen inches equivalent focus.

J. E. G.—We do not think that there is a better one than Hare's automatic.

E. J. SMITH.—Thanks. We shall investigate the matter, and correct where necessary.

J. E. P.—The firm have no right to detain the negatives. Threaten an action for illegal detention.

TRANSPARENT.—Any waterproof material would do for covering the tent, so long as it is light-tight.

J. DAVIES.—A cement formed of a solution of celluloid in amyl acetate may be used to mend your tray.

A. E. G.—Messrs. Tunny & Co., Maitland-street, Edinburgh, produce burnt-in opals. Apply to that firm.

MOUNTS.—We fear that this is one of the mysteries in photography that will remain unsolved for perhaps several years yet.

A. M.—Such classes as those to which you refer are held at the Polytechnic Institution, Regent-street, London. Write for a prospectus.

H. A. G.—Inasmuch as the markings appear to be on both sides of the film, we should imagine the plates to be at fault, but we cannot hazard the cause of the markings.

NITCHEGO.—Both articles mentioned have been made and sold for many years; the stand by the Scovill Manufacturing Company, and the lens shade by Ross & Co.

W. BIRRELL.—Our correspondent wishes to know the address of any firm who manufactures articles in glass—glass-blowers, in fact. Can any reader give the information?

A. KIRKWOOD.—By all means employ a condenser. It is immaterial whether you use coal gas or an oil lamp for such a small degree of enlargement, but only one light must be used.

OPERATOR.—In the formula named we should think the quantity of sulphocyanide insufficient. The precipitate should be redissolved, otherwise, as you note, there is a loss of gold.

F. B.—We cannot quite recommend such a course as that suggested, nor do we know of a competent teacher in your part of the country. There may be several, only we do not know them.

ANXIOUS.—The only thing we can suggest as likely to be useful in increasing the light is to employ corrugated mirrors fixed outside the window, on the same system as Chappuis' reflectors.

AMATEUR.—Directions for making blocks will be found in our last ALMANAC. We do not know where lessons can be obtained. The electrotype process for making surface blocks has proved too slow for this high-pressure age.

TERRA.—1. The markings are very singular, and, if elsewhere, would be considered beautiful. We cannot give an explanation of the cause. 2. Terra-cotta toues may be obtained by printing deeply and fixing without gold toning.

LIGHT.—Erect a large sheet of white card at an angle behind the negative, and illuminate this by any powerful light. Place the camera at a suitable distance in front, and the large negative can thus be reduced to the small-sized transparency required.

B. H. R.—You are by no means the first that has been told by the country druggist that hyposulphite of soda and sulphite of soda are the same thing. No wonder that the plates were spoilt! and it is very annoying. Sulphite of soda is rarely kept by the village chemist.

P. EGLI.—We do not recommend particular makes of hand cameras. See the advertisement pages of the ALMANAC and JOURNAL for particulars of innumerable varieties, among which you should be able to find one to suit you. The "Hawkeye" camera was described in last week's JOURNAL.

T. KELSEY.—In copying the water-colour drawings a better result will be obtained by employing plates that have been treated with the orthochromatising mixture referred to. With the monochromes, ordinary plates will answer quite as well, if the paper upon which they are is, as we assumed it to be, white.

T. KIRBY.—The majority of the lantern slides seen in the shop windows are by the wet-collodion process. Very few are now made in albumen, or, at least, in this country. If they were made, we imagine that a higher price would be charged for them, as by that method they are more troublesome to make than collodion slides.

G. YEMANS.—The zinc plates employed at the Ordnance Survey Office are not supplied ready for use, but are smoothed and planished on the premises, or, at least, they were two or three years ago, and we have not heard of any change being made since. Zinc, as well as copper, plates are now supplied ready for use by all the dealers in lithographic materials.

C. W. C. sends some prints in which there is a decided blurring or doubling of the image. He says, "The camera was used on a stand, and the shutter worked by a pneumatic release, so that he doubts if the blurring is due to movement."—It certainly is, however. Evidently there is a jerk on the shutter, when it reaches the full opening, or as it begins to close.

H. S. W.—You are under an entire misconception in the matter. No one is entitled to style a thing "patented" that is not. Any one doing so renders himself liable to a heavy penalty. The mere fact that a provisional specification has been lodged does not confer the right to use the word patented. All you can legally do is to say in the prospectus, "patent applied for."

COLNE.—So far as we know, the orthochromatised collodio-bromide plates referred to have not been put on the market. The method was not patented, nor do we see how it could be, as the earliest experiments in orthochromatic photography were with collodio-bromide emulsion; indeed, the process was really brought up to its present state in conjunction with dry collodion.

R. T. JONES inquires if there is any objection on the score of permanency to using the fixing bath for P.O. P. for two or three days in succession, the same as is done with the fixing bath for negatives?—Yes, there is a grand objection to such proceedure if stability in the prints is a consideration. A fresh solution should be made for every batch of prints. Hyposulphite of soda is a very inexpensive salt.

D. CRAIG.—As the collodion splits off the glass as soon as it is dry, it shows that it is of too contractile a character. This may be got over by the addition of a very small proportion of castor oil. Do not use more than is absolutely necessary. One or two experiments will determine the quantity. Methylated ether and alcohol will do very well for enamel collodion provided they are tolerably strong.

ALF. EVANS.—1. If the paper has become as brown as described, it will not yield pure whites, whatever toning bath may be employed, the vendor's assertion to the contrary notwithstauding. 2. The sulphocyanide bath can be used for albumen paper, but there is no advantage in doing so, as the latter tones evenly in any of the ordinary baths. 3. The best strength for fixing solution is half a pound of hyposulphite of soda to the quart of water.

LONDON, E. asks if there "is anything that can be mixed with kerosene oil that will avoid the unpleasant smell given off when it is burnt in the lantern, as it is only in that that it is offensive? The same oil used in an ordinary lamp does not smell."—Different things, such as camphor, have at times been suggested, but they are not really effective. The smell complained of is generally caused by oil outside the lamp. If the lamp and wick tubes be carefully wiped with a clean cloth just before the lamp is lit, there ought to no smell.

B. SCOTT wishes to know if he makes up a silver bath for negatives according to the formula given in the sixth edition of Hardwich's *Photographic Chemistry*, and gets Mawson's collodion, he can develop with any of the new developers made according to the formula supplied with them, or the ferrous-oxalate developer, with the working of which he is familiar?"—No, they will not answer. If our correspondent desires to work the wet-collodion process, he will have to employ the developer suited to it. Dry-plate developers are of no use for wet collodion.

T. C. BENN.—The print shows the lens to be a very good one, although it bears no maker's name. The lack of marginal definition is due to its being worked on too large a plate. A lens of five inches equivalent focus, and an aperture of *f*-5·6, must not be expected to cover a five by four plate sharp to the corners, unless it is somewhat stopped down. With a small stop it will, doubtless, cover a larger plate than that mentioned. We should say, taking the aperture and focal length into account, there is nothing whatever to complain about. If that size plate has to be covered sharp all over, with an aperture as wide as that named, a lens of greater focal length must be obtained.

SAXON.—This correspondent writes as follows:—"I send herewith four copper plates and prints therefrom. The plates were produced by the method described by Mr. Dennison some time ago. If you will kindly examine them, you will see that the etching is quite as deep as an ordinary mezzotint plate (of which I possess two or three), and yet the impressions are poor and flat. In fact, in one of them, the half-tones print stronger than the shadows. The proofs were printed by a professional copper-plate printer, so that I do not think the printing is at fault. I shall be obliged for your opinion on the subject, and also for the return of the plates, for which I enclose stamps?"—The etching is quite deep enough—indeed, much deeper than is necessary—but it has no ink-holding power, owing to the absence of grain in the deepest parts. Hence the ink wipes out as the ink is cleared off the surface. This is not the case with the lighter tones. We can only assume that the etching was carried too far in the first instance. Plates and prints returned as requested.

H. H. C. says: "I have to make some negatives, copies of engravings, and my customer particularly wants them by the wet-collodion process. Now, this is a process I have never actually worked, though I have an old manual on it. I think it would scarcely pay me to learn the process, unless it is an easy one to acquire, on purpose to copy these few pictures, less than a dozen, as probably I shall never have to use it again. Will you please answer the following queries for me? 1. Is the wet-collodion process to be easily learnt by one of seven years' experience with dry-plate photography—say, in two or three days? 2. Can the plates be bought partially prepared, that is, for dipping in the bath? 3. Failing collodion, what dry plates and developer will give negatives most like collodion in character?"—In reply: 1. The collodion process is not difficult to work by those *au fait* with it, but the necessary ability is not to be acquired with only a few days' practice. 2. No; the plates must be prepared at the time of sensitising. 3. Any of the slow plates, specially prepared for photo-mechanical work, developed with formulæ supplied with them, will yield negatives somewhat approaching collodion in character.

PHOTO-CERAMICS.

We invite attention to a report on another page, in which an account is given of a demonstration at the London and Provincial Association last week, by Mr. Haddon, on the preparation of enamel plaques on which to produce ceramic, or burnt-in, photographs. As Mr. Haddon has confined himself to the production of the enamels, we will take advantage of the mooting of the subject to carry it a stage farther, and describe in what manner such tablets may be used for producing those beautiful, and undoubtedly permanent, photographs which charm all by whom they are examined.

But, previous to doing so, let us state that the production of ceramic photographs is very far from being a new thing, although so little known, for it dates so far back as 1854, in which year a patent was obtained, in this country, by Peter Armand le Compte de Fontainemoreau, whose invention consists "in fixing, vitrifying, and colouring photographic images taken by the collodion process upon enamel, metal, stone, porcelain, glass, china, and all kinds of earthenware." This, it will be observed, is moderately comprehensive. His method, when boiled down from the technical terms in which it is couched, consists in making a proof upon a plate of glass, and, after fixing, washing, and subjecting to a bath of bichloride of mercury, afterwards placing the film upon one of the substances above enumerated, and baking it in a porcelain furnace. There may, perhaps, be earlier notice of the invention, but this is the first of which we are aware.

This application has by several persons been usually attributed to Lafon de Camarsac, but his first publication was made some time after the other, being June 11, 1855, in *Comptes Rendus*, and in this he seems to be careful in avoiding the giving of such information as would enable any one to produce practical results.

There are now several methods by which photographs may be made upon or transferred to enamels or plaques for subsequent vitrification. Of these the simplest is that of collodion transfer. A plate of glass receives a coating of bromo-iodised collodion. This is then immersed in a thirty-five-grain solution of silver nitrate for two or three minutes. A transparency is developed upon this, but it must be carried to a farther extent than would be the case were it intended for a lantern slide.

The image thus obtained must now be toned, for, if the picture were to be burnt in without this, it would prove of a yellow colour, and not at all pleasant to behold. But, previous to toning, the picture must have been fixed with cyanide of potassium, washed well, and the collodion film removed from the glass plate. This removal is effected by placing the plate in water which has been acidulated with a few drops of sulphuric acid. It will not have been long in this before it is found to have had its hold upon the glass loosened, when it will soon be floating in the water.

The selection of a toning agent is one that involves judgment and the exercise of taste, and it is possible that no two photo-ceramists will employ exactly the same substances. Chloride of platinum has long been a favourite toning bath, used sometimes alone, and sometimes modified by the presence of gold, iridium, and other metals. It is in the selection and proportions of these that the ultimate colour of the burnt-in picture depends. We possess enamels of a rich dark violet tone, made with platinum alone as the toning agent. The tones obtained by iridium are warmer, but there is no difficulty in getting almost any tone desired. Whatever bath be ultimately selected, it is of importance that the toning be carried to such an extent as to obliterate the details of the silver image and bury them in a mass of blackness. The necessity for this will appear when it is borne in mind that the silver which is allowed to remain in the image, and which, as above stated, burns in of a yellow colour, conduces to modify the tone. Let any one who desires to satisfy himself as to this transfer an ordinary collodion positive or negative to a piece of white porcelain dish, and, in absence of a furnace, push it between the bars of a clear coke fire until it becomes red. When removed and examined after it has cooled, the negative or positive, as the case may be, is found to have been burnt in in a yellow colour.

To effect the complete removal of the silver, the services of a solvent are occasionally had recourse to; but this is not always necessary, especially when a toning agent is selected that is not adversely affected by any trace of silver remaining, and when the toning has been carried to the extent suggested. The enamel tablet having been cleaned, it is placed in the vessel of water in which the film is being washed, and by a little dexterous manipulation the film is floated in position and the water decanted. Pressed close up against the surface, the film then is tucked up around the edge, and, as it were, plastered around the back to prevent it from becoming displaced. It is then placed aside to dry, after which the plastered-down portion that was overlapped behind should be removed by means of a pad wetted with ether, or by a scraper.

The fire-clay furnace to which it is now transferred need only be small, and is most conveniently heated by gas. Experience alone can tell when the picture is properly vitrified, but such experience is quickly attained. A convenient way is to insert the blade of a long and otherwise worthless table

knife under the enamel, which, when in the furnace, rests on the top of a plaster of Paris block with a convex top, and lifting it out subject it to a brief examination. It will probably now be found to be bright and full of clear detail when contrasted with the black smudgy appearance it had previously to the heat having been applied. We have seen them returned to the furnace more than once after examination, in order to ensure the desired effect being obtained.

Good vitrifications are also produced by the dusting-on process, fusible enamel powder, which can be obtained in commerce in a variety of colours, being dusted on to form the image, which is afterwards fused by heat.

By means analogous to carbon printing, a vitrifiable powder being used in the tissue instead of carbon, ceramic pictures can be produced without difficulty.

An advantage in the employment of the two methods last mentioned is found in the fact of uniform tones being obtained.

There are some charming example of ceramic photographs in the Pall Mall Exhibition at present open to the public, to which we would invite attention. The absolute permanence of this class of picture is undoubted, and from the hasty outline of proceeding we have now given it will be seen that it is not attended with any inherent difficulty, or one which cannot be overcome by ordinary care.

HEATING THE DARK ROOM BY GAS.

Some correspondence on this subject, which has recently appeared in these columns, renders it probable that a further elucidation of the subject will be of use to some of our readers. It is very difficult to lay down a general rule, inasmuch as dark rooms vary so much in size from the mere cupboard of the tyro to the magnificent laboratory of some workers. The first consideration, one of paramount importance, is the healthfulness or otherwise of gas as a heating agent. This subject is not usually fairly looked at. Most of us are familiar with the lighted gas burner used for illumination, and any remarks about any unsanitary qualities it possesses are taken little heed of. A gas used for a stove, under ordinary conditions, is neither more nor less hurtful than an equal quantity of gas used for lighting purposes. Where the danger comes in is that stoves being only lighted up to produce heat that is just the time when ventilation is most interfered with by closing all doors and windows. We then get the products of combustion in the atmosphere, and experience their evil effects, but not more than if the gas were burnt at ordinary open illuminating burners. There is, however, the possibility of a larger amount of gas being used to produce heat than is ever likely to be employed for illumination, and then the danger comes in. We believe that when gas has been employed for heating water for a bath, the products of combustion have proved quickly fatal, at least one life having been so lost. Hence, for dark-room heating, it will be advisable as a matter of safety to have all products of combustion carried away by a chimney. There are chimneyless stoves sold, which are supposed to condense the products of combustion. They condense the water produced and some of the acid; but the more injurious product of burning of coal gas, the carbonic acid, is practically untouched, and contaminates the air just as with any ordinary stove. We would never advise such a stove to be employed for dark-room work, though all the actual heat produced is, as it were, turned into the room. It is, however, quite possible to have a stove which permits a part of the heat to escape through the draught into the chimney, but which at the same time is as efficient a heater as the other. The efficiency of a stove depends not only upon the heat it produces, but rather upon the way it is distributed. Heat all in one spot is apt to cause a quick upward current of air which fails to cause the whole apartment to gain the benefit of what is really generated. The patterns to choose from are of the most varied character, and should be chosen for the mode in which they spread the heat and prevent its being wasted up the flue. As a matter of fact, the actual heat produced from the consumption of a given quantity of gas in one or other burner varies only to an insignificant extent in any maker's pattern. The vital points are distribution and waste.

Formerly a very large proportion of the heat obtained went outside through the chimney; but of late years there have been made patterns of stoves on the regenerative principle, which utilise some of the heat left in the spent gases before allowing them to pass into the chimney. It is, of course, not for us to name a particular maker.

One well-known pattern of stove is a very important modification of the usual mode of utilising them. It has an egress for spent gas and one for ingress of fresh air placed close together, the result being to render it independent of ordinary chimney or flue. These two apertures are to be connected with the outer air.

The getting rid of the effluent fumes is the one difficulty with gas stoves, yet it must be said that, when used with discretion, they need cause little more trouble than a coal fire, the "smoking chimney" being not an unknown phenomenon with coal. It should be said, however, that no chimney which does not possess a good draught should be used for gas fires. The fumes from the latter are invisible, while smoke tells its own tale; hence danger might lurk in heating a dark room through the fumes conveyed into the chimney failing to rise and being disseminated into the apartment.

There is difficulty in conveying the gas through a flue directly into the open air through an aperture in the wall. The draught will not always act. But we may inform the reader that if he contemplates putting a gas heating apparatus in his dark room he may be sure that, if he write for advice direct to the maker of a stove proposed to be used, he will be well advised on any difficulty anticipated by the maker, and will have simple explanations courteously tendered.

REFLECTED LIGHT IN THE CAMERA.

Probably more negatives are ruined and plates spoilt by the access of light into the camera than is imagined, even by those who fancy themselves constantly on the alert to guard against such accidents, and we should, perhaps, be not far from the truth in asserting that the majority of the complaints made about faulty plates are really traceable to the same cause.

There are, of course, many different ways in which stray light may reach the sensitive film; that is to say, light other than that legitimately employed in the formation of the image. Defects in the construction of the camera, badly fitting or damaged woodwork, minute cracks or perforations in the bellows, flanges not properly screwed up, and similar accidents are sufficiently familiar, and are usually sought for when there is reason to suspect that trouble is being caused by the improper action of light. But, although these are the most commonly *recognised* forms in which the evil is experienced,

we doubt whether more frequent and greater injury does not arise from other causes less readily recognised or suspected, namely, from light passing through the lens and suffering reflection from some portions of the interior of the apparatus; it may be of the lens mount itself, or it may be of the body of the camera.

Most instruction books direct the beginner to examine carefully the interior of the camera for such palpable defects, but few go farther in calling attention to the possibility of an injurious, or, we may say, ruinous amount of light being reflected from the sides of the camera itself. Yet this is the case, but more especially with wooden-bodied cameras, either solid or sliding, the broken or zigzag sides of a bellows camera tending in a measure to neutralise the ill effects of reflected light. In bygone days, when the wooden-bodied camera was more in vogue, both in the studio and the field, this danger was more palpable, and was, consequently, more generally recognised than at present; but that it still exists in an extreme form was forced on to our notice a short time back by an examination of a hand camera, with which, under certain conditions, it would be perfectly impossible to take a picture.

The instrument was one of fixed focus, the body being of wood, and the interior entirely open from the lens to the focal plane; it was fitted with a lens of the modern rapid rectilinear type, that is to say, one of large aperture, and when this was used at full power it admitted a considerable volume of light, much of which fell upon the smooth sides of the camera, from which it suffered reflection directly on to the sensitive plate. What wonder, then, that almost every plate proved to be hopelessly fogged. This camera, we say without hesitation, was constructed with an utter disregard for the most elementary rules of common sense.

Another instance of a similar kind was found in the case of a sliding-bodied camera, with portrait lens, that was being used for outdoor portraits and groups; the negatives were invariably, more or less, veiled, and it was obviously from extraneous light on the camera, although the latter was most carefully and completely wrapped up in the focussing cloth in order to cover up any undiscoverable leaks. It was not until it was pointed out that the smooth floor of the interior of the camera reflected a perfect "blaze" of light coming through the lens from the sky that the cause of the trouble was suspected.

It is only with such instruments that this trouble shows itself in such an aggravated form, though even with a bellows camera, quick plates and lens worked at full aperture quite sufficient reflected light will reach the plate to seriously degrade the purity of the shadows, and we have no doubt very many of the cases of fog laid to the charge of the plate-maker are really due to this cause. It is, of course, with the more rapid kinds of plates that the evil is most seriously felt, such being more readily impressed by feeble rays of light, and these are generally the plates that secure the greater share of blame.

How to guard against the trouble is the question to be considered. In the first place, the most obvious step to be taken is to avoid as far as possible working under such circumstances as will conduce to it. Thus, never work with the full aperture of the lens unless compelled to do so, and never, when it can be avoided, employ a lens of the rapid doublet type when there is a large volume of light from the front, whether sky or water, or, when such a course is unavoidable, be careful not to permit the light to fall directly on the lens. In dealing with subjects of this class, landscapes with a wide expanse of sky, or with the sun almost in front of the camera, or more particularly with seascapes, a single lens with the stop in front is far preferable to the doublet with its large surface of glass presented directly to the source of light. Not only does the projecting tube shield the lens from the direct impact of the light, but the stop itself, if in proper position, will, by curtailing the field of view, cut off a great portion of the rays of light that would otherwise fall on the interior of the camera. There is no reason why lenses of the rapid type should be used for the class of subjects we have named; on the contrary, they are just the ones that will most readily permit of the employment of a comparatively slow lens, although a single lens, with stop in front, need not be particularly slow; they may be used with very satisfactory definition with apertures of *f*-11, which is far more rapid than is required for seascapes.

A very useful lesson may be learnt by pointing the camera fitted with a lens working with large aperture to an open landscape with a clear sky, and if the sun be in that quarter so much the better. Level the camera in such a manner that the sky line is almost at the bottom of the plate, the whole of the subject being practically landscape. If now a small white card or an envelope be laid inside the camera close to the focussing glass, it will be found that an image of the clouds is thrown upon the white surface, upon which it is perfectly distinct, although on the black lining of the bellows it may pass unnoticed. If a single lens be used with the stop placed at such a distance in front that the field of view is restricted to little more than the area of the plate, the amount of image falling upon the card will be comparatively small; hence the recommendation to employ such a lens under those circumstances.

If now the focussing glass be placed in position, and the image examined under the focussing-cloth, a patch of bright light will be seen to be reflected from the white card showing distinctly in contrast to the black lining of the camera, and demonstrating only too plainly the reality of the danger that exists. If another card or envelope be taken and placed in a perpendicular position inside the camera—it may easily be propped between the folds of the bellows—a position will be found in which it just cuts off these useless or superfluous rays, and prevents their reaching the sides of the camera, and consequently their reflection on to the plate. This gives the cue for a very simple remedy against light reflected from the interior of the body of the camera.

It consists of a simple screen of blackened cardboard, thin wood, or metal fixed inside the camera at a short distance from the lens, and having an aperture of such dimensions as to permit the passage of only such rays as fall directly upon the plate. All others, those which fall upon the front of the screen, are confined in the narrow chamber formed between it and the camera front, when they are lost or made harmless. This screen also acts as a safeguard against any accidental flaws or defects in the front of the camera, its weakest point. The screen can be easily fixed, and can remain always in position, as it interferes in no way with any of the ordinary functions of the camera, or it can be made removable, if preferred, and completely guards against any reflections from the camera.

But not so easy is it to guard against reflections from the interior of the lens, which may be, and sometimes are, very

serious. We have in our possession at the present time an old portrait lens of French make which is capable of fogging hopelessly any plate placed behind it. The internal blacking has become with age partly polished, and if the camera be turned towards a well-lit subject, and the inside of the tube examined from the back, the focussing glass being raised, it shines into the camera almost like a mirror. Not being fitted with Waterhouse diaphragms, the whole of the tube is open, which makes matters considerably worse, although any lens of the rapid doublet form will thus reflect a very dangerous amount of light unless the blacking be constantly kept in good order.

The lens we refer to is easily cured by simply sliding in a piece of black cotton velvet cut to the proper size to line its interior, and it is kept in position by the rather elongated cells carrying the two combinations. These in turn are provided with two rings of the same velvet, which effectually prevent reflection and convert an otherwise useless lens into the reverse. For smaller lenses we should use a good matt black varnish, though we have yet to find one that will equal velvet in its power of arresting reflection when the latter can be used.

In conclusion, we would suggest that any of our readers who may be quarrelling with their results, and probably blaming the plates, should make a careful examination of their apparatus for reflected light as distinguished from leakage light. Possibly a good many may be surprised.

Civic Honour to a "R.A."—A little while ago, it will be remembered, we alluded to the generous gift by Sir John Gilbert, R.A., of several of his works to the Corporation of the City of London for their Art Gallery at the Guildhall. The handsome present is highly appreciated by visitors at the Gallery and also by the Corporation. One day last week, at the meeting of the Common Council, the freedom of the City was conferred upon Sir John, the presentation being enclosed in a gold casket. This, we believe, is the first time such an honour has been conferred upon an artist. It is generally reserved for crowned heads, members of the Royal Family, and other noble persons. It is to be hoped that the example set by Sir John Gilbert will be followed by others, particularly as the Government is so niggardly in the purchase of pictures for our national collections. Still, after all, it may be mentioned that the English possess more pictures that cost the nation nothing than any other country, not excepting France and Germany. It is somewhat to be regretted, however, that so few good photographic copies of them are available for art students.

Artistic Vignettes.—More than once attention has been called to the generally inartistic appearance of the majority of vignettes issued by professional portraitists; indeed, it may be said that, in the matter of vignetting, we are no better off than we were a couple of decades ago—it is still the same monotonous pear-shaped picture. Some time ago we alluded to a great improvement in this respect in some pictures we had just then seen. They were platinotypes on rough paper with hatched backgrounds, after the style introduced by the late Mr. Oliver Sarony many years ago, but we have not seen any like them since. We have, however, recently had the opportunity of seeing some others very much after the same style. These were large heads, cabinet size, on very rough drawing-paper of various tints, with a slightly hatched background, and vignettes, of course. The process appeared to be gelatino-chloride, toned with uranium, as some of the prints were almost a Bartolozzi red, while others were of a sepia, and also of a good black tone. So good were the pictures that they closely resembled the once famous Richmond heads in miniature. It is just possible that, if this style of picture were taken up by some in the profession, it might give a fillip to their businesses, particularly amongst clients of the impressionist school. It may, however, be mentioned that the pictures in question were perfectly sharp, or, at least, as sharp as the coarseness of the paper would allow them to be.

Effect of Photographic Chemicals on the Skin.—At a recent meeting of one of the London Societies, a member called attention to the circumstance that, after working somewhat largely with the new developer, metol, he found it produced an unpleasant effect on the fingers, although no other member appeared to have had a similar experience. Others of the newly introduced have also been charged with having a pernicious action on the skin, but only, as in the instance referred to, in isolated cases. The skins of some persons are peculiarly constituted as regard alkalies, and it is these, we fancy, that are the cause of the trouble. We well remember, when the alkaline system of toning was first introduced, that there were many complaints that the toning solution produced an eruption on the hands of some workers. Some laundresses, we are informed, frequently suffer from the action of the alkalies they use, causing a slight eruption of the skin of the hands. The action of the alkalies on the skin is to soften it, and, even in a very dilute form with some skins its action is very marked, and, if it be allowed to dry on it, to afterwards have the opposite effect, to harden it. If, after working with any alkaline solutions, whether new developers or not, the hands were well rinsed with cold water, and the solution never permitted to dry upon them, we think no inconvenience would be anticipated with any solution employed in photography. The same remark applies also to the more pernicious chemicals, such as bichromate of potash, bichloride of mercury, &c.

A Plea for the Photographers' Benevolent Association.—The report of the last meeting of this deserving Institution shows that there is a great necessity for it, and we fear there will be a still greater as the winter advances. There are now between two and three hundred Photographic Societies in Great Britain, and the larger number of them are now arranging their programmes for the winter season. We therefore take this opportunity of reminding them of the suggestion we have made before, namely, that they should follow the example of the Photographic Society of Great Britain and devote a Lantern Evening to the benefit of the Association, who are in need of increased funds to carry out its laudable objects. Much has been said of late of the alleged injury done by amateurs to the profession; and, as the majority of the Societies are largely composed of amateurs, it is not too much to ask them, without considering as to whether the allegation is well founded or not, to consider the distressed among the profession, particularly when is is considered that a Lantern entertainment with a little music is an enjoyable evening, quite apart from the pleasure of contributing to a deserving object. The report referred to is quite sufficient to convince every one that the funds of the Benevolent Association are carefully administered, so that those helping have the assurance that the money is not wasted. If each of the Societies were, by the means suggested, to raise but a single pound, the income of the Association would be considerably more than doubled. Possibly a polite circular to the different Societies would bring the subject more prominently before them.

Reproductions.—One of the first things considered when ancient manuscripts are discovered—and they are now continually being found—is to have them reproduced by photographic means. Then the question arises as to how they are to be rendered; that is, as they are in their present condition, or to reproduce them as nearly as possible as they were when the writing was first executed? This subject has exercised the minds of the authorities of most museums containing ancient documents, and is exercising them still in some quarters where it is yet a vexed question. It seems that the majority are in favour of having the copies as an exact representation of the originals as in their present state with all the imperfections wrought by time. On the other hand, some prefer to have the reproductions as nearly approaching, as they can be made, what they were in their pristine condition. We recently had the opportunity of seeing

the same manuscripts reproduced both ways. The former were by the collotype method, and the stains and discolouration of the parchment and paper were exactly rendered. The latter were by photo-lithography, as presumably by an orthochromatic method and also by dodging the stones all these were obliterated. The contrast between the two reproductions was great, yet the writing itself was the same in both cases, except that on the clean surface of the photographs it appeared more distinct. In the collotype, where the stains on the original were very strong, the lettering was scarcely readable. Whatever may be the opinions as to this question as regards old manuscripts, we imagine there is not a divided opinion as regards paintings. No one, we surmise, would care to have copies of the old masters with all the cracks in the paint conspicuously reproduced when by skilful treatment in the lighting they can be, and usually are, considerably ameliorated.

CHICAGO EXHIBITION—AWARDS.

The following awards have been made in the Photographic and Apparatus Sections :—

British Society for the Promotion of the Employment of Women, photographs.

Mr. Henry Wilkinson, instruments to indicate the action of engine valves.

Messrs. Riley Brothers, optical lanterns and slides.

Messrs. Ross & Co., lenses, field-glasses, and instruments of precision.

Messrs. F. Darton & Co., meteorological instruments.

Mr. J. Lafayette, photographs printed in carbon.

Mr. H. Mendelssohn, portraits.

Sheffield High School, photographs.

Educational exhibit (Mrs. Ayrton's line divider and Miss Gregory's geodoscope).

Mr. A. Baker, photographs.

Mr. W. Byrne, photographic portraits.

Mr. J. Dore, photographic lantern transparencies.

The Esmail Enamel Company, miniatures on enamel.

Mr. Henry Flather, carbon photographs.

Messrs. B. Lemere & Co., architectural photographs.

Mr. Lyddell Sawyer, photographs.

Messrs. Symonds & Co., photographs of British ships.

Mr. Henry Van der Weyde, electric-light photographs.

Mr. W. M. Warneuke, photographs.

Messrs. Alfred Werner & Son, photographic portraits.

Messrs. Window & Grove, photographs.

Mr. W. W. Winter, photographic lantern slides.

Messrs. W. Watson & Son, (1) mathematical, astronomical, surgical, and English instruments; (2) lanterns; (3) photographic lenses, &c.

Mr. W. Clement Williams, photographs.

Messrs. R. & J. Beck, photographic apparatus.

DENSITY AND COLOUR IN COLLODION EMULSION.

I have before me a letter from a correspondent on the above subject, upon which I wrote a couple of articles in these pages last November. As my correspondent has carried out the suggestions there made with only partial success, there may be others in the same position as himself, for whom my reply to him may have an interest.

The gist of the present complaint is briefly as follows: Although immediately after emulsification, the emulsion was of a rich ruby-orange colour, and gave transparencies of good density and excellent tone, after ripening for six to eleven days, the colour by transmitted light changed from the rich red to a cold grey colour, and after pouring out, drying, washing, and re-dissolving, it would only produce images of a bluish-grey tone.

Bearing in mind what I have already said in my previous articles on the subject of unsuitable pyroxyline, I think there can be little doubt in this case that the cause is too-prolonged ripening, combined, it may be, with a partially unsuitable cotton—*i.e.*, one that will not bear long emulsification. Different samples of pyroxyline vary as much in this way as in any other respect, but their behaviour during the progress of ripening may usually be taken as a pretty safe guide as to how to act. Some specimens—and they are wholly unsuitable for the purpose—will give at the very outset an emulsion possessing a grey, blue or lavender colour by transmitted light, and under no conditions whatever a red colour. Others may present more or less of a yellow or orange tint at first, but rapidly lose it, changing to the cold blue or grey, and these should be regarded with suspicion, as they will rarely if ever pass the ordeal of washing, even if they should prove of any use unwashed.

But when the pyroxyline is of such a character as to give to the emulsion the rich transmitted colour described by my correspondent, it may, in nine cases out of ten, be relied upon to stand washing without losing any of its good qualities, if properly treated, and, in this connexion, the period of ripening forms an important item. The change of colour of the particles of bromide mark, in fact, the progress of the ripening both in collodion and gelatine emulsion, and although with the latter the cold grey or blue colour may be a desirable indication of great sensitiveness, it is to be avoided on all counts with collodion. It may be a sensitiveness, but it is an equally sure sign that all the "body" has gone out of the emulsion—that, in fact, it is over-emulsified.

But with regard to the question of sensitiveness, I doubt whether any greater rapidity is secured—that is to say, rapidity of a practical character—by eleven days' emulsification than by one or two, if the emulsion be mixed in the proper way. In earlier days, when an excess of soluble bromide was the rule throughout, it was the regular plan to allow a very long period for the complete combustion of the salts; but when excess of silver came into vogue, not only was the period of ripening considerably curtailed, but it became necessary to employ a large proportion of restraining acid in order to prevent fog, and to keep the emulsion from passing into the grey stage.

Prolonged emulsification in the acid state and in the presence of free silver may perhaps result in the very highest degree of sensitiveness that is obtainable with collodion emulsion, but for all practical purposes, and especially for lantern-slide work, a much better result will be obtained by a very brief submission of the constituents of the collodion to the action of free silver without the restraining acid, and then a further few hour's ripening after the excess of silver has been converted. Thus, if the plan I mentioned in the first of my articles last November be adopted, namely if a portion of the bromised collodion be held back in sensitising and the remainder have added to it the full quantity of silver so as to show an excess, the accessory requirements will be fulfilled. The emulsion may remain in this state for an hour, half an hour, or only two or three minutes—the period is not very material, but perhaps half an hour is ample—and the remainder of the bromised collodion is then added and well mixed.

The emulsion may be poured out to set *at once* if desired, or may be allowed to ripen for a few hours longer, and will prove at the finish to be just as sensitive as, and a good deal better in other respects, than if it had been allowed to ripen for days. It must be borne in mind that the ripening proceeds during the drying of the "pellicle," and more especially during the latter portion when heat is applied, and many an emulsion that is poured out in just the right condition is spoilt by forgetting this fact.

I should advise this course in connexion with any sample of pyroxyline, though there are, of course, some sorts that require such treatment less than others. The only commercial sample I am aware of at the present time that is altogether independent of any special treatment, except care in not over emulsifying, is Rouch's. The best kind I ever used in years gone by for washed emulsion was an American sample known as "Pary's Cream," I think was its name, and there were two or three grades of it, what I used being "No. 2." I doubt whether it is made now, but Mr. J. J. Atkinson, of Liverpool may know.

It is a hopeless task for an amateur to make his own pyroxyline with any chance of uniformity, as working on a small scale it is absolutely impossible to secure regularity of temperature, or, indeed, of any of the conditions requisite to success. Otherwise, I should advise those who want good results to make their own pyroxyline. It gives

the best results as regards quality of image and colour, but it has a serious fault for lantern work—it is very apt to dry slightly opalescent. This, however, is not a necessary characteristic, and when it does occur varnishing removes it.

In conclusion, I may say that the kind of cotton that is best suited for washed emulsion is one that gives a film that is neither "rotten" nor "horny," but which when rubbed with the fingers after washing has a "soapy" feel, and is rather short in texture.

W. B. Bolton.

ELEMENTARY STEREOGRAPHY.

[North Middlesex Photographic Society.]

A Plea for Stereoscopic Photography.

A correctly prepared stereoscopic slide or transparency, when examined in the stereoscope, shows us the original view with all the realism that invested it at the moment we exposed our plate upon it. Stereoscopic pictures, binocularly observed, take us one step further than does the faculty of memory. The latter recalls to the mental gaze scenes invisible to the material eye; the former re-create, if not the veritable scenes themselves, at least transcriptions of them, perfect in all respects but two, namely, movement and colour. Atmosphere, distance, solidity, height, depth, and breadth are more than merely suggested in stereographs; to the eye, or rather to the brain, they appear as though they were really present in them. No single or monocular photograph, however skilful or cunning in the management of its lights and shadows, suggests more than a faint similitude of the attributes of actuality I have enumerated. The æsthetic beauty of good stereographs is inferior to that of Nature herself alone; their fidelity to that original can be scientifically demonstrated, and yet, while they allow little rein to the fads and freaks of your modern photographic impressionists, they are, nevertheless, artistic, as most of us understand that indefinable yet easily realisable term. The delight at viewing stereographs is so genuine and lasting, they are so easily prepared, and the educational advantages of stereography are so considerable, that there is room for wonder at the comparatively few photographers who practise it. Stereography is an art within an art, and it is readily acquired by anybody having an ordinary acquaintance with monocular photography. I have called it a thing of beauty. That it is a joy for ever, that its fascinations are of an enduring nature, may be proved by broaching the topic to most veteran photographers. The deep affection they retain for binocular work, their regret at its decadence, their pleasure at its resuscitation, can only be understood by stereographers.

Some Mistaken Ideas.

I have been extremely surprised, and just as much amused, at the large numbers of photographers—professional and amateur, veterans and novices—who are ignorant of the fundamentals of stereography, and whose ignorance leads them into all kinds of blunders when they come to talk or write of it. The supposition that stereoscopic effect is obtainable from two similar pictures is a common fallacy, and quite recently has formed the groundwork of articles and papers by people posing as teachers of their subject. As two dissimilar pictures are necessary to obtain stereoscopic effect, the absurdity is manifest. The other day, too, the novel property of "stereoscopicity of effect" was claimed for negatives on multiple-coated plates. Then, not long ago a writer of considerable scientific eminence said he had stood outside a shop window filled with monocular photographs, and, at a distance of several feet, saw them stereoscopically. Such a thing can't be done by any mortal man. Consider: I am quoting photographic "authorities" who enjoy the profit and dignity attaching to that agreeable reputation. I can the more readily excuse the ignorance of a bystander (an amateur, I divined, by his conversation) who, when I was recently using a binocular camera in Norfolk, told a friend who was with him that the function of my two lenses was to "unite the two images in the camera;" but even he, like the supposedly better-informed gentlemen I have quoted, had two eyes, and could not have known how, why, or what he saw with them.

Stereography in a Nutshell.

For here—in the philosophy of eyesight, in binocular vision—lies the whole subject of stereography ready cut and dried for assimilation by the meanest capacity. With our two eyes we see stereoscopically—that is, through them two dissimilar or unlike pictures of an object are carried to the brain, which combines them to form a third, which is what we think we see with the two eyes simultaneously. Now, mark the analogy between the eyes and the stereoscope. In the latter, two lenses are placed side by side to enable us at short focus to look at two dissimilar photographs—that is, photographs taken from slightly different points of view—and these pictures are conveyed through the eyes to the brain, which combines them to form a third picture having all the illusion of reality. That there are two points of view in binocular vision necessarily follows from the fact of the eyes being separated, but anybody can practically test the point for himself by using, first, the right eye alone, and then the left to look at a view or object, when it will be seen that the right eye takes in more of the right side of the view or object, and the left eye of the left side, while the picture seen, or supposed to be seen, by the two eyes differs from both the monocular pictures. Furthermore, the convergence of the optic axes upon near or distant objects enables us to appreciate solidity, relative size, and relative distance, and when looking through a stereoscope at two dissimilar photographs, convergence of the optic axes by refraction again comes into play to separate the planes of the subject, and to, in short, impart to the picture what I have already termed the realism of the original view or object.

Now suppose a pair of lenses, mounted on a camera front and separated by about the distance that separates the eyes, and a twin or binocular negative to be taken. The point of view of each lens was different, hence there must, in theory, be a dissimilarity in the two pictures, just as we have seen that there is in the two pictures seen by the two eyes. Practice agrees with theory in this. The right-hand negative has more of the right side of the picture than the left-hand negative has, and the left-hand negative has more of the left-hand side of the picture than the right-hand negative; and where the two negatives are joined the amount of subject included on those sides is severally less than that on the corresponding sides. Prints from such negatives having the same relation in the matter of right and left, and inclusion of subject as the double view as seen by the two lenses had, fulfil every condition necessary for binocular examination. Put it in another way. Imagine the lenses to be your eyes. They saw two dissimilar pictures of the view, and your positive prints are, practically, what your eyes or your lenses saw. The stereoscope lets you see the two views under the same angular conditions as they were taken, the result is a coalescence of the dissimilar results in the brain, and Nature herself over again, a perfect *facsimile* in miniature.

The Stereoscopic Camera and Lenses.

Although not essential to the production of binocular pictures, I shall assume the use of a binocular camera in stereography—that is, a camera fitted with a pair of lenses and a collapsible division extending from back to front, and virtually making two cameras of one. The lenses must be accurately paired as regards focus and diaphragms. For most kinds of work single lenses are employed, although rectilinear doublets have an advantage in the matter of extra rapidity and for short-focus work in giving freedom from distortion. A focal length of five inches will be most convenient; but for confined subjects a pair of wide-angle doublets, of about four inches focus, and for distant objects a pair of singles, of, say, seven inches, are desirable. Beyond that focal length it is seldom desirable to go, and I shall show you later that the occasions when even a pair of seven inches would be found serviceable are not frequent in the course of ordinary work. I do not wish to dogmatise on the debated point as to the distance of separation of the lenses when mounted on the camera front, but, from my own experience, would recommend three inches from centre to centre. The acme of convenience is, of course, gained by having the power of adjusting the lenses to suit near and distant objects, the rule to follow being, the nearer the object the less the separation, and the more distant the object the greater the separation. Three inches, however, will be found to strike a happy mean, and will obviate exaggeration of relief in most subjects. It need hardly be said that such a shutter must be used as will allow of simultaneous exposure of the two halves of the negative. Some photographers use a double cap.

A camera of the old-fashioned square bellows form is necessary, with an extra front for the twin lenses, and the collapsible septum already spoken of. A half-plate or larger camera is a stereoscopic camera *per se*, and can be converted for practical use at a small cost. As to size, I do not recommend anything larger than $7\frac{1}{2} \times 5$ or 8×5; using whole-plates and upwards for binocular work is a waste of plate area, and renders contact work, either for lantern slides or stereoscopic transparencies, out of the question if one wishes to have choice of the whole of the subject. Briefly, anything larger than half-plate is unnecessary, and has its drawbacks.

Mention of the camera gives me an opportunity of condemning the, it is to be feared, still existent mania for taper-bellows cameras. These, perhaps, have some slight advantage in lightness, but often put a barrier

in the way of the effective use of the rising and sliding fronts, and are useless for stereoscopic purposes. For these and other reasons I would strongly recommend the beginner to procure a camera of the square form. Many of my friends lament having sacrificed so much for the privilege of knocking off an ounce or two's weight. Up to about ten or a dozen years ago, such makers as Lane, Meagher, Spicer, and others, always sent out their square-form cameras with a detachable elastic division, to be used for binocular work. In those times, however, the division was rarely, if ever, required, stereography being virtually a dead letter, and I remember that, in the establishment of a well-known firm with whom I was then connected, there was quite an accumulation of these useless divisions. By-and-by, the makers ceased sending them out altogether.

Selection of Subject.

As this is a branch of stereography upon which little has been written, I enter upon it with peculiar pleasure. Most subjects are suitable for binocular treatment. In exercising the faculty of selection, a safe rule for the young stereographer is to split up his subject into several planes, and to assume that, in the foreground, the middle distance, and the distance, some prominent object, or series of objects, is placed. Such a rule simplifies the selection of subject considerably. Ninety photographers out of a hundred working monocular cameras, would either despise or overlook subjects capable of producing the most charming effects in the stereoscope. Conceive a bank of reeds in your foreground, a stream of water, with a gnarled tree overhanging it, a distance of shelving bank studded with brake and bramble—each of us can recall dozens of such rural vignettes, but most of us would not think them worth a plate in the monocular camera. Yet how entrancing and riveting in its realism, how astonishing to note each nodding reed standing out like life itself, each bough, twig, and branch solid and round against the sky, the liquid transparency of the water, the wonderful effect of distance in this simple picture when binocularly treated, and how one is tempted to stretch out one's hand—to look behind the picture as it were—to grasp the substance of what, after all, is only a shadow? An old cottage behind a rustic gate backed up with sheltering trees, a crazy bridge over a willow-lined river, shipping, most architectural subjects, interiors, tree studies, flowers, statuary, portraiture—all pay for binocular treatment. Nevertheless, open landscapes and seascapes, and subjects on one plane, however truthfully rendered, fail in binocular effect—indeed, long-focus work generally is scarcely satisfactory, and in that category possibly come instantaneous views of rapidly moving objects, though street life, and scenes deriving animation from the presence of people and other animals form capital subjects. Hand-camera studies of animated life always convey to me the negation of animation, but binocular hand-camera work gives me an idea of movement—of having a better approach to visual effect. Some binocular street scenes of Plymouth, taken by Mr. Seaman during the late Convention, struck me as wonderfully successful in that respect. With a stand camera it is not always possible to obtain such pictures, and therefore a hand camera must be used. Hence I regard the stereoscopic hand camera as the hand camera of the future. It will be a valuable adjunct to stereography. I refrain from saying how much it will benefit its users physically and mentally, how much it will increase the rapidity of plates, sharpen our nerves, add to our weight and our banking account, assure artistic expression to all our pictures, and decrease the distance between us and the photographic millennium; or I do not, alas! make hand cameras, do not sell them, have not a mandate to boom the hand camera, and sing its praises on every conceivable occasion. Hence this silence.

Reverting, however, to selection of subject, it will, I think, be found that there are more subjects within the scope of the binocular camera than the monocular—that is, there are subjects which are worthless as single pictures which well repay binocular treatment. Of course, the ideal amateur should be ready for both kinds of pictures as occasion may arise.

Stereographic Printing.

Stereoscopic negatives should be well exposed, and, if anything, incline towards softness, so that the prints may be without violent contrasts of light and shade, and too prominent high-lights printing out white. Indeed, flat-looking prints are preferable for binocular examination. I have a daughter aged eight. When she first saw some stereoscopic slides she thus summed up their principal charm and commonest defect, "They look quite real," she said; and of one of them, "Did it snow when you took that picture?" This snowiness is fatal to the best results, and, if unavoidable in the negative, should be obviated by a careful sunning down of all white patches in the prints. A surface paper is essential, as all rugosities are magnified in the stereoscope. Gelatine or collodion prints are preferable to albumen prints; enamelled bromide prints are also suitable. Tone is, of course, a matter of individual taste, but warm tones are, I think, more agreeable than cold ones, and contribute better to fidelity of effects.

We come now to a part of our subject which is very puzzling to the beginner, that is the transposition, trimming, and mounting of the prints. Still, all difficulty vanishes if we consider for a moment what it is we desire to produce in our finished print. We have taken two pictures. The one taken with the right lens must come on the right side of our mount; the one taken with the left lens, on the left side of the mount. But in the print from our negative the two pictures occupy reverse positions, so that the print must be cut in two in order that the two halves may be made to change places. For the sake of brevity, I will summarise the procedure necessary.

1. Both prints must have an identical base-line.
2. Each print must be two and a half inches wide.
3. Three inches in height will be sufficient; a little more or less is immaterial.
4. Trim the prints so that on the left of the right-hand picture and the right side of the left-hand picture a little more of the subject is seen than on the other sides of the pictures. Or, to put it another way, the sides of the prints which come together in mounting should each show more of the subject than the outside sides. A difference of from one-sixteenth to an eighth of an inch is usually a sufficient margin.
5. Allow a space of from one-sixteenth to an eighth of an inch to separate the prints.
6. Trim by foreground objects, and let a distance of not more than three inches separate them.

Spots or other defects in one of the prints show in the combined image, but if one print be printed a little deeper than the other it is hardly appreciable.

Stereoscopic Transparencies.

We must concede that stereoscopic prints do not compare in beauty of effect with stereoscopic transparencies; but I do not go so far as some in counselling transparency making alone, for in the preparation of prints one can graduate in the small niceties of stereography, and let them find ultimate expression in transparency work. Besides, sensitive paper is cheaper to learn on than glass plates. In actual practice, transparencies are easier to make than prints. What I have said of the desirable qualities of stereoscopic prints as compared with monocular prints applies, in a like degree, to binocular transparencies as compared with lantern slides. The ideal brilliancy, clearness, and transparency of the latter are not necessary; indeed, they are in the nature of drawbacks. Of the methods of making glass stereographs, commend me to that by copying in the camera. The following outline of a working method will supply such details as will enable an amateur to undertake stereoscopic transparency making at a very small outlay of ingenuity and money. At the back of an open box, having a central partition, the negative is placed in a suitable holder, inverted as regards top and bottom, film side out, and facing the light, which may be either direct or reflected. The binocular camera used for the negative should be fixed to a rigid board and register secured between negative and ground glass. The space between the objective and the negative holder should preferably be covered in with opaque material. The two images, as seen on the ground glass, will not be inverted, and will be in their proper positions as regards left and right, and consequently will not need transposition. The same rules as to identity of base-line and inclusion of subject must be observed as with prints, but you will easily see that they are considerably simplified. I myself use a special camera for the purpose. When the transparency is developed and dried, it is masked and bound up in the usual way, and, being viewed through its glass support, is backed up with either plain or ground glass.

For viewing slides and transparencies, a stereoscope of the familiar Holmes form will be found convenient, but it is very seldom found made in accordance with theory, as it should be so adjusted as to allow of the separation of the lenses to suit degrees of separation found in the eyes of individuals.

The Stereoscopic Revival.

I quote this oft-used term only to anathematise it. It is time we heard the last of it, for stereography is well past the revival stage. For a long time anterior to 1887 it was virtually moribund, but in The British Journal Photographic Almanac for 1887 appeared an article by the Editor which handled the subject in a succinct and instructive form, and was instrumental in rescuing stereography from neglect. Mr. Chadwick, of Manchester, subsequently devoted a great deal of attention to the subject. Some of his writings have been republished as *The*

Stereoscopic Manual, which, with the ALMANAC named, will tell a beginner all he need know at the outset. If he cares to dive into the profundities of the stereoscope and binocular vision, let him consult Brewster's *Stereoscope*. I conclnde with a question. Why do not promotera of photographic exhibitiona have classes for stereographs? A double end would be gained. Photographic exhibitions which stand sadly in need of novel attractiona would possibly secure one, and stereography among amateurs wonld receive an encouraging fillip. THOMAS BEDDING.

A SUGGESTED IMPROVEMENT IN THE CORRECTION OF LENSES FOR PHOTO-MICROGRAPHY, PHOTOGRAPHY, AND PHOTO-ASTROGRAPHY.

[New York Medical Journal.]

PRIOR to the time of the late Col. J. J. Woodward, M.D., surgeon of the United States Army, say twenty-five years ago, photo-micrography was in its infancy. It is true that photographs of microscopic objects had been made, but they were crude and unsatisfactory, and were all made with what we would call low-power objectives. Although the objectives then made were of excellent construction and well adapted to the revelation of the structure of minute objects to the eye, yet the photographs made with them were greatly inferior in clearness and sharpness to the virtual image appreciated by the retina. The cause of this was not far to seek, and was due to the lack of coincidence of the visual with the so-called actinic focus. At the period mentioned, the art of photography was almost exclusively practised with the aid of collodio-iodide plates, which were very sensitive to the blue, violet, and ultra-violet (more refrangible), and but feebly sensitive to the green, yellow, and red (less refrangible) rays. *Per contra*, these latter rays impress the eye so forcibly that the effect of the more refrangible rays is almost obscured, that is, when mingled with the others, as in ordinary white light. The practical outcome of this condition was that, when the ground glass of the camera was in a position that gave the sharpest image to the eye, this image could not be duplicated as to sharpness in the developed photographic plate occupying the plane previously occupied by the ground glass.

In order to obtain a sharp photographic image it was necessary either to shorten the anterior conjugate focus, which involved the veriest guesswork, and was practically unavailable, or else to move the plate to a point nearer the lens where the actinic rays came to their posterior conjugate focus. This was perfectly practical, and by repeated experiment the relation of the actinic to the visual focus in a given lens could be ascertained. Although practical, this method was hardly satisfactory.

In ordinary photography, the difficulty attending this difference in the natural positions of the actinic and visual foci had already been overcome by making the visual focus correspond with the actinic by constructing the lens so that it should be left in a state of moderate "under-correction," as it is termed by opticians.

Among the first to appreciate the value of this, as applied to photo-micrography, was Colonel Woodward, and the first opticians to give it practical form were, I believe, Mr. William Wales, of New York, and Mr. Ernst Gundlach, then of Berlin, but now for many years a practical optician in this country. This example was followed by Tol[illegible]s, of Boston; Powell & Leland, of London, and others.

Woodward was one of the most accomplished microscopists, so far as the manipulation of the instrument was concerned, that ever lived. His skill in securing the virtual image, and in projecting the real image, was at that time equalled by few and probably surpassed by none.

With Woodward'a skill, and the possession of lenses specially adapted to his purpose, the results obtained by him were the wonder of the scientific world.

Since his time, photo-micrography has, in the main, followed the paths he marked out, and the improvements in the art since then have simply kept pace with the gradual improvement of the objective, and especially in the direction of increased apertures. One notable advance in the technique, however, is Abbé's happy conception of the projection ocular.*

The collodio-iodide gave place some years ago to the gelatino-bromide plate, which, like its predecessor, is especially sensitive to the blue and more refrangible rays, and almost wholly insensitive to those which give the strongest visual impression.

In order to obtain the sharpest image on such a plate, the lens must of necessity be under-corrected, as already stated. In accomplishing this, however, there is a certain loss of visual excellence, which, however, is of little moment in ordinary photography. That this under-correction of lenses for photo-micrography results in an impairment of their visual excellence is well known to opticians, but has thus far received but little notice from the actual users of the lenses in question. A few recent writers, however, have directed attention to the matter.

Londe (*La Photographie Médicale*, Paris, 1893) says: "The first and most important question is the choice of objectives. These may be excellent for observation and more than mediocre for photography."

Mercer (*Journ. Royal Micro. Soc.*, June, 1892) in speaking of some of the objectives used by him in photo-micrography, says: "The Wales objectives are corrected spherically for the violet ray. The violet image is therefore somewhat superior to the visual, with which, however, it is coincident."

Czapski, in a letter published in Van Heurck's treatise on the microscope (London, 1893), says:—"In every case the objectives specially constructed by opticians for photography can never be advantageously employed for observations and inversely."

From the foregoing it will be clear that lenses which were best for visual purposes were not the best for photographic use, and it was necessary, therefore, when the most perfect results were sought in both departments, to have a double set of objectives, and many investigators did provide themselves with such an outfit.*

The inconvenience and lack of economy involved in this arrangement are manifest, but how to obviate it does not appear to have occurred to opticians or others interested in the subject.

Having been practically familiar with photography and photo-micrography for upwards of twenty years, I have had the opportunity in that period to become reasonably familiar with the inherent defects of their technique, but it waa not until the latter part of 1891 that I perceived that a way out of the difficulty might be readily found.

During the past five or six years the manufacturers of gelatino-bromide plates have placed on the market plates which are extremely sensitive to yellow light, and but feebly so to the blue, violet, ultra-violet rays of the spectrum.

If, now, the objective be corrected for yellow instead of for blue or violet light, the negative being made on one of these yellow-sensitive, or so-called "orthochromatic" plates, there should be an exact correspondence of the visual and chemical foci, and the resulting picture should be superior to the one that could be obtained by the ordinary procedures—that is, an under-corrected lens and blue-sensitive plate; and at the same time the objective would not have its visual excellence impaired, supposing, of course, that the optician performs his part with care and skill.

In order to test the practical value of this theoretical reasoning, I requested Mr. H. R. Spencer, now of the Spencer & Smith Optical Company, of Buffalo, N.Y., to calculate the formula and construct a lens which would fulfil the stated requirements. The result was a lens of one-sixth of an inch equivalent focus, and possessing a numerical aperture of 1·35. With this objective I have resolved and photographed the *Amphipleura pellucida* in lines, and have photographed both the *Navicula rhomboides* and the *Van Heurckia crassinervis* in lines and beads.†

In ordinary histological work, with amplification ranging from 200 to 400 diameters, the results with this lens have been very much more satisfactory than I have been able to obtain by any other combination of lenses or plates.

With a quarter-inch objective of the same construction, made by Spencer & Smith on the order of Dr. J. A. Fordyce, of this city, I have resolved the *A. pellucida* with white light, and have demonstrated the resolution to him and to others. With a one-fifteenth of an inch of the same construction, the property of Dr. J. H. Kellogg, of Battle Creek, Mich., I made the photograph of the podura which accompanies this paper (see plate).

In order to further test the correctness of the principles involved, I requested Mr. Turner, of the Gundlach Optical Company, Rochester, N. Y., to make a three-quarter inch lens of moderate aperture (N. A. 0·33). Considering the power, aperture, and price ($12), the lens gave very satisfactory results, and wholly confirmatory of the theoretical demand.

* Peculiar advantages have been claimed on behalf of objectives constructed according to the so-called "apochromatic" system. These lenses, however, possess certain disadvantages, which restrain me from giving them unqualified commendation.

* It must be admitted that some of the apochromatics of short focus (2 mm.) obviate in a measure this difficulty; but those of longer focus have not, at least in my hands, proved satisfactory.

† As regards the last-named object, it has been previously photographed in beads, so far as I am aware, only by Van Heurck with the aid of a lens of higher power, one-eighth of an inch and much larger aperture (N. A. 1·60).

In using these lenses with yellow-sensitive plates, there is a distinct gain in definition and purity of image, both visual and photographic, if the object be illuminated with light of corresponding refrangibility (λ 5892). This may be obtained absolutely by employing a sodium flame, or approximately by intercepting the white light with a medium capable of absorbing the rays of short wave-length.

For the greater part of photo-micrographic work, and especially that which deals with histology, I unhesitatingly recommend the technique here described, which, briefly stated, consists in the use of objectives whose correctness shall be adjusted to the D instead of the G or H lines, and in connexion with plates specially sensitive to D light, and having the object illuminated as near as may be with rays of the same refrangibility.

If, however, we have to deal with objects in which we must resolve or optically separate particles, whose approximation to each other is less than, say, $\frac{1}{125000}$ of an inch, the foregoing statements do not apply.

The studies of Helmholtz and of Abbé have placed us in possession of a formula which appears to be theoretically and practically true, and may be expressed as follows:—

$$\text{R.-p.} = \frac{\text{n. x sin u.}}{\lambda}$$

"R.-p." here indicates the resolving power of the objective; "n." the refractive index of the medium lying between the cover glass of the object and the front lens of the objective (be the same air, water, glycerin, or oil); "u." the semi-angle of the aperture of the objective; "sin" the natural sine of said semi-angle; and "λ" the wave-length of the light employed. Now, the "numerical aperture" of the lens is equal to n. x sin u., and the equation becomes simplified into—

$$\text{R.-p.} = \frac{\text{N. A.}}{\lambda}$$

From this it will be seen that, if we desire to obtain extreme resolution, it is necessary to employ objectives of the greatest numerical aperture, and employ in connexion therewith such visible rays as possess the shortest wave lengths. For the photographic reproductions of such images blue-violet sensitive plates, with under-corrected lenses and approximately blue or violet illumination (Woodward's technique) will give the best results. At the present time Mr. E. M. Nelson, of London, is devoting special attention to the development of this branch of photo-micrography.

It will be noted that the formula above given does not take into account the equivalent focus or magnifying power of the lens; in other words, that this factor has no influence on the resolving power of the objective. This is correct. A well-connected 1-inch objective will resolve exactly as well as an equally good ¼-inch, provided the factors N. A. and λ remain the same. I here allude to this matter, as every few years some one imagines that he is on the verge of great discoveries, to be brought about by the simple feat of increasing the amplification of the image. Let us assume that a photograph be made with an amplification of 3000 diameters, with N. A. the greatest and λ the least possible. This photograph may then be further enlarged to 30,000 or 300,000, but the enlarged pictures will not show any finer or more intimate structure than was delineated on the original smaller picture.*

Although orthochromatic or isochromatic plates have been regular articles of commerce for several years, they are used by practical photographers to a limited extent only. This is due to the fact that, despite the acknowledged superiority of the plates themselves the negatives made on them with the lenses ordinarily at command, have not yielded as satisfactory results in some respects as were obtained on the older blue-sensitive plates. The reason of this is almost self-evident. All ordinary photographic lenses at present constructed are under-corrected, and intentionally so, in order to make the visual image agree with that formed by the shorter wave-lengths, to which alone the old-style plates are sensitive.

If, for any reason, the photographer desires to use orthochromatic plates, either for copying, for portraiture, or in general landscape work, the only rational procedure is to use lenses that are specially corrected for them. To carry out this idea, the Gundlach Optical Co. kindly constructed an 8 × 10-inch "rapid-rectigraph" lens of 13-inch equivalent focus, corrected for the D instead of the G line of the spectrum. The performance of the lens has fully justified the induction that led to its construction.

When orthochromatic plates first came into general use, the astronomers seized on them with avidity; but it was not long before they became dissatisfied with the results. At a recent astronomical congress in France, the sentiment of the majority of those present was that more faithful and satisfactory images of the heavenly bodies were obtained on the blue than on the yellow-sensitive plates.

Little of value had been done in photo-astrography until the late Mr. Lewis Rutherford, of New York, produced some photographs of the moon which greatly surpassed any of the sort that had been previously accomplished with the refracting telescope.* Rutherford used a telescope with the objective so extremely under-corrected that it was almost useless for visual purposes. This lens, it is almost needless to say, was specially corrected for the shorter wave-lengths, to be used in connexion with wet-collodion blue-sensitive plates, the only ones at that time available. Some astronomers employ a telescope corrected for best visual definition and a duplicate specially corrected for photography, and it is the latter that they have usually employed with the orthochromatic plates. The reason, then, that these plates have fallen into disfavour with many of them is due to the fact that they have used the wrong lenses with the right plates.

One of the principal advantages connected with yellow-sensitive plates is their ability to record the details of distant objects in a more satisfactory manner than is possible with the ordinary ones. Some four years ago the writer called attention (*Anthony's Photographic Bulletin*, February 9, 1889) to the *graphotelic* properties of these plates in connexion with landscape photography. If this special attribute of yellow-sensitive plates is of value in connexion with distances limited by, perhaps, a score of miles, it certainly seems that it should not be overlooked by those who work their lenses with the anterior conjugate focus many millions of times greater than the posterior.

HENRY G. PIFFARD, A.M., M.D.

*Some months ago a friend, who is a sub-chief in one of the principal bacteriological laboratories of this city, remarked to the writer that the height of his ambition was to possess and work with a Zeiss $\frac{1}{12}$-inch apochromatic. I replied that, if he fancied Zeiss lenses, he had better select a $\frac{1}{12}$-inch, as with it he would be able to do more and better work in the line of research and discovery than with the $\frac{1}{18}$-inch. My reply was evidently received with extreme incredulity. If we refer to Zeiss' catalogue, we shall find that the numerical aperture of the $\frac{1}{18}$-inch is given as 1·18, but the $\frac{1}{12}$-inch of the same maker has a N. A. of 1·30. He makes still another $\frac{1}{12}$-inch, N. A. 1·40. Applying these figures to the equation above given, and assuming for white light λ 5269, we shall find that the $\frac{1}{18}$-inch will resolve or differentiate particles that approach each other as closely as about 114,000 to the inch, while the $\frac{1}{12}$-inch of N. A. 1·30 will resolve particles as close as about 125,000 to the inch, and the $\frac{1}{12}$-inch, N. A. 1·40, will take optical cognisance of lines of particles that approximate each other to within about $\frac{1}{125000}$ of an inch.

*I am not unmindful of the magnificent work done by Dr. Henry Draper with his reflecting telescope.

PHOTOGRAPHY FOR ILLUSTRATING THE PRACTICE OF MEDICINE AND SURGERY IN A GREAT HOSPITAL.†

THE photographer in charge of the illustrative department of a great hospital should at all times be attentive to his duties. He should be respectful, and command respect from others. He should remember the responsibilities of his position, and maintain the dignity of his profession. Patients should be received in a quiet, respectful manner, and if in any way reluctant to be photographed, which is seldom the case, they should be led to understand that all is being done for their own and others' good. They should be kindly and gently instructed how to do their part as to position and immobility. In their treatment, age, disease, and personal traits must be considered. In some cases where a time exposure is required, it is advisable to momentarily suspend respiration, especially if the part under treatment involves the chest or abdomen. With proper instruction to the patient, and the use of a good pneumatic exposure device under strong light, this is quite easy to accomplish. The acquaintance of the photographer with peculiarities of various diseases will enable him to produce better results than he is likely to obtain through optics and chemistry alone. Hence his less crowded hours may be profitably spent in study somewhat outside of the ordinary photographic curriculum. No little part in the successful illustrating of many cases devolves upon the physician or surgeon having them in charge. His opportunities for their study enable him to point out to the photographer the especial features of greatest interest to be shown in the illustration. He should at all times accompany to the photographical department, or send with the patient an instructed assistant who knows something about the subject. All patients should be accompanied by a written statement, giving name, age, nativity, occupation, disease, date of admission to the hospital, number of ward or bed, and page of hospital history book where the record of treatment is entered. Upon this statement the photographer should place date of making negative, size of

†Concluded from page 626.

plate used and its serial number, for future reference. The accompanying form shows the method followed at Bellevue :—

Appointments should be made with the Photographer one or two days in advance of sending patients to the Photographic Department.

REQUISITION FOR PHOTOGRAPH.

BELLEVUE HOSPITAL.

.....189

Ward No.....Medical Division No.....Hospital History Book, Page No.....Name.....Age.....Nativity.....
Occupation.....
Date of Admission.....
Disease.....
Date of Operation.....
Operation, by whom performed.....
Visiting Physician.

NUMBER OF EXTRA COPIES WANTED.....
House Physician.

Visiting Physician's or Surgeon's Copy (to be) mounted on Cardboard ?

House Physician's or Surgeon's Copy (not to be) mounted on Cardboard ?

☞ One copy of the Photograph made on this requisition will be furnished FREE to the *Visiting Physician or Surgeon* of the division whose autograph it bears. Also one copy to the *House Physician or Surgeon* whose autograph it bears, and one copy for the *Hospital Record Book*, which copy is to be fastened in the book, with the History of the case.

All further copies made are classed as Extras, and must be paid for when ordered.

Properly filled out and signed requisitions must be sent in advance or accompany each patient.

The physician, assistant, or nurse in charge should prepare the patient for photographing. Removing bandages, dressings and cleansing wounds is *not* a part of a photographer's work; all this should be done, as far as may be, before taking the patient to the photographer. It is important that patients who have been photographed before and during treatment be again photographed before their discharge from the hospital. Thus a comparison may be made of the condition at the two or more periods. The hospital staff should be instructed that the preparation of pathological specimens in any fluid of non-actinic colour is detrimental to their illustration by photography. Most such specimens submerged in fluids of proper density are more successfully treated than in the open air. The essentials to successful photographical work in hospital service are suitably constructed and lighted operating, chemical, and printing rooms, ample apparatus, order, and system, and a photographer who is prompted in his work not alone by the small pecuniary reward which it may bring. He should have an interest in the progress of science and the relief of human suffering.

O. G. MASON.

THE CAMERA AND THE PULPIT.

Read at the Congress of Photographers.]

THE art of writing or recording by means of light, which we understand by "photography," has come to be recognised as one of the most valuable instruments of modern civilisation. There is scarcely a line of human achievement which has not found in it a servant whose assistance has become indispensable in bearing old burdens and in assuming new ones. Especially is this the case in the wide field of education. Intellectual culture and moral culture both have found it profitable and necessary to lay tribute upon the photographic camera and upon its necessary adjunct, the optical lantern.

In all education the true method is to proceed from the concrete to the abstract—from the objective to the subjective. This is true not only in school life, but in the large education of the masses of the people. It is interesting to notice the vast development of the illustrated material now presented to the public in the periodical press as well as in the stately volume. Hardly a daily paper do we find which does not boast of its special artist, and every subject must have its appropriate woodcut, engraving, or photogravure. This has been brought about, to a great extent, by the use of the camera, by which the vast majority of this illustration is made possible.

General science, the fine arts, commerce, the secular school, have all invoked the light of heaven to shine upon them. Why should not the teacher of religion also invoke the aid of this servant of God to render vivid and clear spiritual truth ?

The camera has received a hearty welcome into the studio, the manufactory, the school-room, the lodge-room. It has also received a like welcome in recent years into the Church. Religion has its basis in history. It expresses its symbols in art. The earliest forms of architecture, as well as the highest expressions of art, are religious in their motive. The temple became the repository of all that was most glorious in sculpture and painting. The history of the religions of mankind cannot well be studied without a knowledge of the monuments of past civilisations.

In recent years there has been a great advance in the study of archæology. Here the camera has come in as a large factor. The growth of the study of history has been very great, and the study of comparative religions has been a part of the general historical movement.

In the teaching of the life and history of the Church, the pulpit cannot do without the camera. Christian art and archæology go hand in hand. The inscriptions are best copied now by the camera. Many places there are where the use of the squeeze paper and brush are indispensable; but in most instances photography saves labour and accurately preserves the record. In the study of the remains of the early centuries of the Church, the religious teacher finds that the picture made on the spot is the best means of rendering clear and vivid the thought he wishes to present. The work done by the Palestine Exploration Fund and the Egyptian Exploration Fund within the past twenty-five years has brought to light a vast lot of material whose richness and importance as contributions to the study of the religious life of these countries is simply inestimable. Thus the study of the Christian evidences, from the standpoint of archæology, the study of the religions of antiquity as preserved in their monuments, the study of the development of Christian art as found in the catacombs and elsewhere, is rendered possible and exceedingly valuable by the rich fruits of the camera.

The Christian missionary to foreign fields now goes to his work armed with his camera and optical lantern. He has found that the masses of the people are attracted by the pictoral presentation of Bible themes. In the great "melas," or fairs held in various parts of India may often be found, in the midst of the thronging thousands, the tent of the missionary, who attracts the attention of the people by his screen projections and gains audience for the truth, which is thus carried through the eye to the heart.

The teacher in the modern Sunday school has likewise added to his maps and charts the aid of photography to educate his fellow-workers. To reproduce a map, to illustrate the life of our Lord or the journeys of His apostles, to bring before the people the manners and customs of Bible lands, the beam of light as a swift-winged messenger comes to his aid. In studying recently the book of Nehemiah and his great reform, during which he built up the diamantled walls of Jerusalem, discussion turned upon the course of the walls and the general topography of the city. From views taken on the spot with my own camera a few months ago it became possible to illustrate the subject in such a manner as to invest it with the utmost reality and vividness.

In the ordinary ministrations of the pulpit the camera is coming to be recognised. Under certain circumstances, and on given occasions, the use of the screen projection is assuredly a powerful adjunct. Its use may, of course, degenerate into a mere spectacular performance which is only a common show; but, in proper hands, beneficent and lasting results must certainly follow. A pastor in England affirms that, through one of his illustrated sermons, delivered at various places, over three hundred persons have been roused to lead a better life. The illustrated sermon may have as real dignity and effectiveness as the illustrated volume, and be more impressive because of the added element of personality.

The existence in England of what is called the "lantern service" is well known. Illustrated themes are published and slides are rented. Considerable space was given to this subject some months ago in the *Review of Reviews*, the article being from the energetic pen of Mr. W. T. Stead. In this country the interest in this kind of work has greatly augmented within the last ten years. Some of our churches are now provided with apparatus for this purpose. One church recently built in Chicago has a laboratory for the manufacture of the gases, and the pastor, who, it is needless to say, is a thoroughly live man, has great success in presenting the truth thus illustrated to his people. Another church, in Minneapolis, I believe, is provided with a screen, stereopticon, &c., all at the control of the pastor by means of electric communications. If he desires while preaching to illustrate his subject, he may, by pressing the respective buttons, unroll the screen, turn out the lights, and signal the operator for the picture. What is more, in many of our theological schools may be found a complete optical outfit for the purpose of teaching Christian art, architecture, paleography, and the latest results in exploration and discovery in Bible lands.

All this serves to illustrate the statement that "science is the handmaid of religion," and none are so ready to acknowledge this as the Christian teacher. Many clergymen are expert amateur photographers, and are finding the camera a valuable adjunct in their work. It must not be understood that the illustrated sermon is in any sense to supersede the ordinary service of the Church, but to find its place in specific lines, as above indicated. The Church is more and more to use the camera: (1) To teach Christian art and archæology; (2) in work in the foreign mission fields; (3) in the Sunday school and normal work; (4) in special services to children; (5) in evangelistic services among the masses; (6) in providing a high class of instruction along the line of art and history.

REV. DR. A. W. PATTEN.

SENSITIVENESS OF PHOTOGRAPHIC PLATES.

THE extensive use of photography in science, art, and industry makes it desirable to know something regarding the sensitiveness of the plate employed for any specific purpose. The subject, however, is one of great difficulty, owing to the fact that we have not been able hitherto to secure a satisfactory standard of light with which to compare plates.

The method now in use by the makers of commercial plates to indicate sensitiveness is far from satisfactory, since there is no direct relation between the numbers used by the same maker, and still less when the plates of different makers are compared. The No. 25 of one maker may indicate greater sensitiveness than the No. 50 of another; and, in general, the numbers do not convey any definite information as to the time of exposure required. It seems to me that it would be an important step in advance if the makers of commercial plates would at least adopt a uniform system in indicating the sensitiveness, so that the numbers (even if arbitrary) would in all cases have the same meaning.

It appears now well-nigh impracticable to use sunlight as a direct standard for illumination, unless a standard plate is adopted for comparison. But I think it is not impracticable to employ artificial light which will give an absolute measure of sensitiveness for the light employed. Artificial light, however, whether it be from the burning magnesium, the electric lamp, or the flame of a candle, does not have the actinic properties of sunlight, and hence different brands of plates, which have the same sensitiveness for any particular artificial light, may be quite different for sunlight.

It seems to be tacitly assumed, however, by most writers that the standardising of a plate in one particular artificial light is all that is necessary. On the contrary, the problem is only partially solved.

During the past ten years I have made hundreds of experiments on the relative sensitiveness of plates in candlelight and daylight, from which it is concluded that the plates of different makers do not necessarily hold the same relation of sensitiveness for the two kinds of illumination. In the standardising of plates, where the minimum visible is used as the measurement of sensitiveness, we meet with a peculiar phenomenon, which may greatly impair, if not entirely vitiate, our results. I refer to the effect of extraneous light received by the plate in its manipulation.

When the wet-collodion plate was in general use, it was imagined by many that the plate became more sensitive if subjected to preliminary or supplementary exposure. In 1884 I experimented on an emulsion plate, and found no change in sensitiveness due to preliminary exposure, and hence inferred that the only effect was simply fogging, which would cause the collodion or emulsion plate to start more quickly in development. I subsequently found that this view of the subject requires some modification. The reason why no difference was noticed in 1884 in the case of preliminary exposure was undoubtedly due to the fact that the plate had already received, in the process of manufacture, all the preliminary exposure it would stand. In the early days of commercial emulsion plates, they were frequently fogged so badly before they reached the consumer as to be greatly impaired, and sometimes practically valueless.

Last year, in making experiments on the actinic effect of ordinary red glass used for dark-room illumination, employing a 10-candle lamp, I found such discordant values for different pieces of the same plate when exposed and developed under similar conditions as to call for an investigation of the cause. The statement has frequently been made that the same plate, in its different parts, indicated great variations of sensitiveness. This idea is so directly opposed to every-day practical work in landscape and portrait photography as to seem well-nigh incredible. In fact, if it were a common occurence, one could not make a correct negative. It occurred to me that the abnormal results which I obtained were in some way connected with the manipulation of the plate during the exposure and development. I accordingly made the following experiment: A Seed No. 26 4 × 5 plate was cut in three strips, using a very feeble light during the operation. Strip No. 1 was kept in the dark; No. 2 received a preliminary exposure of two seconds in the dark room at one foot distance from the red glass window; No. 3 received a supplementary exposure of two seconds in the same way. The three pieces of plate were successively exposed in the sensitometer to the light of a candle for ten seconds, placed at ten feet distance. They were then developed together in total darkness. Strip No. 1 printed the figure 40; Nos. 2 and 3, 8 and 10 respectively. This experiment indicated that, when a plate received a preliminary or supplementary exposure, it appeared to be about five times more sensitive.

I had observed a similar phenomenon in the case of wet collodion in October, 1891, but attached no importance to it at the time.

The most sensitive wet-collodion plate which I have used requires an exposure of 2·5 seconds for a naked candle at one foot distance to make a legible impression; but, by a suitable amount of preliminary or supplementary exposure, the time may be reduced to 0·3 second, indicating an apparent increase in sensitiveness of eight times. A great many experiments have been made with various kinds of emulsion plates in candlelight, feeble daylight, and through red glass, all giving similar results. In order to get the maximum effect, the plate should receive all the preliminary exposure it will stand without producing dense fog. If there is too much fog, the numbers will be buried under it.

This peculiar behaviour of photographic plates in light of feeble actinic energy explains very clearly why experimenters have got such discordant results in attempting to standardise them. The phenomenon probably disappears when strong daylight is used, for we know by experience that preliminary exposure does not make a plate more sensitive when used for a landscape negative. The subject may, however, have an important bearing in astronomical photography where the light has very feeble actinic energy, as in the case of stellar photographs.

The following appears to me to be the explanation of the apparent increase in sensitiveness, due to preliminary exposure. A photographic plate may receive a certain amount of light, and when placed in the developer show no visible blackening of the film. This fact is apparent in using a slow plate like wet collodion. A plate, therefore, which has had a certain amount of preliminary exposure, may be under such strain that a small amount of additional exposure will enable the developer to reduce the bromide of silver. Under this conception the actinic effect should be measured by the intensity of the light multiplied by the time, plus a constant, the constant being a function of the original sensitiveness. In landscape photography the constant would be such a small interval of time as to be entirely lost.

In view of what has just been stated regarding the behaviour of plates in light of feeble actinic energy, it is readily seen that our present method of standardising plates, by using the minimum visible, is open to very serious objections, owing to the difficulty in manipulating plates in the dark room. With the more rapid commercial plates a single second exposure before the developing lamp is sufficient to materially modify the result.

After considerable thought on this subject, it has occurred to me that we can most readily get a uniform system for designating the sensitiveness of plates by adopting an arbitrary plate as the standard of reference, and making our compositions by daylight as well as artificial light. The wet-collodion plate has frequently been suggested as a standard of reference; but it has been objected to on the ground that the sensitiveness would not be constant. As a matter of convenience, I presume a slow emulsion plate would answer the purpose better, since such a plate could be interchanged among the makers of commercial plates. By adopting such a method we would at least have a homogeneous system.

I have at different times determined the sensitiveness of nearly all well-known brands of commercial plates for daylight, candle-light, and for red glass. My normal collodion plate is used as the standard of reference for daylight comparisons.

The following are some general results for sensitiveness in daylight:—

Wet collodion	1
Slow lantern-slide plate	10
Rapid emulsion	120
Most rapid plate examined	220.

For candle-light, or any other artificial light, the absolute time required to make a legible record can be ascertained. For a naked candle, at one foot distance, the following are some of the results:—

Normal collodion	2·5 seconds.
Slow lantern-slide plate	$\frac{1}{10}$,,
Rapid emulsion	$\frac{1}{120}$,,
Most rapid isochromatic	$\frac{1}{300}$,,

PROFESSOR GEORGE W. HOUGH.

THE PREPARATION OF TABLETS FOR VITRO-ENAMELLING.

BEFORE the members of the London and Provincial Photographic Association on Thursday, September 28th, Mr. A. Haddon read a paper, accompanied by a demonstration, on this subject. He hoped, he said, to show that plaque-making was not a formidable undertaking. With a little care, plaques could be made quite as good as the best that could be purchased, and cheaper. It was surprising that so few photographers prepared vitrifiable images, as they were permanent, and would stand any amount of magnification without loss of detail. Many amateurs never heard of a vitrifiable image; some fancy that it required a life of study to produce passable results; others would like to try their hand at it, but they had been told that the wet-collodion process must be used for it. No good book in the English language had been published on the subject, and, if one had to buy all the plaques required in one's early experiments, it required a long purse, so that to many mere expense is a powerful cause for not taking up the subject. He would endeavour to remove the last reason by demonstrating the preparation of plaques. Whatever method of preparing the positive image was employed, a muffle was necessitated. Any one could build a small furnace at a cost which need not be a serious item. Fire bricks could be purchased at about 3*d.* each.

Enamel was nothing more than very fusible glass with some oxides in it, in order to make it black or white, as occasion demanded. White enamel was not worth making when it could be obtained commercially at a low figure. Mr. Guilbert Marten, of Monkwell-street, sold it for 6½*d.* a pound for a bag of twenty pounds, 7*d.* for a single pound. The enamel he (Mr. Haddon) had used was given him by Mr. Bolas. If he had had to purchase all the plaques he had used in his experiments, it would have cost him over 20*l.*, whereas it had only cost him a few shillings for copper foil. A plaque 1¾ × 1¾, making allowance for the copper basis, held forty-three grains of enamel. Ten plaques of the size named could be made from one ounce of copper, and 150 from one pound. If one used a pound of enamel (7*d.*) and a pound of copper (2*s.* 6*d.*), one would be able to produce 150 plaques for that small sum; and, if they sold 1*s.* each, they would cost 7*l.* 10*s.* The enamel should first of all be reduced to a certain consistence by being pounded with a hardened steel pestle in a wooden mortar. It is then sifted through a sieve of a certain size of mesh, the coarse particles being again subjected to pounding. The enamel powder is then soaked in a solution of nitric acid 1 : 4 for from three to twelve hours; this removes all metallic impurities, particles of wood, &c. After further treatment, the coarse particles of the powder are separated from the fine by placing it in water and then separating it into two solutions. The particles

will have subsided in two hours, when the water is poured off, and the deposits washed a third time to remove any acid left.

As to the basis of the plaque Mr. Haddon said copper was found to be the best, as the enamel adheres to it more firmly than to other metals. Virgin copper was best, and it was recommended to use it only recently rolled, but he found that age made little or no difference to its properties. Having remarked that the thicknesses of the copper varied with the size of the plaque, he said the copper foil should be annealed and then cooled, and next freed from oxide with a nail-brush dipped in a one per cent. solution of nitric acid and brush charged with powdered flagstone. Deprived of all dirt, it presents the appearance of pure metallic copper.

In determining the size and shape of the copper plaque a piece of zinc or brass the exact size of the shape required must be used. The copper must be a little larger than the zinc or brass, and the shape traced on the copper by means of a small steel tool that has been previously hardened and tempered. It is better to work to about one thirty-second larger than is wanted. The copper plaque being trimmed, the edges are turned up all round, so that it has the appearance of an oval tray. The shape is then placed on the copper, and both shape and form are gripped between the jaws of a small hand vice, burnished over and the edge raised up. Burnishing enabled the plaque to resist deformation in the vitrification; if the edges were not raised, the enamel would run off, and the curved copper would not remain true in shape. If placed on a flat piece of wood, and the excess of edge filed off with a fine cut file (a coarse cut file would indent the edges). Generally the copper plaques are filed on box wood; copper filings should not be allowed to get in the enamel, as black of green specks result.

As many boxwood shapes will be required as forms of plaques are wanted, the shape being imparted by the use of curving tool, resembling a spatula, being pressed over the back of the copper when in contact with the shape. The copper plaques are pickled to remove oxide, &c., from the surface, in sulphuric acid solution 1:5; then thoroughly rinsed in cold water, passed through sawdust, wiped carefully, and dried.

The enamel powder having settled, the water is poured from the two vessels. The copper shape is now placed with its concave surface upwards on some concave support. The fine enamel is applied to the concave surface by means of a hog's-hair brush. It should be of a creamy consistency, and should be spread uniformly. The water is got rid of by the application of blotting-paper. The coarse enamel is applied in a similar manner to the front or convex side of the copper form, and finally, when the desired evenness of surface has been obtained, the moisture remaining is removed by evaporation over a Bunsen burner. The plaque is then placed on a suitable support for firing, some recommend a refractory eathenware, the latter being treated with a coating of kaolin or rouge to prevent fusion. He did not know were this earthenware could be obtained in thin sheets. He had tried platinum, nickel, and iron for the purpose, and preferred the latter.

Muffles were of two kinds, open and closed. Generally speaking, enamellers preferred the open to the closed; these were made of very refractory clay, and open at both ends. When using white enamel, retort carbon is preferable to ordinary coke, as it is much denser, and less likely to throw off particles of carbon. He had had no experience with the open muffle; it was practically more difficult to use, in consequence of black specks being thrown off. Prefatory to the introduction of the plaque, the muffle should be placed in a gas furnace and raised to a cherry-red heat. To guard against black oxide of iron being thrown on the surface of the plaque, he recommended the inside of the muffle being smeared with red lead and water, red lead combining with the silicates present to form fusible glass. The plaque must not be pushed in the muffle suddenly. When in the muffle, and the temperature is sufficiently high, the first thing observed is that the surface of the plaque resembles that of a ploughed field. It fuses in contact with the copper first; then the little globules gradually coalesce until a smooth surface results. If the temperature is not high enough, mottling results, but if raised high enough the enamel acquires a perfectly glossy surface. If continued too long, oxide of copper will enter into combination with the silicate, and a green colouration will result. Generally speaking, there was one point in the muffle where the temperature was highest, and the plaque should be turned accordingly. The best tool for the purpose was one of thin steel, with the end turned over and having a wooden handle. Unevenness in coating can be remedied by rubbing down with flagstone powder and water. The plaque should then be refired. Black specks are removed with a steel tool used tangentially. The holes are then filled up with powder, and the plaque re-fused.

ECONOMY IN PHOTOGRAPHY.

[Anthony's Bulletin.]

The most economical, and, at the same time the safest, mountant I know of is simple starch well boiled, and not kept over from day to day. The best way to make it is to rub the lumps of starch into a very thin cream with cold water, and slowly bring to the boil, stirring all the time.

When large amounts of the ferrous-oxalate developer are used for bromide printing, the saving of the oxalate of potash might be worth while. The spent developer may be collected in a glass jar, and greenish crystals will be seen to fall to the bottom. The jar and its contents are warmed about as hot as the hand will bear, and the green crystals re-dissolve by stirring. A strong solution of caustic potash being ready, it is added to the spent developer until there is no more precipitation of oxide of iron. The warm solution is then filtered to separate the iron, and sufficient dry oxalic acid added to neutralise the alkalinity of the excess of potash. A ready means of ascertaining the strength is to use an hydrometer or "silver meter" which has been previously gauged by the standard oxalate solution employed for developing. This operation is neither troublesome nor mussy.

Though foreign to the purpose of thia article, I will say that, in spite of all the new and fancy developers for negativea, there are many points of advantage about ferrous oxalate. I saw proof of this in the work of one of my most expert friends who made an extended tour in the North-West. He told me that all the photographers who saw him expose platea laughed at him for the long time he gave. He knew his plates, however, and timed them for ferrous oxalate. His negatives, including subjects of the most varied character, are marked by a wonderful uniformity and absence of stain, many of them resembling wet cellodion, which I believe to be the highest compliment I can pay to a photographic negative.

But our modern rapid gelatine plates have introduced one very important element of economy into the art. Formerly, certain kinda of difficult work could only be attempted with very expensive lenses, and lenses of commener kinds could not be used at all. But now it is possible (though not advisable) to use almost any kind of lens, and depend upon "stopping down" to get sharpness. The stops may easily be cut to the required size out of thin lead or vulcanite, and, the centre having been accurately located, the opening is bored with a countersink. All diaphragms or stops should thus present a mere sharp edge to the entering rays of light, and not a surface more or less bread, as would be the case if not countersunk. If the lead, when cut, reflecta too much light, apply a little lamphlack mixed with spirit varnish. The sharpnesa of the photograph, however, will depend upon other things than mere focussing. If the achromatic corrections of the lens have not been specially made with a view to the actinic or photographic action, it may very well happen that no sharpness can be obtained in the negative, even if the image on the ground glass appears perfectly focnsaed. Should any one possess such a lens, whose visual and chemical foci are non-coincident, it will be an easy matter to rectify things. Set up a pile of boeks with printed titles on their backs in an incline before the camera, as if on a flight of steps. Focus on the central one, and, having developed the negative, examine with a magnifier, to see which title is sharpest. This being ascertained, carefully mark the position of the ground glass on the tailboard of the camera, and then rack it in or out until the title appearing sharpest on the negative is sharpest alao upon the ground glass. Note the distance the ground glass has had to move; then, removing the ground glass from its frame, insert or remove a thickness of wood equivalent to this distance, and replace the ground glasa. The ground glass and the plate-holders are thus thrown out of regiater by the exact distance which represents the separation of the visual and the chemical foci of the lens, and the pictures will be sharp. In the early days of photography this expedient was frequently resorted to.

Stereoscopic negatives are most conveniently made with a pair of lenses of matched foci; but the two lensea are by no means a necessity. Stereoscopic work of excellent quality can be made with one lens mounted on a small camera, the whole being arranged on a board two or three feet long, so that the camera can be shifted laterally a distance of twelve to twenty inches. The farther off the subjects photographed, the greater should be the separation between the points where the camera is situated at either end of the board. Before exposing, the view is carefully focussed, and the camera directed ao that the centre of the field is occupied by the same object, no matter at which extremity of the board the camera may be. Both positiona of the camera are then distinctly marked, and two plates are exposed for the same length of time, one from each position. The two negatives, after being dried, are trimmed down to the proper size, *i.e.*, three and a quarter inches between centres, and mounted on a piece of glass. When landscapes are photographed in this manner there is much greater relief and natural effect in the picture than when the regular form of twin-lens camera is used. If groups or portraits be attempted with the single-lens camera, the separation between the exposing points should not exceed four inches at the maximum.

It is to be regretted that paper in the form of *papier-mâché* is not more made use of. The French have numerous articles like developing traya made of this substance, and they are both cheap, clean, aud durable, as are also the large dipping-baths sometimes seen. The idea of constructing a dark room in any conveuient place with walls of stout pasteboard squares let into light wooden frames, made of laths by the edges, is quite an old one, as also is the idea of an entire portrait studio suitable for a lawn or garden made of the same cheap material. By setting the studio (which would also contain the dark room) in a proper position, no skylight is needed, the opening to the north blue sky serving the purpose instead. A mat, to keep dampness from the sitter's feet, and a bucket of water with a "siphon-tap" in the dark room, would pretty well complete the list of necessary articles for such a useful help to outdoor portrait-making.

Ellerslie Wallace.

News and Notes.

CENTRAL PHOTOGRAPHIC CLUB.—October 6, Lantern slides, 13, Smoking Concert, Mr. J. Traill Taylor in the chair. Musical members are requested to bring up music.

SIR CHARLES RUSSELL opens the Hackney Exhibition on the 17th inst. at thirty minutes past seven.

NEWCASTLE-ON-TYNE AND NORTHERN COUNTIES PHOTOGRAPHIC ASSOCIATION.—Tuesday, October 10, 1893, Ordinary Monthly Meeting.

WEST LONDON PHOTOGRAPHIC SOCIETY.—The opening meeting of this Society takes place at the School of Arts and Crafts, Chiswick (near Turnham-green Station), on October 10, when intending new members will find it a good opportunity for sending in their names for election.

THE Infallible Exposure Meter Company, Wrexham, are preparing a new edition of their book of instructions, and would be glad to receive two or three plates of each of the different kinds manufactured to test the present speeds for their revised list of speed numbers. They will pay cost and postage.

LEYTONSTONE CAMERA CLUB.—October 7, Along the River Roding (third section), starting at George-lane. Leader, Mr. Tom Symmons. The Club will proceed by the train leaving Liverpool-street (G.E.R.) at thirty-five minutes past two p.m., calling at Leytonstone at fifty-two minutes past two, arriving at George-lane at fifty-nine minutes past two. This will conclude the excursions for the season. Open Special Evening at headquarters at eight o'clock.

DEATH OF MR. JOHN HOMERSHAM.—A once-active member of the Field Club and for some time a contributor to our ALMANAC has passed away at the ripe age of eighty-one. For several years Mr. Homersham had retired from living in London, in favour of Dover, the climate of which better suited his declining years. He was of a genial, although retiring, disposition, and his demise will be regretted by many photographers of a bygone period.
